FEARS for the fish stocks in the North Atlantic will be strengthened by the reports of experimental trawling carried out in the sixties by the Fisheries Research Board of Canada (Technical Report 260). Operations on the Scotian Shelf, south-west of Nova Scotia, have been systematic enough in the past few years for accurate estimates of fish stocks to be possible. The Biological Station at St Andrews, New Brunswick, estimates that the standing crop of cod on the Scotia Shelf amounts to 464 million pounds. Argentine, pollock and haddock come next in order, with standing crops of 453 million pounds, 428 million pounds and 391 million pounds respectively. In case this should seem plenty of fish for all the trawlers now operating in the region, however, it is relevant that the laboratory's estimate of the "maximum sustainable yield" of cod—140 million pounds a year—is already less than the sum of the commercial landings of cod each year, 190 million pounds or so. In the circumstances it is forgivable that the report should draw attention to the largely unexploited stock of squid on the Scotia Bank, enough to provide 121 million pounds of edible or nearly edible food a year,

ASLIB is about to take over from the Department of Education and Science the thankless task of trying to maintain an advance list of international scientific conferences. Nobody will begrudge these tireless librarians the £8.00 which they propose to charge subscribers for their quarterly list, but it will be interesting to see precisely how Aslib tries to solve the awkward problem of separating international conferences proper from those to which the organizers have invited a few ritual foreigners, sometimes in the hope that the hospitality will be repaid.

THE first full-scale nuclear power station to be built in Sweden, the 440 MW boiling water reactor plant at Simpevarp on the east coast, supplied electricity to the Swedish grid for the first time last month. Its output is expected to reach 350 MW by the end of this year and full capacity will be achieved during 1972. Most of the construction work was carried out by the Swedish mixed state-private company, ASEA-Atom, which has developed a commercial boiling water reactor capability independently of the United States. A second nuclear power station (580 MW) is expected to commence operation in 1974. During the 1980s, the construction of a further four nuclear power plants is planned and the total nuclear generation capacity should then be about 5,000 MW.

A NEW research vessel for the Natural Environment Research Council, RRS Challenger, was launched last week. The Challenger is the first Council vessel to be purpose-built for research, the other eleven in the NERC fleet have all been converted; she will operate from the council's research vessel base in Barry, Glamorgan. RRS Challenger has a displacement of 1,440 tons but is not the largest of the fleet. The new vessel has accommodation for nine scientists and is equipped for marine, geophysical and other oceanographic research. The Natural Environment Research Council expect the Challenger to be operational by April 1972 and most of her cruises are expected to be in the north Atlantic.

"To conserve is the Museum's first priority; to educate and entertain is a close second. To conserve for future generations whilst ignoring the present generation would be absurd", is one of the opening remarks of *Museums in Education*, Education Survey No 12, HMSO, 50p, published this week. The survey conducted by Her Majesty's Inspectors of Schools, while admitting that much progress has been made in the use of museums in education, calls for a still greater use of them. The desirability of museums and educational institutions to cooperate to a greater extent is emphasized, as is the need for museums to cooperate more. The report says the "happy camaraderie among professionals needs to become a much more flexible and extensive exchange of exhibitions and professional services in many fields"

Clearing the Air from Geneva

from a Correspondent

THE second World Administrative Radio Conference for Space Telecommunications, organized by the International Telecommunication Union, was held in Geneva from June 7 to July 17, 1971, and was attended by some 650 delegates from 100 nations. The decisions taken at the first such conference in 1963 have stood the test of time, but developments in space technology and radio astronomy have made new international agreements necessary to cater for the needs of the next decade.

The demand for radio frequencies shows no signs of abating, and as there is a limit to the extent of the radio spectrum which can be exploited the same frequencies should be used by more than one service whenever this is technically feasible. Much of the discussion, and most of the difficulties in reaching agreements, were concerned with problem sharing. As technology advances some of the increased demands can also be met by using frequencies higher than 40 GHz, the previous upper limit of the allocated bands, and allocations have now been made up to 275 GHz.

There has been a remarkable expansion in satellite communications since 1963, and the next decade is expected to see the implementation of satellite services for aeronautical and maritime navigation and communication, for direct broadcasting to the public (at least on a communal basis), for the study of the Earth's resources, and for monitoring the environment. It is also becoming clear that recent discoveries by radio astronomers are providing new insight into the fundamental physics of matter, and that greater protection from interference in several frequency bands is necessary for this important branch of science to develop.

Most of the work of the conference was organized in three committees. The first was concerned with the administrative procedures by which international negotiations may take place as services are introduced or expanded. It has been necessary to revise the procedures laid down in 1963, particularly as the greater emphasis on frequency-sharing calls for clear and more comprehensive procedures by which different countries may coordinate their activities. An interesting departure from custom is that there is now provision for the adoption of new technical criteria on frequency sharing when these are recommended by the International Radio Consultative Committee (CCIR, an advisory committee of the ITU) without waiting for another administrative conference. Countries will have the option of retaining the existing criteria or adopting the revised criteria when these become available.

The second committee was concerned with establishing the technical criteria such as limits of radiated power and power flux densities which are considered necessary to enable services to share frequencies without mutual interference. This committee also provided the technical data needed first for calculating the coordinating distances within which consultation with other countries need take place, and then for calculating the likelihood of interference, and the necessary separation distances, taking into account the actual radio links in operation or planned. Agreement on comprehensive technical standards, in the available time, was made possible only by the thorough preparatory work carried out in February 1971 by a special joint meeting of relevant Study Groups of the CCIR in Geneva, and before that by a CCIR working party in Nice in December 1970, which assembled the latest data on radio propagation necessary to enable the more general studies to proceed.

Since 1963 it has become clear that the future development of space communications is vitally dependent on the exploitation of geostationary satellites, which remain fixed in relation to the surface of the Earth. The technical committee therefore gave considerable attention to the need for the efficient use of the geostationary satellite orbit, and the criteria which must be adopted to avoid interference between links using different satellites in this orbit, and between these links and terrestrial services.

Although the preparation of administrative procedures and technical criteria is fundamental to the development of communications, it is the frequency allocations themselves which will excite the widest interest. The revision of the frequency allocation tables was the task of the third committee, and some difficult problems were encountered. Although space services can be operated over a wide range of frequencies, certain parts of the spectrum have marked advantages and are in heavy demand. One such range, for example, is in the region of 2–3 GHz; wide bandwidths are not available at much lower frequencies, and propagation at much higher frequencies can be seriously affected by adverse meteorological conditions. This desirable part of the spectrum, which is already used extensively for terrestrial services, is also in demand for Earth exploration satellites, for broadcasting satellites, and for increased bandwidths in space research. An acceptable compromise was finally achieved, by which it should be possible for these services to share certain bands, provided that there are only a few Earth stations for space research and Earth exploration, that the power flux density from broadcasting satellites is kept below an agreed limit, and that full consultation takes place before any new system is established. Similar problems in other parts of the spectrum were treated in similar ways.

The final agreements on frequency allocations are inevitably the result of compromise, and operators of most services will be disappointed that not all their hopes were realized. It has not been possible to make new primary allocations for space research, except in the newly-allocated part of the spectrum above 40 GHz, but several special provisions have been made which will, it is hoped, enable the necessary arrangements for specific operations to be made by negotiation. The basis of this philosophy is that successful operation of a few Earth stations in the space research service, even though a high degree of protection is required, need not inhibit the use of the same frequencies for other services in other parts of the world.

Radio astronomy has received improved status in several bands, and has obtained a new exclusive high frequency band near 22 MHz and new bands above 40 GHz. There is increased recognition of the importance of bands needed for observing natural line emissions. On the other hand, the expected increase in transmissions from satellites, for all purposes, constitutes a threat to radio astronomy which cannot be avoided by locating observatories in remote areas. As an example, there is now an allocation for broadcasting satellites in a band adjacent to the exclusive radio astronomy band at 2,690–2,700 MHz. Careful planning and much goodwill is needed if radio astronomers are to be able to use this band without danger of serious interference.

The new regulations will come into force, formally, on January 1, 1973. But as they reflect the established policies of most countries, many of the provisions will already have been adopted for practical purposes, and others will no doubt be followed well in advance of the formal date of implementation.

NRC Committee Knocks Anti-knock

by our Washington Correspondent

A STUDY of the health hazards associated with airborne lead, conducted by the National Research Council*, achieves the remarkable feat of providing sound biological reasons why lead should be banned from use in petroleum as soon as possible, while at the same time cutting the ground from under the feet of the most vociferous critics of the automobile industry. The chief conclusion of the study is that while airborne lead does not provide a serious threat to the health of the average city dweller—even in Los Angeles—young children and some groups of workers may get enough lead into their bodies from car exhausts to produce biochemical damage and, in severe cases, even clinical signs of lead poisoning. The study, which was conducted under contract to the Environmental Protection Agency by the Panel on Lead of the Committee on the Biologic Effects of Atmospheric Pollutants (a special committee of the National Research Council), will be scrutinized carefully by the EPA, for it is planning to introduce regulations controlling lead in petroleum in December this year.

Based on an extensive survey of the literature on lead pollution, the study comes up with the finding that the concentration of lead in the largest cities in the United States is twenty times greater than over sparsely populated rural areas, and more than 2,000 times greater than in the air over the centre of the Pacific Ocean. There is "little doubt as to whether man has substantially contaminated some parts of his environment with lead", the panel concludes, and "it is also clear that one major source of general environmental contamination is the combustion and dispersal of lead alkyl compounds used as automotive fuel additives".

Before this conclusion can be used as a stick with which to beat the car manufacturers, however, the panel points out that the average lead content in the air over major American cities has not changed greatly for the past fifteen years, and even if cars carry on discharging lead into the atmosphere, there will be little change in the magnitude of the effect on biological systems "for some years to come". The panel also concludes that much the most important source of lead in the blood comes from food and drink. In any case, the average city dweller in the United States receives insufficient doses of lead from both the air he breathes and the food he eats to pose a threat to his health.

Although the panel offers no suggestion on the level of lead in the blood that can be considered safe, running through the report is the assumption that blood lead levels below 40 μg per 100 g are not biologically harmful because it is only above that level that synthesis of the haem part of the haemoglobin molecule is affected, and the first clinical symptoms of lead poisoning (which are usually mild anaemia, headaches and generalized muscle aches) are not noted until blood lead levels exceed about 80 μg per 100 g of whole blood. In contrast, the panel report cites studies that show that the average person living and working in the city of Los Angeles—where the concentration in the atmosphere is twice as high as most other cities—will have a blood lead content of less than 25 μg per 100 g of whole blood, and inhabitants of other cities are likely to have about 15 μg of lead in every 100 g of blood.

On the other hand, however, the panel puts children who live in large cities and some groups of workers, such as policemen on traffic duty and parking lot attendants, at a high risk from airborne lead. The latter group is more or less continually exposed to high concentrations of airborne lead, which may result in blood lead concentrations greater than 40 μg per 100 g of blood, but the panel also points out that "even within this small population, this level of blood lead concentration is probably attained by only a relatively small proportion of those exposed. To reach the very high level of blood concentration compatible with clinical lead poisoning would probably require in these special groups a five-fold increase beyond current levels in lead assimilation for a long period".

But the exposure of city children to airborne lead and also to lead paint and other sources is a much more intractable problem. For one thing, recent studies have shown that many city children have blood lead concentrations of 40–60 μg per 100 g. Leaving aside the ingestion of lead paint, which is a major problem in the poorer areas of large American cities, the panel suggests that children living in large cities are exposed to a high risk of lead poisoning through dust and grit in the streets. Such dust often contains more than 2,000 μg per g of lead, and if a child manages to eat only about 40 mg of dust each day, his blood lead content could be taken above the 40 μg limit. Or, more drastically, if he ate 0·4 g a day, he would show symptoms of clinical lead poisoning, possible even resulting in damage to the central nervous system. This, says the panel, "is an undesirable level of exposure". Unfortunately, but not surprisingly, nobody is clear about how much dust and grit is swallowed or inhaled by children in large cities because no such studies have yet been reported. That is a social study which the panel suggests could well be carried out.

Asked last week whether these findings of blood lead concentrations call for a ban on lead in petroleum, Dr Paul B. Hammond, the panel's chairman, said "on strict biological grounds, I would say that a case could be made out for banning lead from gasoline, but I could also make out a case, on strict biological grounds, for banning the automobile as a lethal weapon". Dr Hammond pointed out that the panel can make a biological judgment, but it is now up to somebody else to make an economic judgment on whether or

Feasibility Study

THE National Academy of Sciences has accepted a contract from the Environmental Protection Agency to determine whether the automobile industry is capable of manufacturing an engine that will meet the standards set by the Clean Air Act. Manufacturers must, by 1975, produce automobiles which emit 90 per cent less carbon monoxide than the engines produced in 1970, and they have until 1976 to reduce emissions of nitrogen oxides by 90 per cent. A committee, under the chairmanship of E. L. Ginzton, chairman of Varian Associates, California, will determine whether it is technologically feasible for the industry to design, mass produce and service such an engine. Reports will be sent to the EPA and to Congress in January and July of each year.

**Airborne Lead in Perspective,* to be published by the National Academy of Sciences, Printing and Publishing Office, 2101 Constitution Avenue, Washington DC 20418.

not lead alkyls should be banned from petroleum. Ironically, it may be the manufacturers themselves who are forced to conclude that they can no longer afford to have their cars run on leaded petroleum, whatever recommendations the EPA comes up with in December. The automobile manufacturers must by 1975 meet strict regulations on the amount of unburnt gases and nitrogen oxides emitted from automobile exhausts, and one method which at present looks promising is to attach a catalyst to the exhaust system to reduce nitric oxide and to oxidize carbon monoxide. Lead, however, poisons the catalysts.

Apart from its findings on the levels of lead in the blood of city dwellers, the panel also pinpointed areas where more research is needed. For one thing, the panel points out that monitoring of both city air and food is totally inadequate to determine either the source of lead which eventually finds its way into human blood, or to provide warnings of potential risk. But the chief areas where more extensive research is called for lie in the biological sciences themselves. For example, the panel says that studies are required to determine whether the body burden of lead increases with age, and the assumption that the non-diffusable fraction is tightly bound in bone, and therefore biologically inert, also requires further detailed examination.

A more important recommendation, and one which throws into relief the panel's tacit assumption that blood lead levels below 40 g are safe, is the suggestion that studies on the biological effects of low levels of exposure to lead are urgently required. "The subtle effects on behaviour of low lead exposure of long duration without prior exposure may be manifest in two types of disorders: the dulling of mentation and chronic hyperkinesis", the panel points out. "No information is available regarding the possibility of cause and effect in what may be an extremely important problem."

TECHNOLOGY ASSESSMENT

Daddario's Kite Flies Yet

by our Washington Correspondent

THE Office of Technology Assessment, like an old soldier, refuses to die. A proposal to set up within the legislative branch of the Federal Government an agency designed to assess the likely consequences of technological projects has been kicking around in the House of Representatives Subcommittee on Research and Development for the past four years, and its ancestry can be traced back a good deal further than that. But, just as the idea seemed finally to have been laid to rest, it has appeared again with enough vigour and support to take it through the rest of the congressional mill and probably even into the statue books. A bill to set up the office was introduced into the House by Mr John Davis, chairman of the Subcommittee on Research and Development and the rest of his committee members a few days before members of Congress dispersed for their Summer vacations. It was referred to Mr Davis' committee, and has since been sent back to Congress without amendment and with a report explaining why it would be "shortsighted in the extreme, if not disastrous" for Congress to turn the idea down.

The bill, which is in most respects identical with a bill introduced by Emilio Q. Daddario, Mr Davis's predecessor as chairman of the research and development subcommittee, would establish an Office of Technology Assessment charged with appraising the impacts of the applications of technology and with helping Congress to determine the relative priorities of the projects before it.

The chief reason for the bill, and without doubt its strongest asset on Capitol Hill, is that the Administration at present has all the resources at its disposal for making decisions on technological matters and Congress is ill-equipped to challenge them. To help redress the balance, the proposed Office of Technology Assessment (OTA) will provide information to congressional committees and serve as an early warning system for likely undesirable social effects of legislation involving technology. All these functions would be performed at a cost of $5 million for the office's first year of operation.

Jobs specifically earmarked for the OTA in the bill are to identify existing or probable impacts of technology, where possible to establish cause and effect relationships between technological advances and social or financial consequences, to determine alternative programmes to achieve specific goals, to identify areas where more research is needed to support the assessment, and to furnish the results of these labours to the appropriate legislative body. The OTA will have the Library of Congress to help carry out its tasks, and the National Science Foundation to cooperate on the development of techniques of technology assessment, and to award grants and contracts for research needed by the OTA.

A panel consisting of eleven members would be responsible for the policy of the OTA and an operational unit, headed by a director, would be charged with the task of carrying it out. Two Senators, two members of the House of Representatives, the Comptroller General, the director of the Congressional Research Service of the Library of Congress, the director of the OTA itself, and "four especially qualified members from the general public" appointed by the President with the Senate's approval would together provide the personnel for the Technology Assessment Board. The director would be appointed for a six-year term and the public members of the board would serve for four years each, with the possibility of being reappointed once. Assessments could be instigated by the board or the director, but the chief users of the office's expertise are expected to be congressional committees whose chairmen could ask for specific studies to be carried out. Like the FBI, the OTA would be expected to furnish a report without coming to any conclusions.

Although the way in which the OTA will in theory carry out its business, and the rationale that underpins the attempt to set it up, is clear, thirteen days of hearings and four years of rumination by the Subcommittee on Research and Development have failed to provide a convincing description of how it will work in practice. For one thing, if the OTA is to be used to check on a particular action of the Executive, it will have to move with sufficient speed to produce a report that is not a post mortem, and for another, independent members of the public who are both equipped and willing to serve on such a body are rare indeed. The new bill has at least alleviated the problem of finding staff for the Technology Assessment Board to the extent that it has cut the number of public members down from seven in the original proposal to six and finally to four in Mr Davis's new bill.

If the bill survives intact the congressional mill—as indeed it stands every chance of doing, for Congress is not noted for turning down measures that are designed to strengthen its hand against the Executive—the Office of Technology Assessment would be essentially Mr Daddario's baby, for it was he who introduced the legislation leading up to the new bill, and it was under his chairmanship that the subcommittee conducted its hearings. Although the need for Congress to be kept informed of the likely consequences of new technology was agreed by all the witnesses before the committee, few aspects of the proposal remained uncriticized. Dr William D. McElroy, Director of the National Science Foundation, for example, told the subcommittee that the office would lack credibility and that it may better serve to coordinate the work of agencies that are already engaged in technology assessment. Those are criticisms that the new legislation has clearly failed to answer.

MARINE POLLUTION

No More Dumping

by our Washington Correspondent

GONE are the days when politicians would complain that there are no votes in sewage, and that there is no political capital to be gained from supporting legislation to clean up the rivers and oceans. With the present public concern about the deterioration of the natural environment, sewage has become a live political issue, and one on which most politicians have something to say. Such was the case last week when the House of Representatives passed, by a vote of 304 to 3, a bill designed to regulate the dumping of waste material in the tidal waters around the United States, and to prohibit entirely the dumping of some particularly toxic material.

In many respects, the bill embodies in legislation the conclusions and recommendations of the Council on Environmental Quality, whose report *Ocean Dumping: A National Priority,* was sent by President Nixon to Congress in October last year. But the bill has already met with opposition from the Bureau of the Budget for extending the council's recommendations to include the designation of marine sanctuaries around the United States and for requesting a further $2 million for research into the long-term effects of marine pollution.

Chief among the provisions of the bill are a total ban on the dumping of chemical and biological weapons and highly radioactive waste materials into the oceans, and a ban on the dumping of other material unless a permit has been issued by the Environmental Protection Agency or the Secretary of the Army. Disposal from outfalls is, however, not covered by the bill because it is already regulated by the Federal Water Pollution Control Act. Permits will be granted by the EPA, or the Secretary of the Army in the case of dredged or fill material, for transportation from the United States of the material to be dumped.

An applicant for a permit must convince the EPA that the dumping will not degrade the environment or present a danger to public health and he may, if necessary, be required to defend his application before a public hearing. If he decides not to bother with the bureaucracy involved in getting a dumping permit, he will be liable to a fine of $50,000 for illegal dumping, and to help ensure that he is discovered in his crime, the bill proposes that members of the public be rewarded by up to $2,500 for providing information which brings the offender to book.

As for research and development on the ecological consequences of marine dumping, the bill provides $2 million to the National Oceanographic and Atmospheric Administration (NOAA) to engage in both long-term and short-term studies. The Committee on Merchant Marine and Fisheries added this clause to the Administration's original proposals because it believes that an early warning system is needed to identify, for example, pesticide residues whose presence is likely to constitute an ecological hazard. Too often, such damage is noticed only when it has become irreversible. The bill also sensibly calls for wide-scale monitoring of the purity of the oceans. The proposal to give more government money to marine research has, however, already fallen foul of the Office of Management and Budget, for Donald Rice, an assistant director of OMB, wrote to Mr Thomas M. Pelly, chairman of the Committee on Merchant Marine and Fisheries, to complain that this section of the act is "unnecessary and undesirable". With curious logic, Mr Rice explained that since the EPA and NOAA are already spending more than $2 million between them on oceanographic research, giving them an extra $2 million may restrict their activities.

An even more curious aspect of the legislation dealing with research is the function envisaged for the National Science Foundation. In the original bill, the NSF was earmarked to receive an extra $1 million along with NOAA, but during the debate, Mr Lennon, from North Carolina, deleted all reference to the NSF and instead substituted the Secretary of State for Commerce. Mr Lennon's amendments were taken immediately after a roll call, and in the confusion, or perhaps in the absence of interest from his colleagues, they were accepted without discussion or division. Mr Lennon later explained, however, that he had decided to cut the NSF out of the bill because NOAA is better equipped to manage the research programme, and by vesting the responsibility in the hands of a single agency, duplication of effort can be cut to a minimum.

The chief fight with the Administration over the bill is likely, however, to involve the section dealing with the designation of marine sanctuaries in which all sorts of activities would be prohibited in an effort to preserve the natural beauty or the wildlife of the sanctuary. NOAA has been charged with the task of deciding which areas of coastal water should be so designated, and the Secretary of State for Commerce will be given the authority to enforce whatever regulations are laid down to protect the sanctuary. Sanctuaries must be designated within two years after the bill is signed by the President, and their siting will be subject to public hearings.

The Administration's chief grumble is that this section of the bill is likely to cost up to $10 million a year for the first three years, mostly for the acquisition of land. But the Administration is also chary of infringing the rights of states whose shoreline borders on a proposed marine sanctuary. A move to delete this section of the bill in the House of Representatives was, however, defeated by a vote of 20 to 33, lack of a quorum notwithstanding, and a motion seeking to prohibit oil prospecting in areas being considered for designation as sanctuaries was turned down with an even smaller vote—10 to 42. But the days of indiscriminate dumping seem over.

Space Collaboration

THE successful meeting of scientists from the USSR Academy of Sciences and from the National Aeronautics and Space Administration (NASA) at Houston in June is to be followed by another meeting between the parties in Moscow in November. The aim of the series of meetings is to discuss the technical requirements for a possible link-up in space between an Apollo-type spacecraft and a Salyut-type orbital scientific laboratory. Even further in the future a link-up between a spacecraft of the Soyuz-type and a Skylab orbiting station might be considered.

The problem facing the scientists is to agree on compatible systems of rendezvous and docking, radio and optical signals, communications, life support and crew transfer. After the Houston meeting it was agreed that the technical feasibility of accomplishing such a docking exists in principle and that further studies would be advantageous.

The current plan is to initiate the Skylab project at the end of the Apollo programme and to launch the first such Earth orbiting workshop in May 1973. Three different groups of astronauts will stay on board for up to twenty-eight days on the first mission and for up to fifty-six days on the second and third missions planned for the end of 1973.

A Salyut spacecraft is already in Earth orbit, and the first stage of the proposed collaboration will ensure that the best developed facets of the United States and USSR space programmes will be combined.

NEWS AND VIEWS

Haemoglobin Synthesized in *Xenopus* Eggs

THE rumours, which have been circulating for the past several months, to the effect that Gurdon and his colleagues at Oxford have observed the translation of mammalian messenger RNAs which were injected into frog eggs and oocytes, were well founded. For on page 177 of this issue of *Nature*, Gurdon, Lane, Woodland and Marbaix describe in detail how to use *Xenopus* eggs and oocytes as an extremely sensitive assay system for amounts of messenger RNA as small as 1 ng. That is not all; with their oocyte system it is now feasible to study the control of the translation of messenger RNAs in living eukaryotic cells. This development, coinciding as it does with the progress several groups have made towards the development of efficient cell-free systems which support the translation of eukaryotic messengers, could scarcely have been better timed. With these two approaches at their disposal, and with the wealth of information about bacterial protein synthesis at hand, biochemists should, with luck, now be able to elucidate the minutiae of protein synthesis in eukaryotes.

9S RNA from reticulocytes is, of course, the most readily available mammalian messenger and the results of initial experiments by Gurdon and his colleagues, which are to be published shortly in the *Journal of Molecular Biology*, proved that oocytes, taken from *Xenopus laevis* induced to ovulate by hormone treatment, synthesize haemoglobin when they are injected with this RNA and haemin. Greatly encouraged, Gurdon's group then set about characterizing more precisely this system and, what is perhaps even more important, proving that the haemoglobin messenger is not a special case and that other foreign messengers can be translated in *Xenopus* oocytes.

Their first problem was discovering the best way to introduce labelled amino-acids into eggs and oocytes. It turned out that injected ^{3}H-histidine leaks out of oocytes far more rapidly than out of eggs; conversely, oocytes take up this label from the medium more rapidly than do eggs. Deciding to label eggs by injection and oocytes by incubation in labelled medium, they followed the rate of synthesis of haemoglobin after the injection of rabbit 9S RNA and compared it with the rate of translation of endogenous messengers. After a lag phase of some 10 to 15 minutes, presumably the time taken for the injected messenger to become associated with the cells' translation apparatus, the synthesis of haemoglobin and the translation of endogenous messenger continues at a constant relative rate for more than 20 hours. Furthermore, experiments with puromycin indicate that both endogenous protein synthesis and haemoglobin synthesis are equally susceptible to inhibition. Plainly there is nothing atypical about the way in which the haemoglobin messenger is translated and the haemoglobin messengers are no less stable in oocytes and eggs than their endogenous counterparts.

The next question to answer was how efficiently do oocytes and eggs translate the rabbit haemoglobin messengers? By measuring the size and specific activity of the pool of histidine in these cells and the amount of this amino-acid incorporated into haemoglobin during given times after the injection of known amounts of messenger preparations, Gurdon and his associates have made an estimate of the number of globin chains made per hour per molecule of messenger. Such estimates are inevitably only approximate for they depend on a variety of unproven assumptions. For example, the size of the pool of histidine in the cells which is drawn upon for protein synthesis might well be significantly less than the total amount of extractable free histidine, which was what Gurdon *et al.* measured. And factors such as the leakage of messenger from injected cells and the failure of some RNA molecules to act as messengers add further elements of uncertainty. Nevertheless the estimates provide a fairly reliable indication of the comparative efficiency of translation of haemoglobin messengers in different systems. It emerges that oocytes are almost as efficient at translating this messenger as are reticulocytes; at 20° C each molecule is translated about 80 times an hour in reticulocytes, 24 times an hour in the best oocyte preparations and a mere 0.1 times an hour in a cell free system, to judge from the published data of Lingrel.

But is the translation of haemoglobin messenger in eggs and oocytes a special case? Obviously if it is the system has only limited potential but, on the other hand, if *Xenopus* oocytes and eggs will support the translation of all manner of foreign messenger RNAs as efficiently as they support haemoglobin synthesis there are countless ways in which this system might be exploited. Unfortunately with so limited a selection of natural messenger RNAs currently available in anything like a pure form, Gurdon's group can only provide a partial answer to this crucial question but their answer is most encouraging. Of the three messengers which they tested a 9–11S RNA from mouse myeloma cells and the synthetic messenger AUGpolyU seem to be translated but phage f2 RNA is not. Oocytes receiving the myeloma messenger incorporate ^{3}H-serine and ^{3}H-threonine into protein which is precipitated by antisera against the myeloma protein and which co-chromatographs on 'Sephadex' with cold carrier myeloma protein. Synthetic AUGpolyU promotes the polymerization of phenylalanine and concomitantly endogenous protein synthesis is severely restricted. In short, more than one natural messenger and a synthetic messenger is translated.

As Gurdon *et al.* point out, this means that oocytes can be used as an assay system for the putative messenger activity of RNA preparations from eukaryotic sources. If injected RNAs either stimulate amino-acid incorporation by these cells or compete with the translation of haemoglobin messenger RNA they will probably be found to contain messengers. And as an example of the sensitivity of this system they show that as little as 2.5 ng of RNA from mouse 3T6 cell polysomes almost halves the amount of haemoglobin made by oocytes injected with saturating amounts of haemoglobin messenger. By contrast 30 ng of ribosomal RNA has no effect on the amount of haemoglobin made. Indeed by increasing the amount and number of radioactive amino-acids in the cells, Gurdon's group calculate that after incubations of about 20 hours it may be possible to detect as little as 1 pg of haemoglobin messenger.

GERONTOLOGY

Living Longer

from a Correspondent

AT the international forum on the control of human ageing, held from September 2–4 at the Gottlieb Duttweiler Institute (The Green Meadow Foundation) in Switzerland, two different points of view became apparent—there were those participants who stated that research in life prolongation must continue and those who were appalled by the social and economic aftermath of such added years.

According to Professor F. Verzar (Institutes für Experimentelle Gerontologie, Basel), this century will be the century of the aged and progress will be made in social gerontology, medical geriatrics and experimental gerontology. A move to the right of the human taximeter clock giving a 10–20 per cent increase in life span may come and batteries of tests to measure ageing rate in the short term must be used. Calorie restriction remains the simplest method of prolonging life and if any active agent such as an antioxidant is used it should be capable of being introduced as late in life as possible to prolong active vigorous life without increasing dependent old age.

The search is now on for a substance which will turn off the process of ageing. Professor B. L. Strehler (University of California) suggested that if the human thermostat could be reprogrammed to 2° C or less life would be increased by 25 per cent.

According to Dr L. Robert (CNRS, Laboratoire de Biochimie du Tissu Conjonctif) immunological manifestations of age related disease are probably themselves part of a general gene-related, differentiation-linked ageing mechanism. Orgel's (*Proc. US Nat. Acad. Sci.*, **49**, 517 ; 1963) theory of the inaccuracy of the protein synthesizing machinery of cells was supported by work with a strain of *Neurospora* (Dr C. M. Lewis, West London Hospital).

Professor I. Sobel (Florida State University) spoke on the employment problem of the over forty-fives. Older workers are already on average unemployed longer. Adding fifteen years to the life span would lead to a period of decline in earnings lasting for twenty-five to thirty years with serious consequential psychological upsets. Each 5-year increase in life span would raise the labour force by about 5 per cent.

Professor W. F. Anderson (University of Glasgow) considered that prolongation of active human life without massive retraining programmes for the older worker and without encouragement to take up part-time employment associated with adequate medical and social resources for the existing elderly would be disastrous.

The pharmacological control of ageing was reviewed by Dr C. G. Kormendy (Bristol Laboratories, Syracuse). He suggested that the most promising substances should be subjected to laboratory studies. Most agents still seem to be too toxic.

Dr M. Goldsmith (Science Policy Foundation, London) stressed that vast socioeconomic implications must be considered before institutions of gerontology are established. Fortunately, gerontologists are unlikely to contribute to demographic pressure before the year 2000 and antioxidants, perhaps the least expensive agents, would have no significant effect until the early decades of the twenty-first century (Dr R. W. Prehoda, Toluca Lake Station, California). Dr R. D. Clarke (Prudential Insurance Company, London) thought that, by 1990, therapies based on two or more ageing theories may extend the life span by 35 per cent. Any modest increase in contraception, abortion or sterilization would have greater impact on demographic pressures in the next thirty to forty years than the probable advances in gerontology.

In discussion, pleas were made for controlled studies now of the effect of certain endocrine substances, for example oestrogens in women, regarding their influence on the life pattern, and Dr J. Huet (International Center of Social Gerontology, Paris) made a forceful argument for an international institute of gerontology under Professor Verzar's administration.

The participants, although differing in the benefits of and means of prolongation of life, were unanimous in the need to plan now for larger numbers of old people. Multidisciplinary action should be taken by scientists, sociologists and physicians.

Drug Resistance in Cancer Chemotherapy

THE problem of the development of resistance to chemotherapy is one of the major difficulties in the path of successful treatment of disseminated cancer. A study of the mechanisms of resistance in man is extremely difficult for most cancers because remissions are uncommon and multiple biopsies of cancer material are not usually possible. A study of resistance to drugs in acute leukaemia, however, is feasible because multiple complete remissions are common and the blood and bone marrow can provide malignant cells at several stages during the development of the disease.

Drug resistance may develop because the agent is not taken up by the malignant cell or because enzymes are produced which catalyse its destruction either in the malignant cell itself or by normal tissues such as the liver. New metabolic pathways may be used to circumvent the metabolic block of the agent used. These types of resistance are likely to be specific for a single group of chemotherapeutic agents with similar modes of action. Another possible mechanism of resistance is less specific and depends on an alteration in the proliferation characteristics of the cancer cell. Such changes could result in an alteration in the effect of all drugs acting on cancer cells at the time of DNA synthesis which includes most anti-cancer chemotherapeutic agents. Resistance to a large number of drugs could therefore develop non-specifically. There is growing evidence that all these mechanisms may be operative in man.

One example of resistance to a drug being modified by metabolic alterations within the cancer cell is provided by the treatment of acute lymphoblastic leukaemia using L-asparaginase. This agent is thought to act, at least in part, by depriving the malignant cells of the amino-acid L-asparagine. Resistance to L-asparaginase which develops during or following treatment has been associated with increased levels of asparagine synthetase activity within the leukaemic cell (S. M. Haskell *et al.*, *Cancer Res.*, **29**, 974 ; 1969).

The response of acute leukaemia in man to treatment with the antimetabolite cytosine arabinoside has also shown a correlation with the rate of uptake of the drug *in vitro* and its subsequent activation by phosphorylation (M. Y. Chu and G. A. Fisher, *Biochem. Pharmacol.*, **14**, 333 ; 1965). Stewart and Burke report in next Wednesday's *Nature New Biology* that leukaemic cells from patients who respond to treatment contain six times less cytosine deaminase than is present in cells of those who do not respond. The concentration of this enzyme, which inactivates cytosine arabinoside, increases following a course of therapy and this is correlated with increased resistance to therapy.

Tests *in vitro* in man for predicting response to the initial treatment using different drugs are unfortunately unreliable—the tests pay no attention to an agent's absorption, detoxication, excretion, distribution and duration in the body. The mechanisms whereby cells can repair or circumvent damage by the agent may be very different *in vivo*. Nevertheless, in acute leukaemia it may be possible to predict the development of resistance, following one course of treatment, to a particular drug. This could well be important in the management of patients relapsing with this disease.

ENZYMES

Proprotease Prospects

from our Molecular Biology Correspondent

IT seems to be a general rule of nature that animal proteases are manufactured in a harmless packaged form, as zymogens, and are activated, generally by the intervention of some other protease, when the organism has need of them. This process may have evolved in part as a device to prevent the onset of a lethal proteolytic activity on completion of biosynthesis, and, more interestingly, as a refined control mechanism, as reflected, for example, in the role of the enzyme cocoonase. This is a serine protease, produced by the silk moth for use as a chemical crowbar to break open its cocoon. It is synthesized as a zymogen, procococoonase, in cells at the mouth of the insect, is deposited on the surface, where it forms a solid crystalline crust, is activated, and then dissolved in a specially secreted potassium bicarbonate solution, with a *p*H corresponding to the activity optimum. The solution seeps into the cocoon, and dissolves out the sericin, a proteinaceous "silk glue", and leaves the moth free to pass into the outside world.

The latest in a series of articles from the two laboratories which have uncovered this scheme (Berger, Kafatos, Felsted and Law, *J. Biol. Chem.*, **246**, 4131; 1971) now describes the nature of the zymogen, and the manner of its activation. An extract of the secretory parts of the insect, at a point in its development some days before emergence, contains no cocoonase activity. The attempts first made at activation of the procococoonase in this solution with active cocoonase resulted in rapid loss of the activity of the latter. This, it transpired, was a consequence of attack by a tyrosinase present in the blood. When this enzyme was inhibited the cocoonase was seen to bring about gradual activation. Trypsin or subtilisin, on the other hand (but not chymotrypsin), caused very rapid liberation of the full cocoonase activity, and it was therefore surmised that free cocoonase can play only a secondary role in activation. One does not, however, have to search far for a source of activating protease activity: at an early stage of adult development the region between the adult and the pupal cuticle is full of a liquid, the moulting fluid, rich in proteases, which serves to digest the pupal cuticle. When the fluid has done its work it is reabsorbed, leaving apparently a residuum of proteases to look after the procococoonase.

Estimates of molecular weights by a number of methods showed that the molecular weight of the zymogen was about 32,000, some 8–10,000 more than free cocoonase. Thus by contrast with trypsin, which it otherwise closely resembles, a large part — about one quarter—of the chain is lost on activation. Benger *et al.* point out that because the activation fragments of zymogens are in effect nothing more than covalently bound inhibitors, the structural requirements may be supposed to be much less stringent than for the active enzyme; and that large differences introduced in the course of evolution in these parts of the chain are not perhaps so very surprising.

Another new zymogen has been discovered by Harper, Bloch and Gross (*Biochemistry*, **10**, 3035; 1971). This is the precursor of the collagenase which the tail of the tadpole carries, as the means for its own annihilation when the moment of metamorphosis is at hand. Collagenases have been widely identified in animal tissue, and especially in diseased conditions, in which the elimination of collagen masses is desirable. The proenzyme was discovered through the observation that anti-collagenase antibodies were absorbed by collagenase-free extracts of tadpole tail-fin tissue. The chromatographic fraction of the extract believed to contain the zymogen failed to generate collagenase activity on treatment with trypsin or chymotrypsin. When, however, the fraction was mixed with a medium in which living tail-fin tissue had been maintained for some days, and incubated at 37° C, activation ensued. The collagenase could be detected by its effect on the viscosity of the substrate, and by the appearance of tropocollagen fibrils with characteristic periodicities in the electron microscope. The collagenase produced under these controlled conditions was identified with the usual preparations by its inhibition by anti-collagenase antibodies. The collagenase has apparently the remarkably high molecular weight (assuming the reliability of the detergent-gel electrophoresis method) of 110,000, or so, and the zymogen seems to be slightly larger. The activating factor is easily inactivated by heat, and is evidently a specific protease, that appears only at the right moment.

Precursors of DNA Replication

THE biochemistry of DNA replication as opposed to DNA repair is still a great enigma and, according to Werner, so it will remain if those intent on elucidating it persist in assuming that DNA replicase uses the deoxynucleoside triphosphates as immediate precursors. For in next Wednesday's *Nature New Biology*, Werner describes experiments which lead him to the conclusion that the enzyme responsible for the semi-conservative replication of DNA in *Escherichia coli* polymerizes some activated form of the deoxynucleoside monophosphates.

Earlier this year, Werner reported in *Nature* (**230**, 570; 1971) that short pulses of ^{3}H-thymidine are incorporated preferentially in small DNA chains, Okazaki pieces, whereas short pulses of ^{3}H-thymine are preferentially incorporated into larger DNA chains. From this he argued that *E. coli* can differentiate between thymidine and thymine using the former for repair DNA synthesis and the latter for replication. His latest experiments are an attempt to identify the pathway of incorporation of ^{3}H-thymine into DNA. When there is a dynamic equilibrium between the intracellular nucleotide pools—a steady-state condition—the pool of thymidine monophosphate is maximally labelled about 1 min after the cells are exposed to ^{3}H-thymine. Maximum incorporation of the thymine into DNA and maximal labelling of the pools of thymidine diphosphate and triphosphate are attained after about 10 min. TMP is therefore not itself the immediate precursor of DNA replication but either TDP or TTP might be.

When, however, the cells are fed ^{3}H-thymine and simultaneously deoxyadenine or thymidine, which act as donors of deoxyribose, the pool of TMP is greatly increased and is maximally labelled within about 10 s and the maximal rate of incorporation of the thymine into DNA is reached within 20–30 s. The pools of TDP and TTP are, however, not maximally labelled until about 2.5 min. From these observations and measurements of the specific activities of the pools of TMP, TDP and TTP Werner concludes that although TMP is not itself an immediate precursor of DNA replication it is on the direct pathway to replication while TDP and TTP are not, and has to be converted to an activated form of TMP before being incorporated into DNA.

Because the size of the pool of activated TMP precursor is much smaller than the pool of TTP, and because DNA is replicated so very rapidly Werner suggests that simple diffusion and collision would be too slow to support the selection and alignment of the activated monophosphate precursors by the DNA replicase. He speculates therefore that some protein like that described by Alberts and Frey (*Nature*, **227**, 1313; 1970) may unwind the DNA duplex ahead of the replicase. The exposed single strands can then act as templates for the preselection and alignment of the precursors and all the DNA replicase has to do is link them together by phosphodiester bonds.

MITOCHONDRIAL DNA

Symmetric Transcription

from our Cell Biology Correspondent

THE transcription of double helical DNA by DNA dependent RNA polymerase is generally assumed to be an asymmetric process with only one of the two strands of the DNA, the coding strand, being transcribed into messenger or one of the stable species of RNA. In *Escherichia coli,* as Travers, Bautz and Burgess and their associates have shown, the ability of RNA polymerase to select and transcribe the coding strand depends on the presence of sigma factor, without which transcription is symmetric.

Mitochondria which seem to have evolved from symbiotic bacteria, not only contain small double stranded and closed circular DNA molecules but also their own RNA polymerase, which is distinct from that in the nucleus of eukaryotic cells. As Küntzel and Schäfer reported recently (*Nature New Biology,* **231**, 265 ; 1971), the RNA polymerase in the mitochondria of *Neurospora crassa* is a much simpler and smaller molecule than *E. coli* RNA polymerase ; it comprises a single polypeptide chain with a molecular weight of about 64,000. On reflexion therefore, Aloni and Attardi's report (*Proc. US Nat. Acad. Sci.,* **68**, 1751; 1971) that both the strands of the mitochondrial DNA of HeLa cells are transcribed *in vitro* is perhaps not all that surprising. Symmetric transcription may perhaps be the evolutionary price mitochondria have had to pay for their simple genome and its RNA polymerase.

The two strands of HeLa cell mitochondrial DNA can be separated by appropriate centrifugation, and Attardi and his colleagues have developed methods for isolating mitochondrial RNA made *in vivo* after pulse labelling with uridine. Determining whether transcription is symmetric or asymmetric can therefore be determined by comparatively straightforward DNA. RNA hybridization experiments. Aloni and Attardi find that RNA made in the mitochondria during short (1–5 min) pulses hybridizes equally to the heavy (H) and light (L) strands, but RNA made during longer pulses hybridizes preferentially with the H strand. They have already obtained evidence which indicates that the entire H strand is transcribed, and this together with the finding that RNA made during short pulses hybridizes equally with H and L strands, and the rapid sedimentation of the L strand RNA, suggests that like the H strand the L strand is extensively and perhaps completely transcribed. The L strand transcript, however, rapidly disappears from the mitochondria either because it is degraded or possibly because it is exported to the cell cytoplasm. Why the transcription of mitochondrial DNA is an exception to the rule of asymmetric transcription remains to be seen.

Schäfer and Küntzel and their colleagues (*Europ. J. Biochem.,* **21**, 478 ; 1971), having isolated the RNA polymerase of *N. crassa* mitochondria, have now devised a method for isolating intact the DNA from these mitochondria. They find it is a circular DNA some 25 μm long, in other words some five times longer than the mitochondrial DNA of HeLa and other vertebrate cells ; this leads them to speculate that the mitochondria in fungi may represent an early stage in the reductive evolution of bacterial endosymbionts which culminated in the mitochondria of vertebrates with their very small genomes. Using mitochondrial DNA from *N. crassa,* Schäfer *et al.* have investigated its transcription *in vitro* by *E. coli* RNA polymerase with sigma factor and conclude that there are about eight to nine specific binding sites for this mitochondrial genome. Some 50 per cent of the RNA transcribed *in vitro* by the bacterial enzyme seems from hydridization experiments to be ribosomal and transfer RNA. Among the remainder of the *in vitro* product are RNA strands which self anneal and may well be the product of symmetrical transcription of regions of the genome other than those which specify the stable mitochondrial RNAs. As Schäfer and Küntzel have themselves shown, however, the mitochondrial RNA polymerase is very different from the bacterial enzyme and it would be interesting to see what RNAs are transcribed *in vitro* by the mitochondrial enzyme.

STOMATA

Response to Humidity

from a Correspondent

TRANSPIRATION in plants is controlled by adjustments in the size of minute pores, the stomata, which perforate the surface of leaves. Each stoma consists of a slit bounded by two specialized epidermal cells, or guard cells, which determine its size. When the guard cells take up water and swell their shape alters in such a way that the pore opens and when they become less turgid it closes. Stomata are normally in an open or partly-open condition during the day and closed at night. As a result, diffusion of carbon dioxide into a leaf, which follows the same pathway as

Seismic Signals from Underground Explosions

IN next Monday's *Nature Physical Science,* A. Douglas, P. D. Marshall and D. J. Corbishley, from UKAEA, Blacknest, suggest reasons why some of the seismic signals from underground explosions are more complex than others. The basis of their idea is that the direct P waves recorded in a complex signal have passed through material with a lower average value of the quality factor, *Q*, and have been alternated.

Most P signals from underground explosions are simple in character and usually comprise a single pulse—two to three cycles long—followed by a tail of lower amplitude arrivals which can be explained in terms of reflexions in the crust or upper mantle. But the less common complex signals have a tail with an amplitude that is similar to or even larger than the first arrival.

Douglas *et al.* point out that, according to their theory, the tails of complex signals should contain more high frequency energy than the direct P waves because high frequencies are selectively attenuated in materials of low *Q* ; complex signals from an underground explosion should therefore point to lower average explosion magnitudes than the simple signals because of the reduction of the amplitude of the first arrivals. To test the whole theory Douglas *et al.* have examined the P seismograms of two underground explosions—one fired near Bukhara in the Soviet Union and the other (the nuclear explosion Longshot detonated on October 29, 1965) at Amchitka in the Aleutian Islands.

The vibrations from the Russian explosion were detected at Eskdalemuir in Scotland and at Gauribidanur in India, and the records from these two stations provide good examples of simple and complex signals from the same source. The record at Gauribidanur is complex and there is clear evidence of late arrivals with a higher dominant frequency than the earlier arrivals. And the magnitude of the explosion as measured from the Eskdalemuir records is higher than that indicated by the Gauribidanur data, suggesting that the direct P waves arriving at Gauribidanur had been attentuated.

Douglas *et al.* detail two examples of complex signals from the Longshot explosion (both recorded in British Columbia) from which the magnitude of the explosion was estimated to be 4.8 and 5.4 ; this is much lower than the average estimate of 6.2 from the data of the arrays operated by the United Kingdom Atomic Energy Authority which all detected a simple signal. They also find that the beginnings of the complex signals have a dominant frequency of ~0.8 Hz compared with a dominant tail frequency of ~1.4 Hz, again in accord with the theoretical predictions.

water vapour, is facilitated during periods of photosynthesis, and water loss is curtailed at night. But stomata also close sometimes during the day where the air is dry and excessive evaporation places the plant under water stress.

It is now well established that light causes stomata to open by lowering the carbon dioxide concentration in the vicinity of the guard cells as a result of photosynthesis. By this device increased consumption of carbon dioxide by the leaf leads to stimulation of absorption and vice versa. The response to changes in the humidity of the air has been less intensively investigated, but it has been generally accepted that it depends on alterations in the water content of the leaf as a whole. Lange, of the Botanical Institute, University of Würzburg, has dissociated himself from this view and in a recent article in *Planta* (**100**, 76; 1971) he and his colleagues put forward further evidence that guard cells respond directly to changes in the humidity gradient existing between the external air and substomatal air space.

Lange *et al.* have devised an elegant technique whereby it is possible to observe microscopically the behaviour of stomata in isolated strips of leaf epidermis when subjected to rapid changes of ambient air of different moisture contents. Induction of opening and closing by alternate exposure of the outer surface of the epidermis to moist and dry air was repeated as many as fifteen times on the same stoma. When different areas of the same piece of epidermis were treated separately the stomata in each part responded independently according to the conditions to which they were subjected.

Lange *et al.* conclude that guard cells act as humidity sensors which respond directly to changes in the gradient of water potential between the air above the leaf and in the sub-stomatal air space. When this gradient increases the guard cells lose water and the pore closes and when it falls they take up water causing the pore to open. This mechanism causes a rapid adjustment in pore size in response to changes in evaporative conditions in the vicinity of each stoma irrespective of the water status of the leaf as a whole. Lange *et al.* assume that the level of carbon dioxide was unaffected by the treatments that were applied and that the changes in turgidity of the guard cells is attributable to a direct influence of the humidity gradient on absorption and loss of water by these cells. The possibility of an interaction between carbon dioxide concentration and water potential gradient in the overall control of stomatal response will no doubt be examined in the future extension of this work.

Satellite Lines in the Solar X-Ray Spectrum

In next Monday's *Nature Physical Science*, J. H. Parkinson of the University of Leicester reports observations of satellite lines in the solar X-ray spectrum. These are lines which are observed close to the resonance transition of each helium-like ion, hence the name "satellite".

During the past few years the study of helium-like ion spectra and associated satellite lines has proved to be of considerable interest to solar physicists. In addition to the resonance line, a partially forbidden "intercombination" line is observed for each ion. A further strong line at slightly longer wavelength than the resonance and intercombination lines was shown by Gabriel and Jordan (*Nature*, **221**, 947; 1969) to originate from a transition which was previously thought to be highly forbidden as a one quantum transition. These authors (*Mon. Not. Roy. Astron. Soc.*, **145**, 241; 1969) then showed that the relative intensity of the intercombination and forbidden lines can depend on the electron density of the emitting plasma.

The satellite lines are caused by transitions in the stage of ionization lower than the helium-like ions, that is, in the lithium-like ions. The resonance line of the helium-like ion is a $1s^2$–1s 2p transition. The satellite lines have a similar wavelength to this transition because they are transitions of the same type but in the presence of a further electron (that is, $1s^2\ nl$–$1s\ 2p\ nl$). Satellite lines have been observed in laboratory spectra for many years—Edlén and Tyrén first reported them in 1939, and proposed the forementioned origin.

As part of the investigation leading to the identification of the helium-like ion forbidden transition, Gabriel and Jordan classified several multiplets of satellite lines, because it was at one time suspected that the strong solar line could have a similar origin. They proposed that the excited levels giving rise to the satellite lines are populated by the process of di-electronic recombination, hitherto not reported as a process important in laboratory plasmas, but thought to be important at the lower densities in the sola corona.

Several groups of workers (at the Aerospace Corporation, the Goddard Space Flight Center, the Lebedev Institute, and the US Naval Research Laboratory) have recently reported the presence of weak satellite lines in solar spectra, chiefly during flare activity. The new observations by Parkinson were obtained with improved spatial resolution by using a collimated crystal spectrometer, and refer to a stable phase of the active region. Parkinson's intensity data indicate that, as in the laboratory, the solar satellite lines are formed by the process of di-electronic recombination; this demonstrates directly the existence of this process in the solar corona. The relative intensities of the satellite lines and helium-like resonance lines are therefore dependent on the electron temperature in the emitting plasma. Parkinson has observed the intensities of the helium-like lines and satellite lines, so both the electron density and temperature in the emitting solar active region can be studied. And because each group of lines occurs over a limited wavelength region it should be possible to obtain reliable relative intensities.

Aspirin and Human Embryonic Cells in Culture

In next Wednesday's *Nature New Biology*, Paine and Nagington report that sodium salicylate—a breakdown product of the common sodium acetylsalicylate or aspirin—inhibits the growth of some human embryonic cells in culture.

Tissue cultures from skin, lung, heart and kidney were prepared from 12, 14 and 18-week old human embryos. The cells were grown in the presence of various concentrations of sodium salicylate. Kidney cells from 12 week old embryos showed the highest sensitivity —2 mM (320 μg/ml.) salicylate completely inhibited growth and 0.5 mM (80 μg/ml.) almost reduced the growth rate by half. Lung cells were also affected, but less markedly. Heart cells were even less sensitive than kidney and lung cells; only 2 mM (320 μg/ml.) salicylate showed any significant effect at all. Skin fibroblasts were not inhibited, even by 2 mM salicylate.

The mode by which salicylates produce this inhibition is unknown. Salicylates have a wide variety of pharmacological effects. There are indications of a correlation between salicylates taken during early pregnancy and foetal defects; but a causal connexion has not been established. Analysis of the foetal blood of 272 consecutive deliveries showed that about 10 per cent had salicylate concentrations of more than 10 μg/ml.; the mean concentration in these infants was 33 μg/ml. (about 0.2 mM) (Palmisano and Cassady, *J. Amer. Med. Assoc.*, **209**, 556; 1969).

Paine and Nagington quite properly point out that one cannot infer that the action of a drug in an intact animal or human is similar to the effect of the drug on cells in tissue culture. But the evidence they present is enough to warrant further investigations.

BIOENGINEERING

Aids for the Disabled

from a Correspondent

THAT the successful design of an aid for the disabled depends on detailed knowledge of the behaviour of the normal was clearly illustrated at the conference on human locomotor engineering held at the University of Sussex from September 7 to 10. The Institution of Mechanical Engineers had assembled speakers from many disciplines and discussion was both brisk and fruitful.

From a number of contributions dealing with the characterization of individual gait patterns in the various phases of the walking cycle, using electromyographic, cine-photographic or force-plate recording, it became clear that there is a need for more data about the functional anatomy of the limbs, and in particular about the exact positions of the lines of action of the various muscles relative to the centres of rotation at the relevant joints. Without this information it is difficult to calculate the force which any specific muscle exerts at a particular time or what the stresses are on the ligaments or articular facets of a joint. Quantitative descriptions of the time courses of several parameters in the gait pattern are required both for the design of the dynamics of artificial limbs and also in assessing the fitting of particular limbs to individual patients. Some of the walkway studies, such as that described by Dr M. Milner (Groote Schuur Hospital, Cape Town) and Dr T. Kasvand (National Research Council, Ottawa), now incorporate computer-scanning of the cine-film to derive the paths of markers attached to the subject over the axes of rotation at the various joints.

The recordable electrical activity of the muscles proves disappointing as a guide to the magnitude of the forces, but it does give useful timing information and an ingenious technique of display has been devised by Dr D. S. Grieve and Mr P. R. Cavanagh (Royal Free Hospital, London). Instantaneous values of the angles at adjacent joints, say, knee and ankle or knee and hip, are plotted against one another during the walking cycle and the resulting locus is marked off to indicate the period during which a specific muscle is active. The patterns generated in this way can be recognized by eye and may prove useful in recording the progress of clinical conditions.

Knowledge of the normal patterns of muscle activity also provides the basis for programmed electrical stimulation of muscles to restore a lost function. Dr E. M. Sedgwick and Mr S. A. G. Chandler (University of Southampton) have developed a neat trick of feeding back the amplitude of the M wave of the electromyograph in a servo to give proportional control of the number of motor units stimulated. This method overcomes the difficulty that the range of intensities that lie between threshold and maximal stimulation is small and is comparable with the variation in the threshold itself.

In the design of artificial joints for implantation, there are many conflicting requirements. Dr P. S. Walker (The Hospital for Special Surgery, New York) concluded that the chief long term problem now is the reduction of wear at the surfaces of contact. New materials need to be tried. The properties of the adhesives at present in use also leave something to be desired, particularly where tensile stresses are involved.

In the field of simulations, Mr D. C. Witt and Mr J. I. Hall (University of Oxford) have made considerable progress with their automatically stabilized powered walking device. This device is about five feet tall and stands on small feet at the ends of telescopic legs a few inches apart. The leg lengths are adjusted by hydraulic actuators to give alternating support, stability being achieved by adjusting the time of dwell on the appropriate side. They use a device modelled on the semicircular canals of the inner ear as an attitude sensor to control the switch-over. In a film, the "robot" was shown walking on the spot and it was not unbalanced when a block of wood was suddenly inserted under the descending foot. Symmetrical fore-and-aft motion of the legs has now been incorporated and the device is making its first steps in forward locomotion.

Professor J. M. Nightingale and Mr R. W. Todd (University of Southampton) described a robot hand which provides complex finely-adjusted movements of the digits to perform acts initiated by electromyographic signals from the operator (patient). The control signals that can be picked up from a patient and made available to control an external device are very severely limited in their information-carrying capacity. Adjustments of the digits to take account of the shape or fragility of the object to be grasped thus need to be delegated to an automaton which can take over the "unconscious" elements in the control task.

Measuring Epstein-Barr Virus Genomes

WHETHER or not Epstein–Barr (EB) virus has any role in the aetiology of Burkitt's lymphoma or nasopharyngeal carcinoma is still a matter of controversy and there seems little prospect of the issue being decided in the next several years. On the other hand, it is now generally accepted, chiefly as a result of the hybridization experiments done by Zur Hausen and his colleagues (*Nature*, **227**, 245; and **228**, 1056; 1970), that cell lines obtained from Burkitt lymphoma biopsies may contain detectable amounts of EB virus DNA even though these cells do not produce progeny EB virus particles. That is of course a familiar situation to tumour virologists who for the past several years have argued about precisely how many polyoma virus or Simian Virus 40 genomes are associated with the genome of a transformed cell. And now the same arguments are arising among those studying EB virus, for in next Wednesday's *Nature New Biology*, Nonyama and Pagano suggest that the so-called Raji line of Burkitt lymphoma cells may contain about sixty genome equivalents of EB virus DNA rather than about six equivalents, which was the estimate of Zur Hausen's group.

Zur Hausen's estimate was based on measurements of the extent to which EB virus DNA hybridizes with DNA from Raji cells and Nonyama and Pagano have measured the extent to which hot RNA, transcribed *in vitro* off EB virus DNA by *Escherichia coli* RNA polymerase, will hybridize with Raji cell DNA. The advantage of this second technique is simply that the RNA can be made some 100-fold hotter than EB virus DNA. Using their high specific activity RNA, Nonyama and Pagano find some 700 genome equivalents of EB virus DNA in a line of Burkitt cells which produces progeny EB virus and some sixty-two genome equivalents of EB virus DNA associated with the mitotic chromosomal DNA of the non-producer Raji line. They also detect between forty-five and a hundred genome equivalents of this viral DNA in human leukaemic and normal leukocytes culture, cells which do not carry detectable amounts of EB virus antigens. By contrast the human HeLa cell does not contain detectable amounts of EB virus DNA, and Nonyama and Pagano believe that their data support the idea that infection by EB virus is required for the continuous growth in culture of human leukocytes.

What Sugawara, Mizuno and Osato have to say in next Wednesday's *Nature New Biology* should also interest anybody working with EB virus. By centrifugation through discontinuous gum acacia density gradients they have separated, by virtue of differences in buoyant density, EB virus carrier cells from cells actively supporting the replication of this virus. As the active replication of the virus in carrier cells is initiated and progresses so the buoyant density of the cells seems to decrease, and their separation becomes possible.

Reminiscences of Rutherford

from a Correspondent

AT the thirteenth international congress of the history of science held in Moscow, August 18–24, one day (August 20) was devoted to a colloquium on the Rutherford centenary and 75 years of radioactive studies. The USSR Academy of Sciences extended a generous invitation to many of Lord Rutherford's former members of staff and students of the Cavendish Laboratory to attend this colloquium and to spend many days in the Soviet Union as guests of the academy. Academician Peter Kapitza (Institute for Physical Problems, Moscow) welcomed the rather small group of his old colleagues who had been able to accept the invitation; he had asked them to include in their addresses personal reminiscences of Lord Rutherford and the Cavendish Laboratory as it was in the 1920s and 1930s.

Professor Kapitza's acquaintance with Rutherford extended over more years than that of any other speaker; he had come to England in 1922 and remained as a member of the staff until his return to Russia in 1935. He spoke of the lessons he had learned from his Cambridge days and the great debt he owed to Rutherford who was not only an outstanding scientist but was the head and organizer of the most famous school of physics at that time. The genius of Rutherford lay in the speed with which he revealed the laws of nature and also in his remarkable talent for selecting young men with creative ability. Professor Kapitza recalled that only an accident had brought Rutherford to England: there were two candidates for the one 1851 Exhibition scholarship offered to New Zealand that year and Rutherford was placed second; fortunately for the world the winner decided not to leave New Zealand. Yet reading Rutherford's earliest works, which today are of no consequence and have sunk into oblivion, even at that time his genius can be recognized; he could not be referred to as a scientist of great erudition but his creative imagination and daring in the development of hypotheses which fitted the facts were the key to his success. Professor Kapitza thought that young people ought to read more of the original works of the great pioneers in science, and that this was especially important for those who are likely to be in charge of a group of research students and who may have to select staff.

Lord Blackett was prevented by illness from attending the celebrations and his contribution was read by Professor N. Feather (University of Edinburgh). He reviewed Rutherford's remarkable career of scientific research and discovery and suggested ways by which a study of this can help science today. He reminded the audience that some of Rutherford's greatest discoveries arose from a keen observation of what may be described as chance or anomalous effects. Air draughts in his room at McGill University spoilt measurements of the strength of a thorium source but led to the discovery of the "emanation" gas escaping from the thorium and thence to the whole pattern of radioactive decay; a few alpha-particles coming back from the same side of a thin metal foil as was bombarded by a strong beam of such particles puzzled him and led him to what is generally regarded as his greatest discovery, the nuclear theory of the atom; and a few exceptionally long-range protons projected forwards from some light nuclei, but not from all, when bombarded by energetic alpha-particles led to the discovery of the artificial disintegration of nitrogen. "May every young scientist remember (these incidents) and not fail to keep his eyes open, for the possibility that an irritating failure of his apparatus to give consistent or unexpected results may . . conceal an important discovery."

Lord Blackett himself had to examine 400,000 alpha-particle tracks to discover only six which revealed the process of disintegration described earlier by Rutherford. In those eventful years Rutherford was right in believing that nuclear physics was one of the greatest if not the greatest single branch of physics and he tended to decry the importance of some of the other branches, notably theoretical physics; he did not see as clearly as he might have done the impact of the study of the electronic structure of the atom on the developing quantum theory which itself was soon to supply the explanation of the range of the alpha-particle. Rutherford was not a mathematician but he used mathematics to great effect in his two greatest experimental achievements and he sought out those fields of research in which little mathematical reasoning was needed. He would have thoroughly enjoyed the early days of the new unstable elementary particles.

Professor Feather then described his own experiences in the Cavendish Laboratory from 1926 up to the date of Rutherford's death; he began as a research student and, apart from two brief interludes, he remained as a member of the staff and was perhaps the last to talk to Rutherford about the work of the laboratory before Rutherford went to hospital for the hernia operation from which he never recovered. Feather's research work for many years involved the use of the Wilson cloud

Professor P. Kapitza addressing the Rutherford colloquium at the thirteenth international congress of the history of science. On Kapitza's right, his secretary, Dr D. Shoenberg, Dr T. E. Allibone and Dr W. B. Lewis; on his left, Professor N. Feather, Professor S. Devons, Mr G. Danin and the chairman of the congress, Professor B. M. Kedrov.

chamber which was operated in those days most laboriously by hand and needed the assistance of a collaborator. During some of those years Rutherford, as president of the Royal Society, had many calls upon his time so his tours of the laboratory were less frequent than formerly, but Professor Feather described an experience shared by everybody at the Cavendish, of hearing Rutherford's heavy footsteps coming along the corridor, and his voice mounting louder as, in room by room, he fired questions about the work in progress, sometimes administering a much-needed prod to "cut out the frills", sometimes half grudgingly applauding good work, always cautious in assessing results, but then when quite satisfied, ensuring prompt publication as in the case of the papers submitted to the Royal Society announcing the discovery of the neutron and its effects.

Professor S. Devons (Columbia University), a product of the last phase of Rutherford's life, gave a vivid description of the undergraduate's contacts with the great men of that age, and then, later, attendance at the meeting of the Cavendish Physical Society. "Rutherford took the chair but was no passive chairman, his vigorous and amiable personality shone as he introduced the lecturer and later opened the discussion; his attitude was always unambiguously expressed." Facts were to be respected and treated differently from theory; though Rutherford greatly respected at least some of the theoreticians he disliked a smoke-screen of verbiage. The era of simple apparatus, the "string and sealingwax" trademark of the Cavendish was slowly passing when Devons began research—it had indeed been almost Henry Cavendish's own trademark 150 years earlier—but the budding research student still had to be "broken in" in the famous attic, making apparatus without assistance, using only the scraps and junk discarded in days gone by. His own choice of work, cosmic rays, had never actively interested Rutherford, possibly, Professor Devons suggested, because they were too complex and, not being under direct control in the laboratory, may have needed apparatus too elaborate for those days, and, as Rutherford had commented, the interpretation of results could prove a trap for the unwary.

Dr D. Shoenberg (University of Cambridge) contributed some delightful asides. Rutherford had once said that science can be classified into physics and "stamp collecting", but, as Shoenberg pointed out "stamp collecting" can yield rewarding results if a general principle can be deduced from the collection of data and Moseley's idea of making a systematic study of the X-ray spectra of the elements did indeed provide an important clue to the nucleus. Dr Shoenberg reminded the audience that Rutherford won the Nobel Prize for "stamp collecting", that is, for chemistry, and on one occasion Rutherford introduced Debye with the remark "although he is a chemist he is really quite a decent sort of chap"!

Dr Shoenberg began his research as one of Professor Kapitza's pupils in the new building, the Mond Laboratory then being erected to rehouse Kapitza's intense magnetic field work and the new work on very low temperatures. Rutherford had taken a very great interest in the magnetic field work and had obtained for several years very considerable financial support for it, certainly considerable as judged by the standards prevailing in the "old" Cavendish. Although Rutherford was no expert in these two subjects studied in the Mond he had an uncanny way of getting straight to the heart of the matter under discussion, seeing what was missing, and asking for key measurements to be taken; and when Dr Shoenberg used mathematical terminology to describe the new theories of metals, Rutherford would say "now just tell me in simple language what that term is that you keep using".

Dr T. E. Allibone spoke of Rutherford's lectures at the Royal Institution and of his visits to the Royal Society Dining Club at which so many eminent Russian scientists had dined starting with Count Razumovski, the president of the Russian Academy who had dined in 1766 with Henry Cavendish, Benjamin Franklin and others. Rutherford was invited to give the Bakerian Lecture of the Royal Society in 1904, a signal honour for so young a man, he dined as a guest of the club that evening, and on the following day gave his first Friday Evening Discourse at the Royal Institution. It was there that he spoke of the energy released by the radioactive elements probably being responsible for a much slower rate of cooling of the Earth than had been calculated by Lord Kelvin—who was in the audience—a few thousand million years compared with Kelvin's estimate of a hundred million years. During the Manchester period he gave several discourses, demonstrating the counting of alpha-particles and describing the disintegration of nitrogen. His lectures were always very popular. Dr Allibone thought it doubtful that Rutherford ever believed in the theory of nuclear structure put forward by Gamow in 1928/29 which precipitated the work on positive-ion acceleration to half a million volts, because when Rutherford opened the new High Voltage Laboratory of the Metropolitan-Vickers Company in February 1930 he asked for millions and millions of volts and a discharge tube compressed into a small-sized room, whereas, if Gamow were to be believed Rutherford ought to have asked for a very large current of positive ions accelerated to only a modest voltage.

Dr W. B. Lewis (Atomic Energy of Canada Ltd) spoke as one of the small band of personal collaborators of Rutherford. Most of the Cavendish men worked either independently or in pairs, responsible to one of the senior members of staff and only a few worked with Rutherford. Dr Lewis spoke of the strict routine to which Rutherford worked and expected his assistants to copy, a routine which had probably contributed greatly to his own success; "stop work at 6 o'clock and go home and think". In a short time this group of which Dr Lewis was a member had unravelled the complexities of the long-range alpha-particles, a subject which had attracted Rutherford's interest for a long time. The success was due to the use of the first of the new generation of "expensive" pieces of apparatus, a magnet designed and made for £250 by the M-V Company. After this Rutherford switched to his last experimental work, the disintegrations caused by deuterium ions accelerated to the paltry voltage of 200-thousand volts, in deference, so to speak, to Gamow's theory. He complained to Allibone about the cost of the 100-thousand volt transformer which the Metropolitan-Vickers Company had supplied. Allibone calculated that it had only cost a farthing a volt, cheaper than the cost of flash lamp batteries in those days, and Rutherford took the repartee in good grace.

Mr G. Danin, a well known Soviet writer on the history of science, discussed the role of Rutherford in the quantum interpretation of the planetary electrons. Published letters and material still unpublished in Copenhagen reveal a complex picture of collaboration between Rutherford and Bohr between April 1912 and March 1913; Rutherford's stimulating encouragement of a man in whom he had great faith combined with a restraining touch "take your time", "don't hurry". Mr Danin spoke of Rutherford's own unpublished attempts to find a quantum solution to the problem of the stability of the planetary model and he concluded that a thorough examination of all the papers and correspondence in the Manchester period would reveal much of interest to the history of one of the most fundamental discoveries of the century.

As each speaker left the rostrum Professor Kapitza presented him with a medal which had been struck in the Soviet Mint to commemorate the centenary, and also with it the first volume of Rutherford's collected works printed in Russian. Dr Allibone also presented to Professor Kapitza on behalf of the Royal Society of New Zealand the medal struck in New Zealand.

T. E. A.

Has Science Never Had It So Good?

by our Special Correspondent

ARE science and society now in a radical confrontation or does their apparent conflict merely represent old issues in new guises? This central question ran through the three controversial themes which dominated the Roche Jubilee Symposium, "The Challenge of Life—Biomedical Progress and Human Values", which was held in Basle from August 31 to September 3. What are the ethical responsibilities which scientists and doctors should assume in response to the advance of biomedical research? Should science and technology be more closely directed, perhaps even restrained, and if so, how? And how are the difficulties of communication between scientists and between scientist and layman to be resolved?

"Humanity is at a hinge of history", said Dr Philip Handler (President, US National Academy of Sciences), when introducing the first session, on biomedical frontiers. But his insistence that the rewards of science have created a critical situation, on whose resolution will depend whether man is a blind alley in evolution, was challenged by Solly Lord Zuckerman (former Chief Scientific Adviser to the British Government) who maintained that: "This is no new issue. This is the oldest issue I know . . . I don't believe for one second that this is a hinge of history. There have been corresponding hinges before. There have been people who hated the development of science and said so before." This disagreement, which was to be repeated during later sessions, foreshadowed the quarrel between idealism and pragmatism which the symposium spotlighted.

Molecular Biology: Threat or Promise?

Assessing the prospects opened for man by the dramatic advances of the past decade in molecular biology, immunology and neurobiology was the task of the opening speakers. Although there is general concern about the implications for man's heredity of the possible development of means for genetic manipulation, Dr Joshua Lederberg (Professor of Genetics, Stanford University) felt that the prophesies of genetic engineering merely bring into sharper focus problems which have been present for some time. There was also general agreement that organ transplantations are exaggerating ethical concerns which are in any case raised by medical immunology.

Particular controversy was aroused by the fear that it may become possible to clone humans to yield many identical individuals, with Dr Salvador Luria (Sedgwick Professor of Biology, Massachussetts Institute of Technology) saying that this idea is of as little scientific interest as the exploration of space; nothing could be learnt from it, he maintained, which could not be found by using the mouse instead. But Professor Lederberg felt that cloning humans would be interesting from another viewpoint, because of how it might help distinguish the effects of environment and heredity on man. Because cloning cattle, for example, might have useful implications for agriculture, Professor Handler asked whether perhaps it would be wise to take a decision on whether to support such research before a technique is developed which could easily be extended to man. The general view of the meeting, which was sanguine that on balance there is only slight risk that genetic manipulations or neurobiological techniques will be abused to change man, was caught by Dr Seymour Kety (Professor of Psychiatry, Harvard Medical School), who noted that identical twins are not deliberately separated at birth to facilitate studies of the interaction of environment and heredity.

Gazing into crystal balls is always a hazard for the scientist, but when asked for predictions of future developments in the biomedical area, Professor Kety thought it likely that the major psychoses will be understood if not eradicated, and Dr Niels Jerne (Director, Basel Institute for Immunology) suggested that allergies and leukaemias are likely to be brought within the scope of medical treatment. Professors Luria and Lederberg agreed that molecular biology has as yet contributed little to modern medicine, but each predicted that it will prove indispensable as the basis of future treatments. Professor Luria specified the intensive research into reverse transcription, which he thinks is likely to be productive in understanding at least some forms of cancer; Professor Lederberg pointed to the extensions which seem likely in the scope of antenatal diagnoses.

The first topic on anyone's list for useful future research should be ageing, said Dr Arnold Burgen (Director, National Institute for Medical Research, Mill Hill), later during the symposium. This should include attempts both to increase the human life span and also to make the later part of life more liveable, although this latter problem is particularly difficult because of the way in which the different systems of the body age at different rates. Although endogenous diseases such as ageing seem likely to prove far more difficult to resolve than those caused by external agents, Professor Burgen feels that significant progress could be made if only a fraction of the funds supporting cancer research were put into such studies. Increases in life span which have already been achieved, however, were identified by Dr Alfred Sauvy (Professor of Social Demography, College of France) as the principal cause of the rise in world population. He is sure that future research will lead to some further abatement, even if it does not yield the dramatic lifespans of 90 or 120 years forecast by some people.

Over population was a topic which had loomed over all the sessions, said Alexander Lord Todd (Professor of Organic Chemistry, University of Cambridge) in his summary of the meeting. He took the consensus to be that Malthusian forebodings of famine are misplaced, but he supported Professor Handler's plea that although man has always had a sense of crisis, this time is different because the resources of the planet are only finite and some are beginning to run out. This contrasted with the earlier remarks of Dr Margaret Mead

Philip Handler.

Solly Lord Zuckerman.

Salvador Luria.

Joshua Lederberg.

(Professor of Anthropology, the American Museum of Natural History, New York) that some people regard population as an evil so great that almost any step should be encouraged to limit it, even if that step were drastically to change the nature of human society. The general opinion of the meeting, however, that society will in any case be changed, greatly for the worse, unless some acceptable way is found to limit population, was echoed by Professor Luria's comment that scientists and doctors have not fulfilled their responsibility to explain the consequences of population growth.

How Should Scientists Report Results?

The purposes which scientists ascribe to research were attacked by Dr Jeanne Hersch (Professor of Philosophy, University of Geneva), who argued that science is itself a vested interest, and that what this meeting really represented was the gathering of an élite of scientists to defend their interest. Promising a cure for cancer is just a ruse to keep funds flowing, she said; the molecular biologist working on "cancer" should recognize that his real motivation is not to cure the disease but rather to pursue truth for its own sake—and he should convey this attitude to others instead of using pretexts to gain funds. But the pursuit of science is in itself a human value and as such needs no further justification, insisted Professor Jerne, who extrapolated this reasoning to suggest that because social evolution may retard and perhaps even stop science, possibly quite soon, those people interested in research should press ahead as fast as possible while there is still time to do so.

The conservative view of science was taken further by Professor Jerne when he argued that scientists have already evolved the most apposite way to communicate their results and that no change should be made in this procedure. Their proper *modus operandi* is to publish original research articles; they should not try to popularize their work because it is philosophically impossible for any such attempt to avoid introducing some degree of distortion. Those who want to follow the conclusions of scientists should learn the language of science, he said. But other participants evidently felt that this attitude is symptomatic of the arrogance which tends to bring science into disrepute with society. The general consensus was with Dr Charles Berry (Director of Medical Research and Operations, NASA), who feels it is vital that scientists should explain their work to the public, and with Professor Lederberg, who stressed how essential it is to reverse the alienation of science for society. The scientist is responsible, he argued, to the community of people from whom he derives the funds which support his work.

There should be two levels of communication of scientific result, suggested Professor Burgen, one for scientists who may wish to repeat a particular set of experiments, and another to enable non-scientists to appreciate the significance of a research result if not the precise means by which it was obtained. Both Professor Burgen and Professor Lederberg think that the communication network by which scientists communicate with each other works quite well on the whole, and Professor Burgen suggested that a similar communication network should be developed to enable scientist to communicate with non-scientist. Professor Lederberg feels that one way to approach this problem might be to make use of the facilities of the professional associations of scientists; these learned societies would be in a good position to provide accurate assessments of research.

Is there a Right to Health?

The conventional view that individuals are entitled to health was challenged by Professor Hersch, who suggested that health implies the ability to withstand minor ailments, which should not be subject to exhaustive treatment as they tend to be at present. When the improvement of health becomes an obsession, she maintained, it becomes an ill in itself. Of obvious relevance to the pharmaceutical industry were the discussions by Professor Berry, Dr Kenneth Arrow (Professor of Economics, Harvard University) and Dr Axel Strøm (Professor of Social Medicine, University of Oslo) of the attitudes of doctors and of how medical care is organized. Max Lord Rosenheim (President, Royal College of Physicians of London) summed up the general view that although new treatments and improved methods of diagnosis will change much of the organization of the medical profession, it is essential that the one doctor–one patient relationship should be maintained.

"The relief of minor symptoms is not only desirable from the point of view of the sufferer but also of the pharmaceutical industry", said Lord Rosenheim when answering one of the questions raised at the beginning of the symposium by Professor Alfred Pletscher (Director of Research, Hoffman-La-Roche): how much effort should the pharmaceutical industry devote to producing drugs to cure minor ailments? Lord Rosenheim's point was that the industry derives much of its income from just such drugs, and it needs the money made in this way if it is to be able to support the development of much more expensive, although less commercially rewarding drugs such as immunosuppressive agents. But in any case, Lord Todd said during his summary, even when the industry has decided how to balance its research efforts, drugs to treat minor ills will inevitably be developed as the result of side effects noticed during research originally designed for other ends. Another problem of some concern, that of the rising extent of self diagnosis and treatment, will also inevitably continue to increase, he observed, with the rising level of education of the population.

The demanding pattern of development of medical research was the concern of Lord Zuckerman's paper. Quoting a former British Minister of Health, Enoch Powell, he pointed out that demand for medical care is for all practical purposes unlimited. "Every advance in medical science creates new

Margaret Mead.

Alexander Lord Todd.

needs that did not exist until the means of meeting them came into existence, or at least into the realm of the possible. For every heart–lung machine or artificial kidney in operation, there must be many times that number of cases to which the treatment would be applicable." As Lord Zuckerman himself argued: "If money is provided for medical research workers, the brilliant research worker will use that money successfully. He will provide some new discovery, the discovery will be applied, and then you get the pattern of demand for the particular advance he has made". Continuing this reasoning, Lord Zuckerman argued that because resources must always be inadequate to meet demand, priorities must be imposed on the provision of treatment. Lord Rosenheim added that the provision of expensive treatments in early days must be limited not only by money but also by provision of trained doctors.

The inconsistencies in the pattern of medical care were remarked by Lord Rosenheim. "Contraception and abortion are preventing the life of an infinite number of healthy people, whilst medicine is keeping alive idiots, hydrocephalics and cases of spina bifida." The medical profession will not change this paradox, he said, which can only be influenced by an informed consensus of public opinion. And as Lord Zuckerman observed: "There is an unquestioned right to health and people have been brought up to believe they have that right. However scientific a treatment may be, it cannot hold its place in the market if there is no demand for it. Nor can the greatest quackery be kept off the market if there is a demand for it."

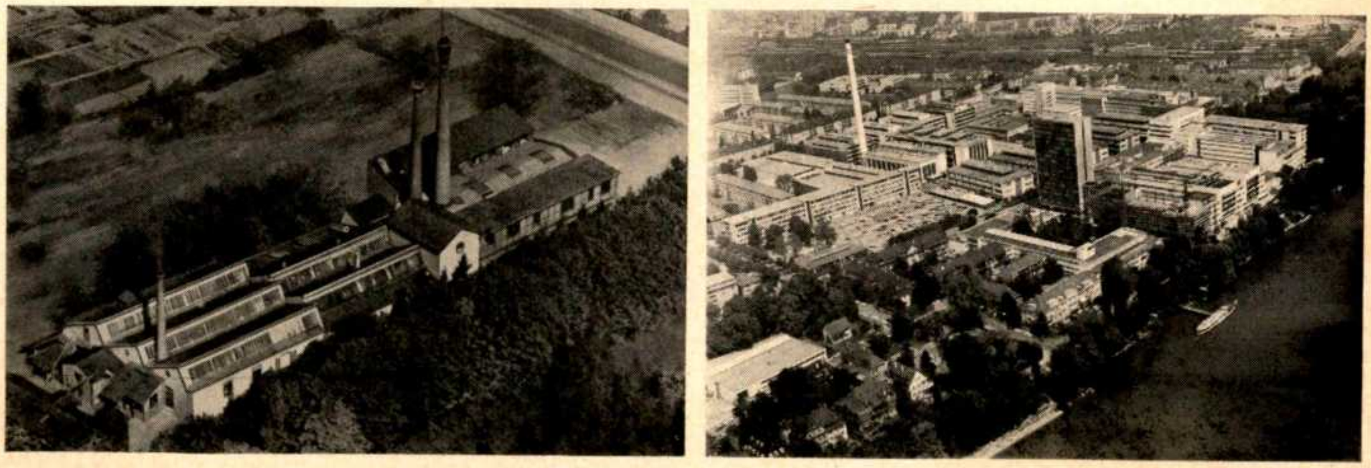
Should Biomedical Research be Curtailed?

Is it irresponsible to allow advances in biomedical research to create demands which cannot be fulfilled? Should some of the funds now allotted to basic research be redirected to support studies of more clearly defined and perhaps more urgent needs? These talking points created considerable controversy. Lord Zuckerman's view was clear: "There can be no question in my mind but that the resources available will be inadequate for the claims of researchers. I am one of those who believe that (one should) beam research funds at certain fields in relation to need."

Both the ethos and the practicality of Lord Zuckerman's ideas were fiercely challenged by Professor Handler. First of all, he pointed out, many diseases which were at one time expensive to treat have now been eliminated completely. The patients who take great resources are those who have contracted diseases of this type which should by now have been eliminated, or diseases for which only supportive rather than definitive treatments are available. The development of expensive treatments such as renal dialysis is just a stage, but a necessary one, on the way to developing a simple and inexpensive cure. The doctors present agreed that routine operations may develop from what is at first an operative technique used only at great expense in individual cases. Both Professor Handler and Professor Luria observed that, in any case, the cost of biomedical research in the United States (quoted as $2.5 billion) is so slight compared with the cost of corrective medicine (quoted as $70 billion) that it is illusory to suppose that there could be any appreciable financial saving from cutting back funds for biomedical research.

Opinions varied on whether society should control the direction of basic research in more detail, but the general consensus was that this is neither desirable nor, indeed, possible, because of the adventitious way in which knowledge advances. Because the motivation of the brilliant researcher who makes the more significant advances is intellectual curiosity, attempts to direct his efforts would be misplaced and unproductive. But the speed of change worried Professor Luria, who felt that we are engaged in a "breathless race with technology" because science and technology progress so much faster than the changes in the values of society which are needed to assimilate new living conditions. But an important distinction should be made, urged Professor Luria, between discovering new facts of nature and developing them into a technology. The critical stage at which to exercise control must be at the development of a technology, because it is not possible to control the development of research itself, nor to control the uses to which a technology is put once it has been developed. And because the acquisition of knowledge is fast in comparison with its application, even a moratorium on research would not halt the development of new medical treatments from existing knowledge for a considerable time yet.

The sense of the meeting was caught by Professor Handler when he argued that because only governments can now afford to pay the bill for research, and because resources are only limited, decisions on general priorities must be taken. Whereas it is an absolute necessity to decide how much goes into biomedical research it would be a very grave mistake to distinguish between the narrower parts of the biomedical sciences. Responding in particular to Lord Zuckerman's comments, he said that "if you mean anything narrower than that cancer research should go into the general properties of cells, you are wrong". Another point was caught by Dr Talcott Parsons (Professor of Sociology, Harvard University) who suggested that it might be of more use to control how



The first factory of Hoffman-La Roche in Basle, pictured in 1903, is shown on the left; the present buildings on the same site are shown on the right.

research is to be done, by setting standards of scientific competence and objectivity, than to control what research is performed.

Should the Sociologist Judge Science?

Although Dr Handler's eloquent assessment received vigorous applause from the meeting, the sociologists and theologians did not agree with it. Dr Franz Böckle (Professor of Moral Theology, University of Bonn) argued that the desire to knowledge must be subjected to certain limitations because it is impossible for the researcher to have a proper grasp of the overall situation. The real problem, he and Dr Jürgen Moltmann (Professor of Systematic Theology, University of Tübingen) argued, is to establish a set of ethics by which to judge biomedical progress, but for which the natural sciences alone cannot suffice and which must depend on the humanities.

This plea was echoed during a more detailed discussion of how research funds should be allocated. Dr Bernard Barber (Professor of Sociology, Columbia University), commenting on the peer review system by which panels of scientists assess for the US National Institutes of Health the values of projects in their own fields of competence, urged strongly that the sociologist, if not to be allowed to sit in judgment on the scientist, should at least play an important part in deciding the lines along which research should be directed. People who know the views of the public, he felt, should have at least some say in the allocation of funds. Professor Mead supported Professor Hersch's comment that scientists are too much an élite concerned only with their own problems, and complained that the accurate predictions which sociologists had made in the past that there would be a backlash to science had been ignored. An urgent need, she said, is for proper studies of the effects of scientific advance on the attitudes of society.

In contrast to the sociologists, Professor Luria is not too worried about the operation of the peer review system in the United States, but pointed to the discrepancy that although basic research is usually assessed by this means, its technological development is ultimately at the whim of the politician. Professor Luria intends to argue strongly at congressional hearings to be held in Washington next month that the new cancer research programme should be directed under peer review.

"I am frightened of peer review," said Lord Zuckerman, "because I know of peer reviews where there is only one peer, or two or three men." In a scathing attack on the way support for research is organized, he said he is particularly perturbed by the ways in which fashions in science can dictate the pattern of research. Professor Handler maintained that many of the options open to man have been generated by research, but according to Lord Zuckerman, "whilst science opens enormous avenues for the future, at the same time it is closing other options by setting fashions". Molecular biology is a notable example of this trend, he implied; in reference to Sir Macfarlane Burnet's recent view (in *Genes, Dreams and Reality*) that molecular biology has contributed little to medicine nor is likely to, he said that: "If six other Burnet's were to share that view, the Medical Research Council should start diverting funds to fields which represent clearly defined needs (such as) the problems of old age . . . which are receiving too little attention".

But would not setting priorities impinge on the freedom of the researcher? "We are already imposing the pattern of social justice on the pattern of medical research and it does not in any way infringe the independence of the medical research worker." Who should decide such priorities? "I dismiss (the medical research worker) because he merely creates demand regardless of need. I dismiss the public and client because he absorbs anything he is given." This left government, which, said Lord Zuckerman, was not desirable either. Referring in particular to medical research, he demanded that peers conducting reviews should hold a wider view of the field than just their own speciality. "Those people who have a sophisticated view about resources and need should choose." *Sed quis custodiet ipsos custodes?*

The problem which Professor Lederberg visualizes is how to improve the social utility of research without damaging other values. But researchers have no less social conscience and probably more compassion than politicians, he suggested, and a "shopping list" made for useful research would in any case very largely list the present pattern of activities. Centralized planning, he argued, would be very likely merely to lead to the excesses of the space programme. Both he and Lord Zuckerman observed, however, that the scientist as such has no particular political franchise; if scientists and doctors wish to be the people who determine the ends to which research is put, they must enter directly into the political arena.

How Many Cultures?

Can the life sciences be integrated with the social sciences in some way? Professor Handler, summarizing his view of the meeting, said that: "All my life I have tried to be amongst those who have maintained, somewhat defensively I guess, that there are not two cultures". But he had rarely seen a better demonstration that there are indeed two cultures. Professor Mead was among those who felt that there had been too much talking and not enough listening. "The only way in which people from different disciplines can learn to understand each other is to look at the same problem."

But Professor Parsons suggested that integration can be provided by modes of thinking which go beyond one particular science, such as the idea of coding. Might there be some parallel between the biological and the linguistic codes, he asked? Lord Todd brought the meeting to earth by asking how integration might be achieved in practical terms, suggesting that perhaps the lack of interdisciplinary thinking is a consequence of the way university courses are organized. Professor Handler, however, maintained that integration of subjects occurs only in individual human brains; the failure of packages of arbitrary multidisciplines at universities in the United States showed that there is no way to contrive integration. Professor Luria agreed that the function of a university is to give a superior training to people who can then use it to communicate effectively and to cross disciplinary boundaries.

Of what value did the conference prove to Hoffman-La-Roche? Introducing the meeting, Professor Alfred Pletscher said that "society has not considered soon and systematically enough the outcome and final consequences of biomedical advances. This omission must be remedied. The aim of the symposium should therefore be to define more clearly the problems created by biomedical progress and to find, if possible, essential facts or clues for their solution." At the end of the symposium, Professor Pletscher said that there could be no definite answer to most of the important questions, but that the symposium had succeeded in formulating more precisely the questions which should be asked. Now that a frame had been set to examine the problems, future conferences would be able to examine more specific problems.

The final discussion was directed by Lord Todd, chairman of the symposium, to answer the questions which Professor Pletscher posed at the outset. No certain way could be seen to avoid the potential harmful effects of research on mankind, but there was a consensus that fears are in general exaggerated. Basic research should not be directed, except in a very general way, and Professor Luria's point was well taken that the only option for control is at the development of a technology. An important target for biomedical research should be ageing, although this will bring other problems in train. And there was general agreement with Professor Burgen's refusal to regard the improvement of health as two edged. In spite of much talk, the most cogent comment on the ethical issues raised by biomedical progress was the lack of an answer to Lord Todd's question: "Can we harmonize biomedical science and human values?"

Science and the Common Market

BRIAN FLOWERS

State House, High Holborn, London, WC1

This article is based on a speech delivered by Professor Sir Brian Flowers, chairman of the Science Research Council, on September 6, 1971, at the meeting of the British Association in Swansea.

In the great debate on the proposed entry of the United Kingdom into the Common Market science has been mentioned hardly at all, and even technology has received only scant attention to bolster up the economic arguments. It would be strange indeed if we were not to explore the likely effects of joining our West European friends on the advancement of science in this country and in Europe. I therefore propose briefly to do so.

But first I must make a declaration. I am a public servant appointed to a non-political post under the Labour government and now serving under a Conservative government and I must therefore make clear that I do not seek to indulge in party politics, nor am I acting, in this article, as a mouthpiece for the Science Research Council, still less for the government. I had hoped—together, I am sure, with many other people—that the Common Market issue would not be one to divide the parties, but alas that was not to be. For that reason the excellent custom whereby public servants do not indulge in party political controversy are best maintained if I confine myself as far as possible to examining the issues as they seem to me to concern science and technology.

Two Freedoms

I think we all accept that the two most basic elements of international science are the free exchange of information and the free movement of scientists across national frontiers. Indeed, one recalls the unhampered travels of Davy and Faraday in continental Europe during the Napoleonic wars. The learned and professional societies, as well as institutions like the British Association, contrive to preserve these international elements in spite of limitations inevitably imposed from time to time by national security and commercial confidence. In recent years the Royal Society with its post-doctoral exchange scheme has been particularly successful in the European context.

It is, however, a matter of quite recent history that the funding of science is also becoming international. This is the consequence of the scale on which some of it must be practised if anything significant is to be achieved; I need mention only nuclear physics, space research and, perhaps in the future, molecular biology. And it is the consequence of the nature of some branches of science, which are international in content as well as in practice: there would, for example, be very little point in trying to explain the British climate using only British data. Indeed, for some branches of science it is necessary to consider the planet as a whole, and so we have bodies like the World Weather Watch and the World Health Organization.

Of course, our experiences of European scientific organizations have been far from uniformly successful. At the one extreme we have CERN, the European Organization for Nuclear Research, which is universally acknowledged not only as a successful scientific venture but as an example of successful international collaboration in general. It was created in 1952 during the post-war wave of European idealism, and its existence has enabled scientists from its member states to regain their position at the forefront of a science that is still of profound significance. Ironically, the UK did not join CERN at its inception—we waited to see whether it would be a good thing. And we hesitated in 1968 when the question arose of taking the next great step in energy to 300 GeV. But again we eventually joined, recognizing not only scientific merit but also the political will of Europe. At the other end of the spectrum we have ELDO, the European Launcher Development Organization, founded in 1962 at the instigation of the UK because we wished to find a use for our own discarded defence rocket Blue Streak; the combined European launcher which resulted has so far failed dismally to put into orbit even a Kruschevian orange. Unlike the more or less federal CERN with its efforts concentrated on its accelerators in Geneva, ELDO is much more a loose confederation of national efforts and it is in competition with the attempts of several member states to achieve a purely national launcher capability, our own included until the recent cancellation of Black Arrow.

Between these two extremes comes ESRO, the European Space Research Organization, which, in spite of acute and still unresolved conflict between its member states over the essential purposes and the scale of effort of the organization, has achieved some notable successes in scientific research in space, and by so doing has enabled a European technology to develop which may soon make its mark in satellite applications such as regional telecommunications, meteorology and navigation. Nearer to the failure end, but this time innocent of British assistance, comes Euratom, the Atomic Energy Authority of the Common Market. Both of these organizations, but especially Euratom, are again in competition with national enterprises deemed to have greater success and significance. There are those who hope that the accession of the UK to the Common Market will bring in fresh air for Euratom to breathe; others believe that asphyxiation would be a better remedy in this case. Unlike the other organizations I have mentioned, Euratom is one of the official Common Market institutions and it will require very close examination in the future.

A more recent case is that of the still embryonic European Molecular Biology Organization, dedicated to exploit on a European scale one of the most exciting developments in all of science, our recent chemical and physical understanding of the nature of biological processes at the molecular level. This began controversially not because of the quality or content of the science, but because of the scale on which it was originally proposed that it should be prosecuted. The attitude of the British scientific establishment at that time was hostile because of the scale and because we were already strong in the subject. On the scale now proposed, however, this is a case where, confident of our own achievements, we might now feel that we have something to give to the other nations of Europe in an enterprise whose effects may yet be still more significant to our understanding of the life sciences, including medicine.

Criteria for Success

The lessons to be learnt, it seems to me, from this brief survey of some of the existing European scientific and technological organizations are five-fold. First, the science must be good science and the purpose of setting up the organization must be clear; second, the initiative for creating the organization must come from the scientists working in the field; third, scientists of the highest quality in each country must want to take part; fourth, the nature of the science must render organization on a European scale either necessary or at least likely to bestow distinct benefit on all participants; and finally, each country must give its support of the organization priority over any residual national effort in the field. CERN has satisfied all these points; the other European organizations I have mentioned have not.

The internal criteria I have described for a successful European research organization seem stringent enough, but scientific research is only part of the whole social activity. There are also economic, political and social criteria which exert a powerful influence on what research is supported from public funds and on how that research is organized. Thus in fields where independent sovereign governments and business concerns believe that the results of research could give their possessor some economic or other social advantage, the pressure to support national programmes may be great enough to prevent successful international collaboration. This has been the case with space technology and with nuclear power. Indeed, attitudes towards collaboration in technology sometimes differ sharply from attitudes towards collaboration in science because of the hope of earlier gain. Even on a national scale there have been many examples of firms failing to collaborate wholeheartedly in government supported co-operative research projects, which could bring benefits to all, because they feared that their competitors might secure the greater benefit. In cases where research can be expected to lead to a fairly early economic or social benefit some obvious common interest is required to ensure real cooperation. For example, all countries are persuaded that it is in their interest to control plague, and realize that this must be tackled on an almost world-wide scale. In economic and political matters, however, our self-interest is not yet enlightened enough for the majority to see that cooperation both in research and in its applications will pay simply because, ultimately, we prosper or suffer together.

It will be a long hard slog to the millennium and, meanwhile, anything we can do to encourage real collaboration between sovereign groups will help enlightenment. Despite all the difficulties I have mentioned, scientific research is a very promising area in which to encourage international collaboration in general. Such collaboration, of course, took place in fundamental science long before the Common Market was thought up. No doubt this will continue if only to meet objectives beyond the scope of Western Europe. But the Common Market will provide a psychological as well as a financial framework within which international collaboration in Europe will become more naturally the rule than the exception.

What is Science?

To be able to discuss the effects of the Common Market upon science, we must first be clear about the nature and purposes of science.

Science in the first place is a cultural activity and, as such, peculiarly a product of European culture. It changes profoundly our comprehension of the world around us and of our place in it. We have only to remember the work of the early astronomers like Galileo and Kepler and of the impact of their ideas upon contemporary philosophical and theological thought, or of Darwin on the origin of species, or of Einstein on the nature of space and time, or of Rutherford on the structure of the atom to see that science is sedition at its best. Modern astronomy is striving for an understanding of the nature and origin of the universe, particle physics for the ultimate structure of matter and the forces which act upon it, molecular biology for the templates of heredity and the nature of biological laws. Their effect upon our understanding of the world about us is likely to be no less profound. It is even a tenable hypothesis that space travel, and the first glimpse it has given us of our world from outside, has helped to focus our attention on the problems that bedevil our sorry planet and its inhabitants. If so it will have paid for itself.

But there is more to it than that. Society demands satisfaction from its investments in science; it has goals it wishes to achieve. It wants better transport, better communications, better housing, better health, better food, more electric power; it wants to be defended, it wants more rewarding leisure, more relevant education: it wants all these things at a reasonable price, and increasingly it wants them not to intrude in unwelcome ways, not to pollute the environment with noise or filth or poison. But none of these things is possible—or at least they would be much more difficult to achieve—without science. For the great majority of people, whatever they may think of science in their leisure hours (if they think of it at all) and whatever its cultural value, science is not a thing in itself but a means to achieve some of the aims of society.

Counting the Cost

The goals I have mentioned are, by and large, recognized in every industrialized country in the world as so important that they each rate a separate government department. Many of them, indeed, can be pursued only on an international basis of some sort. They are not so much national goals as goals of the human race to be striven for independently of national politics, and in some cases in spite of national economies. It is in the hope of achieving these aims of society, and not for the sake of science itself, that the industrialized nations of the world devote something like 2% of their gross national product to research and development, including something like a tenth of that to fundamental scientific research. Scientists cannot expect support on this scale—indeed they should not have it—unless their work can be seen to form part of a pattern which as a whole produces substantial public benefits.

Of the science-based industries—those that depend especially upon automation, instrumentation, electronics, chemistry, and materials science—most are in favour of joining the Common Market. The reason is that many of them believe that a home market of 50 million poeple is insufficient as an export base, and that 300 million is nearer the mark. And, in turn, the reason for this is often that only on such a basis can the huge research and development overheads be covered in an economic manner—aerospace is the notorious example, but nuclear power and computers are others. And in some cases—transport and communications, for example—it is only by adoption of a much larger measure of standardization than is possible on a purely national basis that economic operations become possible, our recent moves towards metrication were, of course, a helpful step in this direction. As far as science is concerned, our postwar failure to achieve a steady economic growth has been due not so much to any failings, real or imagined, in our achievements in pure and applied research, but to our inability, with a home market increasingly confined to the UK, since the loss of an empire, to find the wherewithal to pay the much heavier development costs (including prototype production) required to profit from expenditure on research.

On a European basis we can expect to be able to afford our share of these development costs provided that we, and our partners, gradually give up the idea of alternative and purely national competing ventures. And in streamlining our research and development efforts within the Western European nations we can afford to devote more than we have done in the past to mitigating some of the undesirable effects of technological growth—for the humane technological society requires more, not less, research.

The six are already working towards a common energy policy, in particular for cooperation between themselves and the oil-supplying countries. This, of course, is basic to all industrial activity. They hope to widen the field of trade with the oil countries and thus improve relations generally between themselves, the oil countries, and the oil companies. They also plan to take joint action to support exploration for new supplies of oil, and to raise loans to finance the building of nuclear power stations, a matter which I imagine will be of great importance to us. But improvement of the quality of life is just as important an objective of the economic and social policy of the community as the quantitative raising of the standard of living. Because pollution does not recognize frontiers and because no country can be expected to act alone to penalize its industries in competition with the less scrupulous, action must be taken by the community as a whole. Joint action has already been proposed to control air and water pollution. The community intends, for example, to support and extend the work of the International Commission for Rhine Pollution Control in order to protect the North Sea as well as the whole of the Rhine basin.

Facing the Competition

The need for a larger home market is perhaps arguable; some would say that it exists already in spite of tariffs. But excessive competition between countries of limited industrial capability reduces the share of the world market available to each. The real competition is very often with the super-states, especially the United States and, increasingly, Japan, and it is in this context that European cooperation can be most effective. I believe that this applies to research and development as much as to production. The result of joining the Common Market can be expected to be a much larger measure of rationalization amongst European firms, some of it painful in the short term. We may complain about the common agricultural policy as a device to protect inefficient European farmers, but we should not forget how many of our own industries are at present inefficient, and depend upon protection of one sort or another in order to survive foreign competition. The multinational industrial corporation may be expected to take the place, to some extent, of national protectionism. There is also great value for both science and technology in having common tasks tackled by teams of mixed nationality, provided that one can extract the best from the varied experience and training of the different nationalities. We have surely all learned by now that British is not always best!

Especially if the social goals I have mentioned are to be achieved, an industrialized and free society like ours can neither afford to go it alone nor can it, in my view, allow itself to become utterly dependent upon a super-state, whether in the east or the west, in which it has no hope of sharing in and contributing to the government. It is better that we join a community of like-minded nations of similar size amongst which our voice must and will be heard. Nor can we allow ourselves to become politically and economically subject to the uncontrolled growth of multi-national corporations which at present owe allegiance to no nation and whose annual turnover in some cases already exceeds the individual gross national products of several European nations. Thus, regardless of whether it is international capitalism or international socialism that we wish to foster—and because we live in a mixed society it may be that we should wish to foster both—we have more hope of achieving an acceptable result within a community of like-minded nations especially when, in both respects, they have as much to offer to us as we have to them.

Watching Over Science

We are much exercised in this country at the present time with trying to match the inner logic of scientific activity to the aims of our society. In this endeavour the research councils have a vital function, for it is primarily their responsibility to look across the whole range of science from astronomy to production engineering, from molecular biology to social behaviour, from botany to meteorology, to see not only that society provides for the needs of its scientists, but that the pattern of scientific research and the training of scientists and technologists in the universities and colleges adapt themselves as time goes on to the changing needs of society. From time to time governments ask themselves whether the research councils should have as much independence as they have at present. Certainly adjustments need to be made at intervals, but the fact is that most countries decide to channel a proportion of their support for research through organizations which are not themselves responsible for the achievement of specific applications. Whatever failings our research council system may possess it is still among the best in the world; it is something in which we can take some pride and something we can offer to others.

If we join the Common Market there will, of course, in time emerge a further layer of committees and consultations in the hierarchy which determines our scientific and technological affairs. This will take time to evolve, and it will bring with it new frustrations for those who feel that the national system is already over-burdened. Be sure it will also bring frustrations to those who have to operate the system! But we can take some comfort from the fact that European nations all seem to be dealing with the same kinds of problems in the same kinds of ways in spite of different national systems. In recent years there have in particular been many discussions between the research councils and similar bodies on the continent. Correspondingly, there has been a series of meetings at ministerial level which have attempted to define priorities in fields of technology which are of immediate concern. From all this can be expected to emerge, in some form at least, a consultative assembly of the various scientific authorities of Western Europe, a new forum for scientists and for governments to discuss issues requiring, for reasons of scale or of content, organized international coordination and funding, whether it be the provision of a new and expensive scientific facility, or the war against pollution, or the rationalization of industrial research and development.

If, as a result, our administrative procedures become more cumbersome and therefore more slow moving—and I fear that this is almost bound to be the case for a time—we must set this disadvantage against the fact that it will enable us to continue to take part in, and certainly in some cases to lead, activities which are rapidly growing beyond the capabilities of individual nations. There will not necessarily be any disadvantage in the longer term, because if we have learned anything from the past few years it is that science can only benefit from a deeper and wider discussion of its content and purpose.

This, for scientists, mirrors in a small way the problem of political sovereignty that worries so many people in this country. By sacrificing a certain measure of our own sovereignty, more often than not over matters which are in any case beyond our sole control, we share in a wider sovereignty within which we can hope to achieve more. And, insofar as scientific affairs are determined somewhat differently in the various European countries, we have perhaps something to gain on that score also. Scientists, too, will have their analogues of the political and economic problems of the development regions. Each country has its scientific strengths and weaknessess and it will be important to see that, while maintaining the strengths, we do something to ameliorate the weaknessess, whether they be in scientific or in geographical areas.

More Collaboration

In recent years we have seen the advantages of university departments and other research institutions with parallel or complementary interests coordinating their activities in order to share more equitably in limited funds and to have access to facilities to which otherwise they can no longer singly aspire. This in microcosm, is the whole story. But even in microcosm it can be extended. There should be nothing to prevent the collaboration between departments of British universities and departments of other European universities, and in principle there is nothing to prevent it now. Indeed, the research councils are already trying to encourage such developments. It is clear that the only real barrier is a mental one: we are not yet, most of us, accustomed to thinking in such terms. Our work will be immeasurably enriched, both financially and intellectually when collaboration at this grass root level has become commonplace. From it will come not only advantages to science, but also a sharing of experiences between universities of different countries on a scale not yet seen. And here again we have something to offer in exchange, for there is a greal deal to admire in the British university system.

It seems to me that much the same can be said of industry. Although there is already a measure of European collaboration between companies, we are not yet accustomed to thinking of it as commonplace, especially among smaller firms. The placing of joint Common Market development contracts would help to speed the processes of collaboration and rationalization without which an economic union is unlikely to succeed at the technical level.

But we shall have to be wary of undertaking scientific or technological ventures for purely political reasons, merely in order to appear European. Building up a new Europe is indeed a worthy end in itself, and one that scientists and others must be ready to accept. But we and our partners will be foolish to forget that, however high our purpose, bad science leads to bad politics and bad technology to bad economics.

The fear has often been expressed that the Common Market is an inward-looking community. This seems to me an extremely odd view of the efforts of a group of nations who have done at least as much as ourselves to foster contacts between east and west and whose record in helping the developing nations is as good as ours. And it comes singularly amiss from individuals who simultaneously insist upon the supposed advantages of our antiquated monetary system, now fortunately buried.

Be that as it may, in science there has so far been, on the whole, a recognition that exclusiveness is not the proper path. CERN was born before the Common Market and its membership has always been open to all the West European countries. It has observers from Poland, Turkey and Yugoslavia, and it has throughout maintained the closest of international working relationships especially with the United States and the Soviet Union. This will remain the case even when its membership is chiefly that of the enlarged Common Market. And in our space affairs, too, there has been the closest relationship with, and indeed a large measure of dependence upon, the United States. Enlightened self-interest as much as idealism is likely to preserve this state of affairs in a world becoming increasingly "the space-ship Earth". Certainly we shall have to play our part in maintaining an outward-looking stance, and our world-wide bonds of common language will help us to do so. The profound historical and economic interests which the European countries, especially France, Holland and Britain, have in the developing nations of Asia and Africa should make possible an extensive attack on problems of tropical medicine and agriculture to which our contributions in this country have already been highly distinguished. The possibility of extending scientific research within the Common Market towards the solution of problems relevant to the developing world, such as the local development of natural resources, could make an important contribution to the relationship between Europe and most other countries.

Funding Science

Until about five years ago post-war science budgets had been growing at about 10 to 15% a year—at about the maximum rate, that is to say, which could be absorbed by the scientific community. It was a mark of confidence in the importance of scientific research and in the ability of trained scientists and engineers to use their talents in the service of the nation. Indeed, wartime experience had amply justified this view. Since then, and not only in this country, a certain measure of disillusion has set in. Our rapidly increasing expenditure on research has not led to the once expected increase in national wealth. We have begun to doubt whether new science leads to new technology, and even more whether new technology is synonymous with progress for the human race. We have been forced to ask whether our priorities were right, whether more effort should not be devoted to mitigating the effects of technological progress rather than to hastening it and whether an increase in the quality of life is not more important than sheer economic growth. And yet, at the end of the argument, the quality of life has to be paid for from the profits of technology, whatever the remedy may be in detail.

In our own case the process has been made more acute by our lack of many vital natural resources, by a home market insufficient by itself to support a highly technological export industry, and by the political vacuum resulting from a lost empire and a slowly deteriorating economic position. Of course we are better off than we were twenty years ago, but we have been slow to realize, in the fastness of our island state, that our competitors have been steadily gaining over us in their standard of living and in their influence in the world.

Modern science and technology can flourish only in the environment of a prosperous industrialized state; it is utterly dependent upon industry, not only for its share of the taxes contributed by firms, but for power supplies, instruments, materials and top-grade manufacture. If the nation is not prosperous, science cannot prosper; this is the immediate effect. But in the longer term, if science does not prosper the basis of a technological nation is undermined and it will never become prosperous. Scientists therefore have to be more outward looking than they have ever been except in time of war. We have to turn our minds more towards the scientific basis of the twenty-first century, more towards mitigating the effects of twentieth century technology and more towards the problems which have arisen for the human race from the technological advances we have ourselves helped to create, not least for the developing world. And we have to do it on a scale that we cannot by ourselves sustain.

If we join the Common Market we shall at least be presented with an opportunity—an opportunity to gain; an opportunity to contribute; an opportunity to refresh our culture and to regain our prosperity within a common European heritage. We shall be joining a community of nations less afflicted by disillusion, who have not lost their faith in the cultural value of science nor in the economic value of its application. It is an opportunity we must not fail to grasp.

Use of Frog Eggs and Oocytes for the Study of Messenger RNA and its Translation in Living Cells

J. B. GURDON, C. D. LANE & H. R. WOODLAND
Department of Zoology, South Parks Road, Oxford

G. MARBAIX
Department of Molecular Biology, University of Brussels, Rhode-St-Genèse

Injected frog eggs and oocytes provide a very sensitive assay system for the identification of messenger RNA and permit the study of translational control in living cells. The translation of each haemoglobin messenger RNA molecule once every 5–10 minutes for at least 24 hours makes it possible to recognize less than 1 ng of this messenger RNA.

EXPERIMENTS described elsewhere have shown that oocytes injected with haemin and purified 9S RNA from rabbit reticulocytes will synthesize haemoglobin; the effect is not obtained with other kinds of reticulocyte RNA[1,2]. This raises the possibility that the microinjection of messenger RNA (mRNA) into frog oocytes and eggs may constitute a generally useful experimental system for identifying and studying the translation of different kinds of mRNA. This system has the unique advantage of enabling purified RNA to be translated and the control of this process to be studied in a normal living cell. In this article we discuss several of the conditions associated with the successful translation of injected mRNA. In particular we are concerned with the treatment of recipient cells, with the duration and efficiency of haemoglobin (Hb) message translation, and with the potential use of this experimental system for translating messages other than that for Hb.

9S mRNA for haemoglobin has been prepared by SDS treatment of the 14S messenger ribonucleoprotein released from reticulocyte polyribosomes by EDTA[1]. For all experiments described here, oocytes and eggs were taken from *Xenopus laevis*. Except where stated, oocytes were taken from frogs which had been induced by hormone treatment to ovulate between 2 and 4 weeks previously. This was done to ensure that the larger oocytes were growing actively. The eggs used were unfertilized, but underwent the usual activation response to penetration. Oocytes were injected dry but without the removal of follicle cells[2], and eggs were irradiated with ultraviolet light to facilitate penetration of the jelly and vitelline membrane[3].

Micropipettes 10–15 μm in diameter were calibrated to deliver a volume of 50–70 mμl., the actual amount being kept constant in each related series of experiments. Samples for injection were kept on ice, as well as under oil to avoid concentration by evaporation. All samples were taken up in, or dialysed into, the following injection medium: 88 mM NaCl, 1.0 mM KCl, 15 mM Tris-HCl, *p*H 7.6. Injected cells were incubated at 19° C in the saline medium described by Gurdon[2].

Labelling of Eggs and Oocytes

Labelled amino-acids can be introduced into cells either by injection or by addition to the culture medium. The choice of labelling procedure is determined chiefly by: (*a*) the rate at which label in the culture medium penetrates incubated cells; (*b*) the rate at which injected label leaks out, and (*c*) the duration of the labelling period.

We have investigated the labelling of cells by ^{3}H-histidine, with the results shown in Fig. 1*A*–*D*. Labelled amino-acids leak out of injected oocytes rapidly, so that less than 50% remains after 1 h, but leakage from injected eggs takes place at a much lower rate (Fig. 1*A* and *C*). In contrast, labelled histidine in the medium penetrates eggs very poorly, but is rapidly taken up by oocytes (Fig. 1*A* and *C*). The incorporation of intracellular amino-acid into protein is shown in Fig. 1*B* and *D*. The general conclusion from experiments of this kind is that when use is made of short labelling periods of up to 1 h or of unfertilized eggs (which do not normally remain metabolically active for more than a few hours), the highest yield of labelled protein is obtained by injection. When oocytes are used, especially for labelling periods of more than 2 h, it is best to label by incubation (at least for ^{3}H-histidine). A minor disadvantage of labelling oocytes by incubation is that the follicle cells and very small oocytes (usually present in ovarian tissue containing large oocytes) will take up label and synthesize labelled "endogenous" protein, but not the protein coded for by added mRNA because they are too small to be conveniently injected. When it is important to eliminate totally the background contributed by follicle cells and small oocytes, unfertilized eggs (which have no follicle cells) should be used.

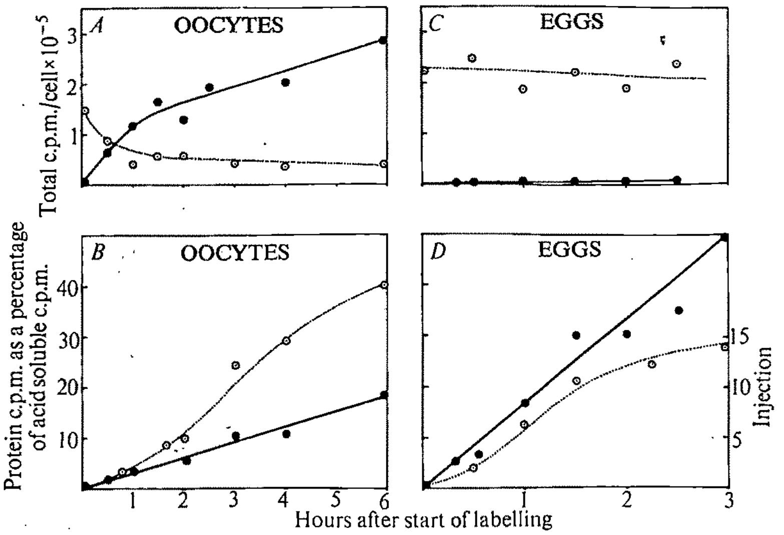


Fig. 1 *A* and *B*, Full size oocytes; *C* and *D*, ultraviolet irradiated unfertilized eggs. For incubation experiments (●) cells were injected with saline solution and incubated at 19° C in culture medium containing ^{3}H-histidine at about 1 mCi/ml. For injection experiments (⊙) each cell received 50 nl. of ^{3}H-histidine at about 6 mCi/ml. At the end of the labelling period, samples of ten cells were frozen. After homogenization in 0.5 M KCl 15 mM Tris, 0.1% unlabelled histidine, *p*H 7.6, an aliquot was dissolved in 90% formic acid and counted to give total counts per sample. The rest of the sample was precipitated in 10% trichloroacetic acid (TCA), and centrifuged. The pellet was taken up in 10% TCA, heated at 90° C for 30 min, pelleted, rewashed in cold TCA, then with alcohol and ether, and finally dissolved in 90% formic acid for counting. From this was determined the amount of labelled protein in the original sample. In *A* and *C*, it is important to note that the total radioactivity includes protein as well as acid soluble c.p.m. The proportion of total radioactivity which is protein can be determined by reference to *B* and *D*.

Translation of Hb Message

The accumulation of labelled haemoglobin in conditions of continuous labelling is shown for injected eggs in Fig. 2*A*. The slow initial rise in the rate of Hb synthesis probably reflects the time needed (10–15 min) for the injected message to become fully incorporated into the structure of the cell in such a way as to serve for protein synthesis; the reduced rate at which labelled Hb is accumulated after 2 h from the time of injection can be partially accounted for by the substantial reduction in the amount of unincorporated labelled amino-acid which remains in eggs injected 2 h before (compare Fig. 1*C* and *D*). The translation of Hb mRNA is compared with that of endogenous mRNA in continuously labelled oocytes in Fig. 2*B*. The amount of Hb mRNA injected was sufficient in these experiments for the labelled Hb to amount to about half that of the labelled "endogenous" protein. It is clear from Fig. 2*B* that both Hb and endogenous protein accumulate at approximately constant rates during the 9 h period of these experiments.

The relative rates of Hb and endogenous message translation have been further examined by pulse labelling oocytes injected with Hb mRNA. Fig. 3 shows that the ratio of Hb to endogenous protein synthesis is similar up to 21 h after injection. Only within the next 10 h is some decrease in this ratio observed. Because no steps were taken to prevent RNA synthesis which takes place in cultured injected oocytes[2], this last result does not necessarily indicate that the rate of translation or stability of Hb mRNA differs from that of the endogenous mRNA already present at the time of injection.

Table 1 summarizes some other respects in which injected and endogenous mRNA translation have been compared. Injected message translation is at least as sensitive as that of endogenous message to the inhibition of protein synthesis by puromycin. The intracellular location of injected message translation is interesting because the nucleus of normal oocytes always has a higher concentration of labelled protein than the cytoplasm, even after short labelling periods (discussed in ref. 4). It has not yet been clearly established whether proteins are synthesized in the nucleus or whether they pass from the cytoplasm to the nucleus very soon after synthesis. From the experiments summarized in Table 1, it seems that injected message is translated in the same part of the cell as most of the endogenous message. The fact that haemoglobin synthesis takes place in oocytes enucleated before RNA injection, as well as in unfertilized eggs which possess no nucleus but only ultraviolet-irradiated chromosomes, shows that Hb is synthesized largely, if not entirely, in the cytoplasm.

We conclude that injected Hb mRNA becomes rapidly associated with components of egg and oocyte cytoplasm so as to be translated in the same way as resident mRNA molecules already in use for protein synthesis. Once started, Hb

Table 1 Inhibitor Sensitivity and Intracellular Location of Hb Synthesis by Injected Oocytes

Recipient cells *	Materials injected		Protein synthesis as % of acid soluble radioactivity		Synthesis ratio: haemoglobin / endogenous
			Endogenous protein †	Haemoglobin	
Large oocytes	9S RNA at 800 μg/ml. and haemin		14.6	43.9	3.01
Small oocytes (half max. diam.)	9S RNA at 800 μg/ml. and haemin		12.5	41.6	3.33
Large oocytes	9S RNA at 800 μg/ml. and haemin	Puromycin at 700 μg/ml.	2.4	3.5	1.46
Large oocytes, enucleated after incubation ‡	9S RNA at 800 μg/ml. and haemin		10.1	33.3	3.30
Large oocytes, enucleated before injection ‡	9S RNA at 800 μg/ml. and haemin		1.5	6.4	4.27

* Each sample, which consisted of thirty oocytes, was labelled by incubation in ^{3}H-histidine for 6 h at 19° C.

† Calculated from 'Sephadex G-100' fractionations as described by Moar *et al.*[13].

‡ Enucleation involved manual removal of the germinal vesicle, which is squeezed out of oocytes after an animal pole incision. The oocytes injected after enucleation did not heal satisfactorily, and incorporation into protein was very low.

mRNA and endogenous mRNA are translated at the same relative rate for at least 21 h; Hb mRNA continues to be translated, possibly at a lower rate, for several hours after this.

Efficiency of Hb mRNA Translation

We wish to know the frequency with which each injected mRNA molecule is translated per minute; this information will permit an estimate of the total number of times an mRNA molecule is translated during its life in an egg or oocyte. The frequency of message translation can be determined from a knowledge of the number of mRNA molecules present in a host cell, and of the specific activity of the intracellular histidine pool (hence the number of Hb molecules synthesized).

The size of the histidine pool in eggs and oocytes has been determined by fractionating on an automatic amino-acid analyser the supernatant of cells homogenized in 0.5 N perchloric acid. One sample of 300 oocytes, from which the follicle cells and ovarian tissue were not removed, contained 36 pmol of histidine per large oocyte. Another sample of 400 oocytes, from which were removed all small oocytes and ovarian tissue except the follicle cells immediately surrounding each large oocyte, contained 23 pmol of histidine per oocyte. A sample of 350 unfertilized eggs, analysed in the same way, contained 91 pmol of histidine per cell. These values for the histidine pool may be compared with the figure of 146 pmol per egg obtained by Kutsky *et al.*[5], using unfertilized eggs of *Rana pipiens*, and 330–700 pmol per egg obtained by Ecker and Smith[6] for eggs of this same species. Since *Rana pipiens* eggs are three times the volume of *Xenopus laevis* eggs, our measurements suggest that a similar or slightly smaller intracellular concentration of histidine exists in *Xenopus* than in the only other amphibian species tested.

Oocytes from the same frogs as those used for estimating the histidine pool size have been injected with Hb mRNA, and the efficiency of message translation has been calculated according to the procedure outlined in Table 2.

To test whether the results summarized in Table 2 are representative of our normal experience, we have calculated in Table 3 the efficiency of translation of the same sample of mRNA used in fifteen other experiments with cells whose histidine pool size was not measured but assumed to be similar to that of other oocytes or eggs. The two samples of oocytes which gave the results in Table 2 were evidently worse in one case, and better in the other case, than is typical. As might be expected, the efficiency of translation is greater at the lowest intracellular concentrations of injected mRNA. This effect is clearly seen in Fig. 4 and is consistent with the observation, reported elsewhere[13], that there is a substantial decrease in translational efficiency at intracellular concentrations of message which exceed 8 μg/ml.

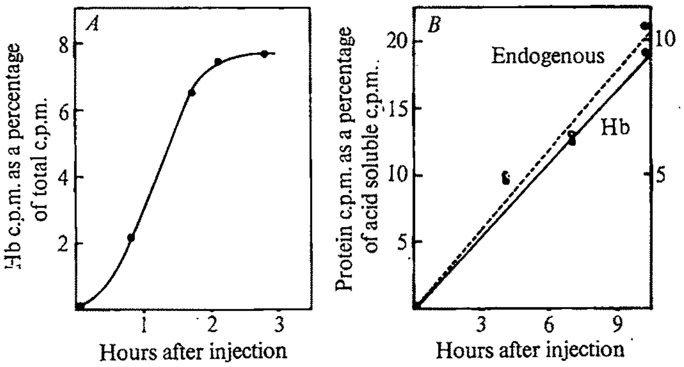

Fig. 2 *A*, Each point is based on a 'Sephadex' analysis of thirty unfertilized eggs injected with 9S RNA at about 800 μg/ml., haemin, and ^{3}H-histidine, and frozen at the times shown. *B*, Each point is based on a 'Sephadex' analysis of twenty large oocytes injected with 9S RNA at about 800 μg/ml. and haemin, incubated in medium containing ^{3}H-histidine, and frozen at the times shown. "Endogenous" refers to protein synthesized from endogenous mRNA, as opposed to the injected 9S mRNA. The ordinate on the left refers to endogenous and that on the right to Hb radioactivity.

In estimating the efficiency of translation, we have made certain assumptions which affect the accuracy of our calculations in the following ways. In determining the specific activity of the histidine pool, our measurements of the extractable free histidine constitute an upper limit to the size of the pool that is actually used for protein synthesis; this could have been

Table 2 Efficiency of Hb mRNA Translation in Injected Oocytes of Measured Histidine Pool Size

	Oocytes of frog A	Oocytes of frog B

6 Pool size of histidine (pmol/cell)	23.2	35.9			
7 Specific activity of intracellular histidine pool (c.p.m./pmol)§	2,845	758	1,392	2,654	1,186
8 Globin chain synthesis‖ (pmol globin/cell/h)	0.157	0.848	0.610	0.243	0.266
9 Number globin molecules synthesized/h/9 S RNA molecule (row 8 ÷ row 3)	2.24	9.77	14.0	11.1	24.35

* These values disregard leakage from injected oocytes, though this is believed to occur (see text).

† Assumes that the molecular weight of 9S mRNA is 200,000. Various published and unpublished measurements by different methods have estimated it to be between 175,000 and 225,000 (for example, ref. 8).

‡ All samples were labelled by incubation for 10 h at 19° C in ^{3}H-histidine of specific activity 52.1 Ci/mmol.

§ Calculated from the histidine pool size and the acid soluble c.p.m./cell recovered from columns of 'Sephadex'.

‖ Assumes 9.5 histidine residues per average (α and β) globin chain.

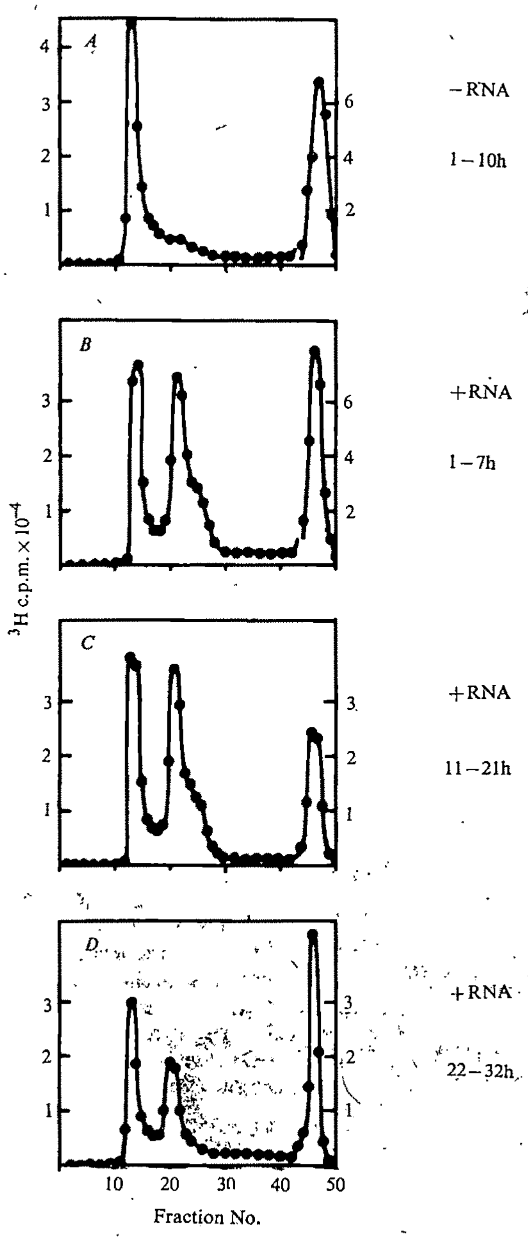

Fig. 3 'Sephadex' analysis of injected oocytes. Each sample of twenty oocytes was injected with haemin, and in the cases of *B*, *C* and *D* with 9S RNA at 400 μg/ml. (about the saturating concentration for these oocytes). Samples were labelled for the periods shown, and frozen at the end of the labelling period; samples *C* and *D* were incubated in unlabelled culture medium until the beginning of the labelling period. The radioactivity on the left hand ordinate of each figure refers to the first two 'Sephadex' peaks; that on the right hand ordinate refers to the right hand 'Sephadex' peak of ^{3}H-histidine.

much smaller, and if negligible would mean that we have overestimated the efficiency of translation by about six times. On the other hand, we have assumed that the same amount of acid-soluble radioactivity as was extracted from oocytes at the end of the labelling period was present throughout the incubation. It is clear from our study of histidine penetration (Fig. 1*A*) that the cell content of ^{3}H-histidine increases during the labelling period, and this will have led to our underestimating the efficiency of message translation. Another factor which could have led to a two-fold underestimate of translational efficiency is the leakage of injected mRNA. We know that about half of all injected ^{3}H-histidine leaks out of oocytes within an hour (Fig. 1*A*). Finally, it is not certain that every RNA molecule within the 9S preparation injected was a potentially functional message. By assuming that every molecule within the injected sample is able to serve as a normal Hb message, we can only have underestimated the efficiency of translation.

In Table 4 we compare the efficiency of Hb mRNA translation in different conditions. It is evident that Hb mRNA is translated 100–1,000 times more efficiently in frog oocytes than in a good cell-free system, and if, as seems possible from the above arguments, we have underestimated the efficiency of injected message translation, then the translation of Hb mRNA in frog oocytes compares very favourably with that in normal living reticulocytes.

Can Other mRNAs be Translated?

The results so far reported do not permit the conclusion that every mRNA could be translated in frog oocytes. The successful translation of rabbit 9S RNA in these cells might depend on its possession of one or both of the following properties: (*a*) it is prepared from a species different from that of the translational system; (*b*) it codes for a protein never normally synthesized (in detectable amounts) by the host cells.

In the absence of a purified mRNA which codes for proteins normally synthesized in *Xenopus* eggs and oocytes, we have not been able to test the importance of these conditions. But the results of injecting three other types of mRNA into frog eggs and oocytes permit us to conclude that (i) rabbit 9S RNA is not the only heterologous RNA capable of being translated in frog oocytes; (ii) some kinds of artificial polymer cannot be translated, (iii) at least one kind of heterologous mRNA cannot be translated. The three types of mRNA referred to are the mRNA for mouse myeloma protein, AUGpolyU, and f2 bacteriophage virus mRNA.

A 9–13S fraction of RNA extracted from the K-41 mouse myeloma promotes the synthesis of the expected myeloma

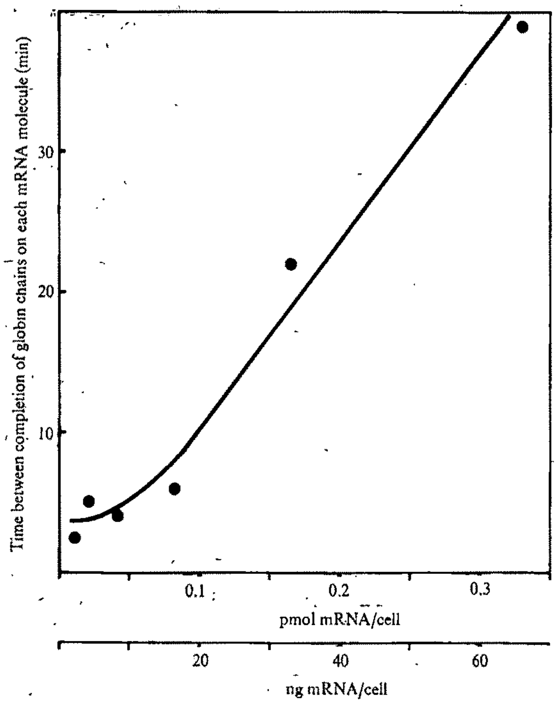

Fig. 4 Each point is based on the 'Sephadex' analysis of twenty oocytes injected with 9S mRNA and haemin, and incubated in medium containing ^{3}H-histidine for 10 h. The various assumptions made in the calculations in Table 2 are also made here. It is assumed that all molecules in the injected RNA sample were translated with the same efficiency. If it is assumed that there is only one ribosome working on each mRNA molecule at a time, then the ordinate scale shows the time taken to synthesize one globin chain.

light chain immunoglobulins when added to a cell-free system[7]. When this RNA is injected into frog oocytes, 2.5–4% of the proteins labelled by ^{3}H-serine in one experiment, and by ^{3}H-threonine in another experiment, were precipitated by K-41 antiserum; this constitutes a four to six-fold increase above the 0.5% precipitation observed in controls. When the precipitated material was dissociated and passed through a column of 'Sephadex', the experimental but not control samples contained radioactivity which migrated with carrier light chain monomer (Stavnezer, Huang, Gurdon and Lane, in preparation).

Table 3 Efficiency of Hb mRNA Translation in Injected Cells of Unknown Histidine Pool Size

10	1,360	2	17.7
5	660	2	14.6
		Average	14.1

This table includes the results of five experimental series, carried out on oocytes or eggs of different frogs.

* Calculated from the known concentration of RNA in samples for injection and from the known volume injected into each cell. Leakage, which may occur on a substantial scale, is ignored. 1 egg or oocyte is assumed to contain 1 μl. of solution.

† Based on 'Sephadex G-100' analyses.

‡ The calculations for oocytes assume a pool size of 30 pmol per cell (average of the two values in Table 2), and those for eggs assume a pool size of 91.2 pmol per cell, this being the value obtained from an automatic amino-acid analyis of 350 unfertilized eggs. In other respects calculations were carried out as in Table 2.

The effect of injecting AUGpolyU and ^{3}H-phenylalanine into oocytes has been examined by Woodland and Browne (unpublished). AUGpolyU seems not to stimulate incorporation of ^{3}H-phenylalanine into polyphenylalanine, but it drastically inhibits the synthesis of proteins characteristic of the host cells.

The possibility that bacterial virus mRNA can be translated in frog cells has been examined in collaboration with Dr A. Garen. RNA was prepared from f2 phage by two cold phenol extractions. Immediately after alcohol precipitation it was injected into oocytes at a concentration of about 1 mg/ml. ^{3}H-tyrosine-labelled proteins were extracted from RNA-injected and control eggs and analysed by acrylamide gel electrophoresis. No difference between the two samples was observed, and in neither case was a peak of radioactive protein seen in the region of the gels that contained ^{14}C-labelled carrier coat protein and replicase. Total protein synthesis was unaffected. Although we have not determined the reason why f2 RNA fails to be translated in frog oocytes, this may be because it requires the translational machinery of bacterial as opposed to animal cells.

Identification of Unknown mRNAs

The opportunity which injected frog cells offer for translating purified mRNA with high efficiency in a normal living cell suggests the application of this system to the identification of unknown mRNAs and their products. The identification of the unknown message for a known protein can be undertaken by separating total RNA into different fractions, injecting these into oocytes or eggs, and assaying for the synthesis of the protein. It is essential to know that the message product is not degraded in oocyte cytoplasm or rendered unrecognizable by complexing with oocyte materials. We have failed to find such effects with several different proteins which had been labelled with ^{125}I.

Table 4 Comparative Efficiency of Hb·mRNA Translation

Translational systems	Temperature of incubation (°C)	No. globin chains synthesized per mRNA molecule/h	Half-life of translational system	Total No. translations/half-life of system
Cell-free system (lysate using added mRNA)	25*	0.8*	60 min*	0.8*
Rabbit reticulocytes in culture (using endogenous mRNA)	37	800†	2–3 h‡ (in culture)	1,840
	20	80†	?	?
Injected frog cells:				
Oocytes (typical)	19	7§	26¶	180
Oocytes (best)	19	24‖	26¶	625
Eggs	19	14§	?	?

The estimates for the efficiency in frog cells are based on various assumptions, one of which is that the amino-acid pool functional in protein synthesis is the same as the total extractable amino-acid. If this were not so, our estimate would be a maximum of six times too high (see the text for the other assumptions made).

* From ref. 9.

‡ From ref. 11.

§ See Table 3.

‖ See Table 2.

¶ See Fig. 3.

If it is required to identify an mRNA and its product when neither have so far been identified, two procedures are available. The first is to look for an increase in the total proportion of intracellular labelled amino-acid that is incorporated into protein. mRNA as pure as our 9S RNA for Hb raises the overall rate of protein synthesis of recipient cells about two-fold when injected at saturating concentrations[13]. The second procedure is to test the ability of a potential message-containing fraction of RNA to compete with a known message (such as Hb mRNA) for a limited supply of the host cells' translational apparatus. Hb mRNA, at a saturating concentration and supplemented by increasing amounts of potential messenger RNA, is injected into a series of test cells; to keep the total RNA injected per cell constant, the increasing amounts of potential mRNA are supplemented with proportionately decreasing amounts of a translationally inert RNA such as 28S rRNA (see below). The existence of mRNA in the potential message fraction is indicated by a reduction in the amount of Hb synthesis when related to acid-soluble radioactivity in the injected cells. Table 5 illustrates the use of this procedure in respect of cultured mouse cell polysomal RNA. Further experiments would be required to prove that the cultured cell RNA reduces Hb synthesis by competition for translational apparatus rather than by some unspecific inhibitory effect; however, this design of experiment can provide a useful means of screening the potential message content of RNA fractions.

For either of these tests to work satisfactorily it is necessary to know that none of the major classes of cellular RNA (that is, 28S, 18S, 4+5S) with which mRNA is likely to be contaminated will affect Hb mRNA translation. The results in Table 5 and other unpublished experiments have shown that 28S rRNA does not inhibit Hb mRNA translation, and it has been demonstrated elsewhere[12] that neither 28S, 18S nor 4+5S RNA from reticulocytes promotes Hb synthesis when injected on their own. We have found that very high concentrations of RNA, especially of 4+5S RNA, are toxic to some samples of eggs and oocytes; therefore the total amount of injected RNA should, whenever possible, be kept below 50 ng per cell, and the total amount of RNA in all samples to be compared should be kept constant. By attention to these details, we believe that oocytes and eggs can provide a valuable assay system for identifying different kinds of mRNA and their products.

Advantages of Oocyte System

For the study of messenger RNA and its translation, the microinjection of *Xenopus* eggs and oocytes has three special merits. First, the translation of purified mRNA is undertaken in a normal living cell, and is therefore less likely to be affected by artefacts than a cell-free system. Second, injected oocytes are capable of translating mRNA with a high efficiency for long periods. Using our normal labelling procedures, we have obtained, over 24 h, as much as 10^6 d.p.m. of labelled Hb from 1 ng of injected mRNA. By increasing the amount and range of labelled amino-acids, it would be possible with this system to recognize as little as 1 pg of Hb mRNA. Finally, *Xenopus* oocytes seem to show very little species specificity with respect to the type of mRNA which they can translate. It seems possible that all kinds of eukaryotic and animal virus mRNA may be capable of translation in *Xenopus* oocytes. The large size, resistance to microinjection, and easy availability of *Xenopus* oocytes have relieved us of the incentive to test the translational usefulness of eggs and oocytes from other animal species.

This work was supported by the Medical Research Council. We thank V. A. Moar, C. Gregory, and S. Ayers for technical assistance. G. M. is "Chargé de Recherches" of the Belgian FNRS, and part of his contribution to this work has been made possible by an EMBO fellowship to work in Oxford.

Table 5 Messenger RNA Competition Experiment

Intracellular concentration of injected RNA (ng/cell)			Protein synthesis as % of acid-soluble c.p.m.	
Hb mRNA	28S rRNA	3T6 RNA	Hb	Endogenous
10	30	0	61.5	111
10	27.5	2.5	35.8	80.1
10	25	5	20.4	35.4
10	17.5	12.5	19.8	45.5
10	10	20	18.4	25.3
10	0	30	12.6	33.2
10	0	0	55.3*	103.1*

The injected cells were large oocytes, which were incubated for 9 h in ^{3}H-histidine before freezing. Analysis was by 'Sephadex'. 3T6 RNA was obtained from polysomes of cultured mouse cells. The variation in values for endogenous protein synthesis is probably due to the variable amounts of uninjected ovarian material in each sample (see text).

* These are average values for three experiments of this kind.

Formation of Antibiotics

M. M. DHAR & A. W. KHAN

Central Drug Research Institute, Lucknow

Antibiotics could owe their origin to detoxication of a metabolite that is detrimental to the culture producing the antibiotic.

It has been suggested[1] that antibiotics, the structures of which consist of heterocyclic moieties attached to peptide sequences, might owe their origin to detoxication of the heterocyclic moieties by peptidation. A consequence of this hypothesis, that introduction of analogues of the heterocycle into the antibiotic synthesizing system should yield analogues of the antibiotic, led to the isolation of quinazolone analogues of the quinoxaline–peptide antibiotic echinomycin both *in vivo*[1] and in a cell-free system[2]. We now suggest that other antibiotics are also microbial metabolites that might owe their origin to detoxication of other metabolites that are detrimental to the culture. It is implied that for its survival, the culture must

have a mechanism for detoxicating this metabolite or that the metabolite can induce the formation of one or more enzymes required for its detoxication.

Apart from the group of antibiotics that have a peptide sequence attached to a heterocycle, several have structures made up of two types of chemical entity; for example, the nucleosides (heterocycles attached to carbohydrate residues); the macrolides (macrocycles attached to carbohydrate residues); the rifamycins (macrocycle attached to an aromatic system) and the penicillins (carboxylic acid attached to a peptide). We suggest that these antibiotics owe their origin to detoxication of one of the chemical entities by attachment to the other.

Nucleoside Antibiotics

If nucleoside antibiotics are formed as a consequence of a detoxication process, two types of structure ought to be encountered. The first, containing unusual heterocycles detoxicated by glycosidation, should contain the usual nucleoside sugars ribose or 2-deoxyribose, and a second, containing unusual sugars, should be glycosides of one of the usual bases: adenine, guanine, cytosine, uracil or thymine. An examination of the structures of known nucleoside antibiotics reveals that they are indeed of these two types.

The antibiotics tubercidin (I), sangivamycin (II), toyocamycin[3] (III) and nebularin[4] (IV) all contain unusual heterocyclic moieties related to adenine. The sugar in every case is D-ribose. On the other hand, psicofuranine (V), decoyinine[5] (VI), 3′-amino-3-deoxyadenosine[6] (VII), cordycepin[7] (VIII), the fluorine containing nucleocidin[8] (IX) and homocitrullylamino adenosine[9] (X) are all adenine nucleosides containing unusual sugars.

The related puromycin[10] (XI), however, seems to be a methylated product of a corresponding tyrosyl adenine intermediate.

The pyrimidine antibiotics gougerotin[11] (XII) and blasticidin[12,13] (XIII) contain unusual peptidyl aminohexoses, but the base in both cases is cytosine. The other cytosine antibiotic amicetin[14] (XIV) also fits the pattern.

The C-nucleoside antibiotics also fit this pattern. The four known ones: formycin[15] (XV); showdomycin[16] (XVI); pyrazomycin[17] (XVII) and oxazinomycin[18] (XVIII) have unusual aglycones but in every case the sugar residue is ribose.

Rifamycin Group and the Macrolides

An examination of the structure of rifamycin B[19] (XIX) suggests that the molecule is derived from a polyketide chain derived from 2-methylmalonate and a 2-methyl-polyhydroxynaphthalene, which must be derived from mavelonate and a hydroquinone or phenol precursor. The fact that these two parts of the antibiotic molecule are probably derived differently suggests that the naphthalene moiety is detoxicated by attachment to the polyketide derived chain.

More than fifty macrolide antibiotics have been isolated from various actinomycetes and their structures found to possess unique correlations with regard to their stereochemistry[20].

It has also been found that the twelve membered lactones are attached to only one sugar residue, a D-4,6-dideoxy or D-6-deoxypyranose, while the fourteen membered lactones are aglycones of one such sugar as well as a L-2-dideoxypyranose. Sixteen membered lactones are attached to a disaccharide: a L-2,6-dideoxypyranose attached to a D-6-deoxy or D-2,6-dideoxypyranose, which as in the twelve and fourteen membered macrolides is attached to form a β-glycoside of the lactone. In view of the unusual nature of the sugars found in these antibiotics, it seems more likely that the formation of such antibiotics may be initiated by a need to detoxicate one of these sugars, the most common one being desosamine. Studies on the biosynthesis of erythromycin[21] indicate that the fourteen membered lactone erythronolide B is first attached to the neutral sugar and the mycarosyl erythronolide B converted to erythromycin by formation of a β-glycoside of desosamine and conversion of the mycarose residue to a cladinose.

Corollaries

There are three corollaries to this hypothesis. (1) The toxic metabolite can be used for strain selection. For example, in the case of the penicillins, it seems that the carboxylic acid is detoxicated by attachment to a 6-aminopenicillanic acid residue. It has been found that only strains which produce penicillin can grow in the presence of significant amounts of phenylacetic acid and that the most efficient penicillin producer can flourish in the highest concentration of phenylacetic acid (P. K. Bhattacharyya, personal communication). Penicillin producers are distinguished by possessing a specific acyl transferase that transfers acyl functions from acyl-coenzyme A to 6-aminopenicillanic acid[22]. Phenylacetic acid, however, has not been found to induce the formation of this enzyme. (2) The toxic metabolite should in some cases be able to induce the formation of enzymes involved in the synthesis of the antibiotic. (3) The introduction of an analogue of the moiety being detoxicated into the antibiotic synthesizing system, should lead to the formation of an analogue of the antibiotic. This has been demonstrated both *in vivo*[1,23] and in a cell-free system in the case of echinomycin, in the case of the penicillins and recently most elegantly in the case of the bleomycins[24].

The hypothesis outlined here is in agreement with two earlier important proposals on the formation of antibiotics[25,26], that antibiotics are secondary metabolites formed by normal biogenetic operations; that antibiotics constitute only a small fraction of secondary metabolites that happen to have been found to possess biological activities and that the formation of an antibiotic requires the accumulation of an initiator. It differs from those earlier views in suggesting that the initiators are toxic to their respective cultures and that a large number of antibiotics are from the group of secondary metabolites that are detoxication products of such initiators.

Formation of Glass Spheres on the Moon

I WISH to draw attention to a remarkable morphological similarity between lunar glass spheres and the glass shot which is formed during the manufacture of mineral wool.

Commercial mineral wool is made by pouring a controlled stream of molten slag and silica from a cupola onto a rapidly turning disk, which throws the melt out as a thin horizontal sheet. Just beyond the periphery of the disk the melt encounters an annular steam blast which breaks it up into small droplets and the resultant mixture of approximately equal parts of fibre and shot is discharged into a large chamber where it cools and settles out. The mineral wool mat formed in this way is used in several applications in which its thermal insulation and fire resistant properties are of value. Some of the shot particles remain in the wool but they can be separated in several ways.

Small amounts of a larger diameter shot fraction accumulate in certain positions in the settling chamber and I have measured the size and shape of several hundred of the shot particles from both fractions with a projection microscope, characterizing them by the parameters measured by Mueller and Hinsch[1].

The mineral wool shot, like the lunar spheres, consist chiefly of almost spherical particles, many of which have a "stalk-like appendage"[1], which is the remnant of the attached fibre. Nearly all the forms found in the lunar shot are also present, including "prolate and oblate spheroids, ellipsoids, dumb-bells with and without a central bulge, filaments, and teardrops"[1]. Rings are evident only occasionally, but I have not identified "crescents, tops, and spindles" because I am not sure how to distinguish these shapes.

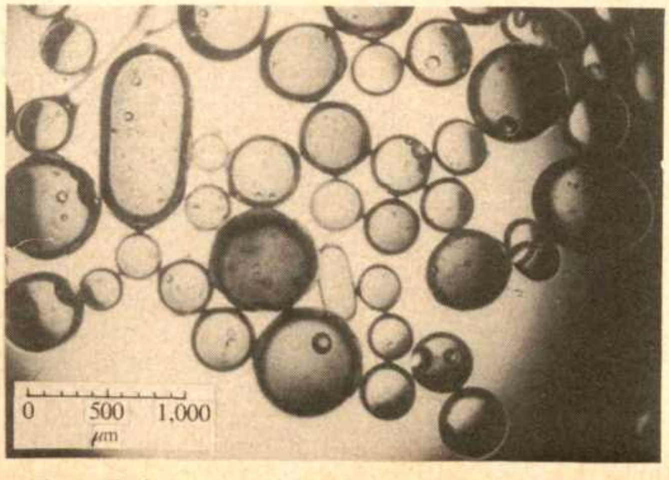

Fig. 1 Typical sample of mineral wool shot showing spheres, ellipsoids and dumb-bell forms (amber to dark brown glass with gas bubble inclusions).

Fig. 1 is a photomicrograph of a typical sample of the mineral wool shot, which may be compared with an example of the Apollo 11 lunar spheres (Fig. 2).

In Table 1 the proportions of the different shapes for both the mineral wool fractions are compared with those found by Mueller and Hinsch for the coarsest fraction of lunar shot. Diameters of the mineral wool shot range from 200 to 800 μm and 100 to 400 μm in the two fractions examined, whereas the lunar shot is from 1 to 500 μm and 70% of the particles are in the 1 to 2 μm range.

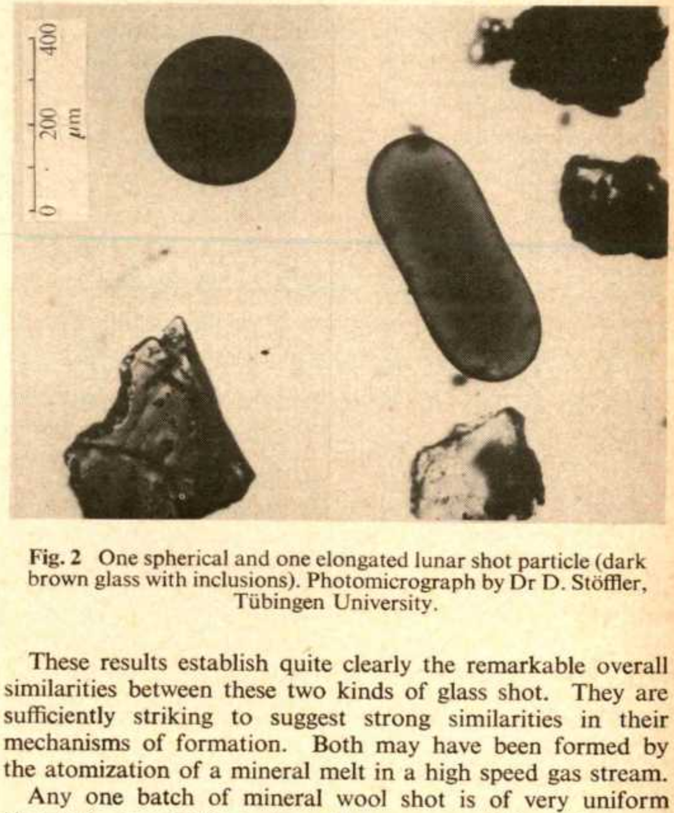

Fig. 2 One spherical and one elongated lunar shot particle (dark brown glass with inclusions). Photomicrograph by Dr D. Stöffler, Tübingen University.

These results establish quite clearly the remarkable overall similarities between these two kinds of glass shot. They are sufficiently striking to suggest strong similarities in their mechanisms of formation. Both may have been formed by the atomization of a mineral melt in a high speed gas stream.

Any one batch of mineral wool shot is of very uniform chemical composition, but there are variations between batches, and between those produced by different manufac-

Table 1 Comparative Morphology of Lunar and Mineral Wool Shot

Sample	Diameter (μm)	No. of spheroids with differing eccentricities 0 to 10%	10 to 50%	50% +	Dumb-bells	Rings	Teardrops
Mineral wool, coarse shot	457	57	29	7	6	0	1
Mineral wool, finer shot	276	39	42	7	8	0	4
Lunar shot	350	64	18	11	4	1	2

turers, according to the nature of the raw materials used in the melt. The chemical composition of the samples described in this communication is compared in Table 2 with analyses for lunar shot[2].

Table 2 Composition of Lunar and Mineral Wool Shot

Constituent	Mineral wool shot	Lunar glass spheres of colour indicated				
		Clear	Pale green	Amber	Dark brown	Black
SiO_2	35.4	49.5	55.4	45.5	41.9	38.1
Al_2O_3	18.3	28.0	1.4	14.0	8.5	4.5
Fe_2O_3/FeO	0.8	2.5	10.4	12.0	17.4	23.8
CaO	34.9	14.0	20.1	12.0	11.0	7.8
MgO	7.9	2.0	16.7	8.0	6.9	11.9
Na_2O	0.9	<0.1	0	<0.1	0.4	0.9

It has been suggested (Mueller, private communication) that the morphology may be influenced by the composition. Although the lunar shot shows marked and highly significant interparticle variation, it is clear that the mineral wool shot contains much more lime than any of the lunar glasses.

The comparison of lunar spheres and mineral wool shot lends additional support to the views put forward by authors such as McKay *et al.*[3], who believe that the lunar shot is produced by high speed primary meteorite impacts, presumably as the intensely hot plasma expands through the surrounding solid particles, causing both melting and atomization. The maintenance of geometrical similarity over the whole range from micrometeorites to relatively large impacts explains the approximately constant proportion of elliptical and elongated forms observed over the whole size range by Mueller and Hinsch[1]. The smallest particles are formed in very large numbers by the very much more frequent impacts of small meteorites at places where the plasma expands from virtually a point source. Large impacts would produce larger shot because of the less sharply divergent flows.

We may suppose that still larger impacts might produce such large molten particles that they would not have time to solidify before returning to the surface. These "meteoric bombs" would give rise to glassy patches splashed on the surface, or at the centres of small craters if the bomb had sufficient kinetic energy. These glassy patches were explained by Gold[4] in a different way. More recent work by Anders *et al.*[5] has, however, shown that they are indeed splashes of foreign molten rock, in which case their identification as secondary impact sites for the molten ejecta from much larger primary impact craters avoids the difficulties encountered in Greenwood's suggestion[6] that they are themselves primary impact sites.

The fact that mineral wool and lunar shot morphologies are so similar should at least inhibit suggestions that the lunar processes must necessarily have taken place at low ambient pressure and great dilution. Mineral wool is made at one atmosphere in a very intensive process, but the shot so formed does not contain either "grape clusters" or changes in shape obviously attributable to the surrounding gas.

One obvious difference is the absence on the Moon of fine glass fibres. One might suppose that these would be formed in substantial quantity at the same time as the shot. Because of their large surface area and fragile nature it is reasonable to suppose that these fibres would be rapidly degraded in the lunar environment. Their broken fragments should form part of the most finely divided solids fraction in the lunar regolith, and it would seem worth attempting to identify these fragments in the soil.

Eddy Viscosity and the Solar Radiation

Dicke[1], although not the first to do so, has proposed that the deep interior of the Sun rotates faster than the visible exterior (see also Roxburgh[2], Sakurai[3]). One result is that the departure of the mass distribution from spherical symmetry would, through its quadrupole moment, cause a contribution to the advance of the perihelion of the planet Mercury, on the basis of Newtonian mechanics, which represents a sufficiently good approximation for this purpose. Unless the fast interior rotation and corresponding interior mass distribution is known and correct allowances made, no precise check of the success of general relativity theory can be made on the basis of the astronomically observed perihelion advance. The main question is whether some such situation concerning the interior rotation can be established, or at least made plausible.

Hide[4,5,6] has stated that, aside from plausible magnetic complications, an equatorial acceleration in planetary and solar atmospheres cannot be maintained by axisymmetric systems of motion (see also Ward[7], Starr and Gilman[8]), but requires what actually amounts to a negative eddy viscosity due to nonzonal disturbances in the motion and pressure. I have studied such phenomena observationally for many systems, including laboratory experiments, and their reality cannot be much doubted[9]. The effect is also manifest in numerically integrated models of the Earth's atmosphere (see, for example, Smagorinsky, Manabe and Holloway[10]). A requirement is that individual eddies possess a systematic asymmetry usually apparent as a "tilt" with respect to normals drawn across the basic or mean flow, in order to result in the needed covariance of downstream and cross-current velocity components.

Thus, as an illustration, in the instance of the Earth's atmosphere there is a broad maximum of zonally averaged eastward angular velocity around 35°–40° latitude in each hemisphere. Superposed on this mean rotation there are nonzonal eddy components of motion, giving the flow an irregular wavelike appearance at any instant. These eddy components of motion show a special type of asymmetry with respect to the meridians, so that their northward and eastward velocities are instantaneously correlated along the length of individual closed latitude circles at a given height. This correlation is positive so that transport of angular momentum occurs horizontally northward across vertical walls of constant latitude in the vicinity of 30° N, into the zone of maximum mean angular velocity. Around 60° N, on the other hand, the correlation is negative, indicating a tendency (weaker in this case) again to transport angular momentum across latitude walls into the zone of maximum mean rotation. Because the effect is exactly contrary to a normal viscous action—tending to maintain the fast rotation through the horizontal exchange of equal masses of eddying fluid parcels across latitude walls, instead of decreasing it—we may call the process a manifestation of negative eddy viscosity. Some fluid dynamicists prefer to call it pseudoviscosity. The whole process requires energy sources within the structure of the eddies.

In view of the fact that the several published theoretical treatments of the solar circulation problem like that of Gilman[11] and of Durney[12], in addition to the observational studies of Ward[7,13], all give evidence of the presence of negative horizontal eddy viscous effects, it is also possible that many stellar interiors have a fast rotation sustained by a vertical inward angular momentum transport due to eddies (see also Starr and Gaut[14], Starr[9]). If the main action of this kind is located in the convective zone, the shear in mean angular velocity would itself probably induce the proper tilt in the upward and downward convective eddy currents to perpetuate the regime against viscosity effects and against possible Maxwell stresses leading ultimately to joule-heating energy losses. I suggest that theoretical and numerical mathematical models should be constructed, which would allow for this possiblity.

Natural Sources of Atmospheric CO

METHANE is produced at the Earth's surface by various processes, chiefly biological in origin. Koyama[1] estimated an annual source of 3×10^{14} g, with rice paddy fields a major contributor, but did not consider the contribution from natural swamps, and his value for the total source may be low by as much as a factor 3. The data of Bainbridge and Heidt[2] suggest that they may have observed substantial methane production from the coastal marshes of Louisiana. The important atmospheric sinks for methane are[3]

$$OH + CH_4 \rightarrow H_2O + CH_3 \qquad (1)$$

$$O(^1D) + CH_4 \rightarrow OH + CH_3 \qquad (2)$$

and

$$\begin{aligned} h\nu + CH_4 &\rightarrow CH_2 + H_2 \\ &\rightarrow CH_3 + H \end{aligned} \qquad (3)$$

These reactions constitute permanent destruction of CH_4. Subsequent chemistry leads to formation of CO and CO_2, and we shall argue that CO is more likely. The source of atmospheric CO due to CH_4 is comparable with, and may be larger than, that associated with the internal combustion engine.

Reactions (1) and (2) dominate below 80 km. The metastable O atom in (2) is formed by photolysis of ozone and its concentration can be readily determined with available data on reaction rates[3,4]. Removal of CH_4 in the troposphere is dominated by (1) with OH produced chiefly by

$$O(^1D) + H_2O \rightarrow OH + OH \qquad (4)$$

The tropospheric chemistry of OH was discussed recently by Levy[5] and our chemical model reflects his discussion. (The rate coefficient for (1) was taken from Greiner[6]. For (4) we used relative measurements by Biedenkapp *et al.*[7] in combination with recent data[8] for the reaction of $O(^1D)$ with O_3.) The reaction

$$NO + HO_2 \rightarrow NO_2 + OH \qquad (5)$$

is an important means for recycling odd hydrogen and we adopt Levy's estimate for the rate coefficient, 5×10^{-13} cm^3 s^{-1}. Computed altitude profiles for OH and HO_2 and $O(^1D)$ are illustrated in Fig. 1.

The methyl radical is removed by

$$CH_3 + O_2 \rightarrow CH_3O_2 + M \qquad (6)$$

and subsequent chemistry leads to production of H_2CO and HCO. The important sink for H_2CO is photolysis[9],

$$\begin{aligned} h\nu + H_2CO &\rightarrow H_2 + CO \\ &\rightarrow H + HCO \end{aligned} \qquad (7)$$

although loss by rain out may be comparable. Removal of HCO is mainly by

$$\begin{aligned} HCO + O_2 &\rightarrow OH + CO_2 \\ &\rightarrow HO_2 + CO \end{aligned} \qquad (8)$$

and elementary considerations suggest that the second path, which requires a minimum rearrangement of chemical bonds, should be favoured. The rate for (8) has not been measured, but HCO is also photolysed[10] to yield H and CO, and we estimate the photolysis lifetime to be of the order of 1 h.

A computed altitude profile for CH_4 is illustrated in Fig. 2. We followed procedures described elsewhere[4] and derived values for the upward flux of CH_4 which are also included in Fig. 2. The computed CH_4 profile is in good agreement with experimental data from a variety of sources. Our calculations imply that reaction (1) is an important sink for CH_4

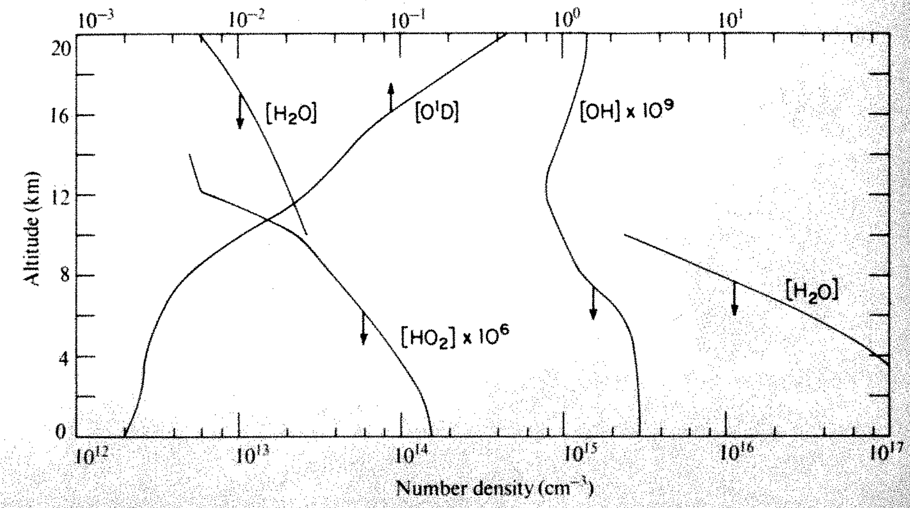

Fig. 1 Average number densities of OH, HO_2 and $O(^1D)$ caluclated for H_2O densities equal to half the dew point values in the troposphere. The tropopause was taken at 10 km and the stratospheric H_2O content corresponds to a mixing ratio 3×10^{-6} by volume. A profile for ozone appropriate for mid-latitudes was used.

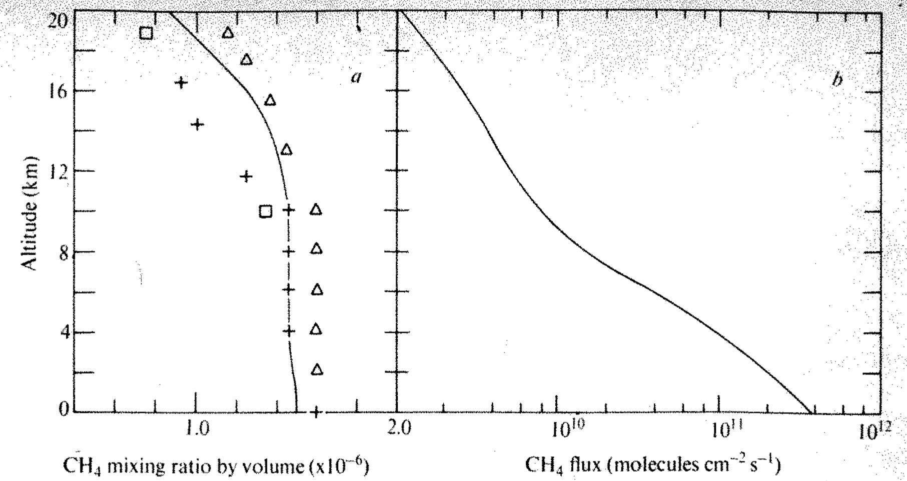

Fig. 2 *a*, Densities of CH_4 calculated by solution of the eddy diffusion equation with diffusion coefficients derived from tracer studies[4]. The solution was constrained to give the observed mixing ratio at the surface and vanishing flux at high altitudes. Measurements by Bainbridge and Heidt[2] are indicated by △ (over Texas) and + (over Louisiana). Measurements by Kyle *et al.*[17] increased by a factor 2 to allow for the reduced stratospheric scale height, are indicated by *b*, globally averaged upward fluxes for CH_4 consistent with densities in *a*. An average flux of 10^{11} molecules cm^{-2} s^{-1} is equivalent to a total flux of 4×10^{14} g yr^{-1}.

and presumably also an important source of CO below 30 km. The need for a significant tropospheric sink for CH_4 was emphasized earlier by Bainbridge and Heidt[2].

The detailed reaction scheme employed here is somewhat uncertain. A mechanism for recycling HO_2 to OH is provided by reaction (5) but the rate coefficient is not well known. Our choice agrees with Westberg and Cohen[5] and is consistent with a lower limit (2×10^{-13} cm^3 s^{-1}) derived by Niki[5]. A preliminary measurement by Johnston[5], however, suggests a somewhat smaller value (2×10^{-15} cm^3 s^{-1}). Other possibilities for recycling exist, including the reaction of HO_2 with Ozone[3] which would be important if the rate coefficient were of order 10^{-14} cm^3 s^{-1}. In addition the reaction

$$CH_3O_2 + HO_2 \rightarrow CH_3OOH + O_2 \qquad (9)$$

followed by photolysis of methylhydroperoxide to yield CH_3O and OH also gives good agreement with the results shown in the figures. It should be noted, however, that even without recycling the OH density at the surface is of order 5×10^5 cm^{-3}. The measurements of atmospheric CH_4, in combination with the known source strength, demonstrate that there must be an efficient tropospheric sink for the gas. The ultimate product is likely to be CO and the yield should exceed the anthropogenic source (2×10^{14} g yr^{-1} or 3×10^{10} molecules cm^{-2} s^{-1}).

The model offers ready explanations for a number of puzzling phenomena. It allows one to reconcile diverse estimates for the lifetime of atmospheric CO. Weinstock[11], as modified by Junge *et al.*[12], derived a lifetime of 0.2 yr using measurements of ambient atmospheric ^{14}CO and calculations for the corresponding source strength. Junge *et al.*[12] performed a similar analysis for ^{12}CO. Assuming the internal combustion engine to be the major source, they derived a lifetime of 1.3 yr. With the additional source discussed here, CH_4, the lifetime is reduced to 0.3 yr, in harmony with the ^{14}CO value. Further, using measurements by Greiner[13] for the reaction

$$CO + OH \rightarrow CO_2 + H \qquad (10)$$

and using the OH profile in Fig. 1, we calculate the absolute value of this lifetime to be 0.3 yr. The predominance of the natural source explains the failure to detect any significant increase in atmospheric CO during the past 20 yr[14], even though production by internal combustion engines has increased by about a factor 2. It further accounts for the similarity of CO mixing ratios observed in the high tropospheres of both northern and southern hemispheres[12]. Some asymmetry would be expected if the car were the dominant source, because its contribution should be concentrated in the northern hemisphere and also because the time constant for interhemispheric exchange is about 5 yr[14]. Measurements in the high troposphere are especially useful in that the influence of local surface conditions, which can act either as sources or sinks of CO, are minimized.

Our model is supported also by measurements of formaldehyde in rain[15]. This gas exhibits the same T/H ratio as atmospheric methane[15]. The rain measurements imply a gas phase mixing ratio, H_2CO to air, of 1.3×10^{-9} by volume at 5° C[16]. The corresponding photolysis rate to yield CO is 5×10^{11} molecules cm^{-2} s^{-1} if we assume a mixed distribution of the H_2CO and adopt mean isolation conditions. Our model predicts a total CO production of 3.7×10^{11} cm^{-2} s^{-1}, in satisfactory agreement with this result.

The internal combustion engine may locally determine the atmospheric CO abundance. There is strong evidence, however, that the global level is governed by natural sources and oxidation of methane is likely to be a major contributor.

Early Precambrian Impact Structure and Associated Hyalomylonites near Agto, West Greenland

WORK on the Isortoq granulite facies rocks of the Nagssugtôqidian mobile belt[1] in West Greenland has revealed an area where the rocks show features believed to be caused by shock metamorphism, while in neighbouring areas small

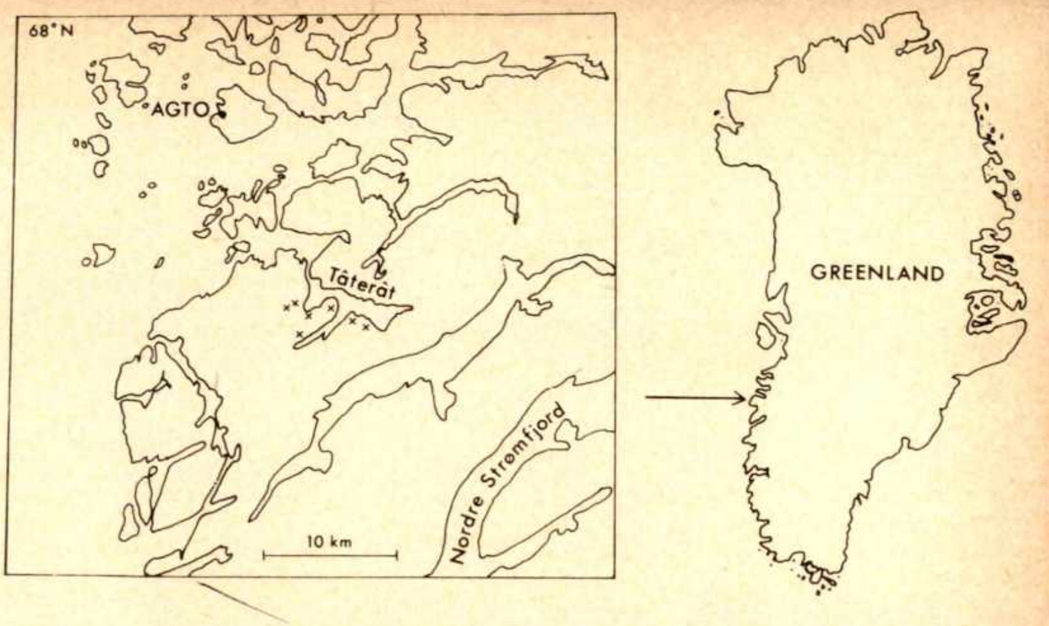

Fig. 1 Crosses indicate locations of shock-metamorphic rock-types.

veins of glass-mylonite (hyalomylonite) have been generated in pre-existing regional thrust zones.

The most convincing evidence of shock metamorphism was found about 20 km south-east of Agto along the western branches of the Tâterât fjord. Although no features suggesting an impact structure can be seen on topographic maps, the enderbitic gneisses at this locality are more or less texturally destroyed and locally more than half of the rocks consist of a very irregular pattern of small black veins embracing gneiss fragments—"pseudotachylytes". The ground mass in these veins is black and aphanitic, and decorated and non-decorated planar elements[2] are seen in quartz, plagioclase and *K*-feldspar both in the gneiss and in the fragments in the pseudotachylyte.

Apart from diaplectic glasses[3] of the above mentioned minerals every transition from diaplectic to normal fused glass seems to be present. Felsic grains in the pseudotachylyte as well as in the surrounding gneiss locally have a rim of fused material shown by gently twisting colourless flow lines in their border zones.

Pyroxenes and amphiboles are filled with additional planar elements, deformation lamellae and deformation twins. The pleochroism is no longer present and the birefringence is reduced to low values[2]. Locally the mafics are destroyed and only black–brown isotropic areas (oxidized pyroxene and amphibole[4]) are present. In the garnets up to four systems of very regular planar features are observed. Apatite also has planar features.

The texture of the gneiss varies between normal hemigranoblastic (with planar elements) to almost completely destroyed mortar-like textures.

Strong shock metamorphic effects were observed within an area of only a few square kilometres but effects have been found locally within an area of at least 30 km².

A hyalomylonite occurs in a thrust zone about 1.5 km from the area showing the most intense shock metamorphism. The thrust zone can be followed over a distance of roughly 130 km from the Inland Ice to the Davis Strait and belongs to an extensive system of fault and thrust zones in West Greenland[5], probably of pre-Nagssugtôqidian initiation. Different types of normal crush-rocks are found in these zones.

The hyalomylonite vein which occurs in a conformably enclosed relic gneiss lens in the thrust zone can be followed about 10 m and measures a maximum 5 cm across. This flat ellipsoidal vein has knife-sharp margins and exactly the same orientation as the thrust zone and the foliation in the gneiss lens. The vein consists of about 85% homogeneous glass and about 15% fragments, which, except for one zircon grain, are entirely of quartz and feldspar, often with planar elements. The glass is in contact with the gneiss, which is highly crushed with planar elements and the mafics locally in an oxidized state.

The glass contains many spherulites a few microns in diameter with dark nuclei. Flow lines are only seen in the glass around the felsic inclusions. Minute, secondary calcite-filled cracks are observed in the glass.

Chemical analysis of the hyalomylonite and the surrounding gneiss both for major and trace elements shows a very close similarity between the two. The refractive index of the glass is 1.530 ± 0.001.

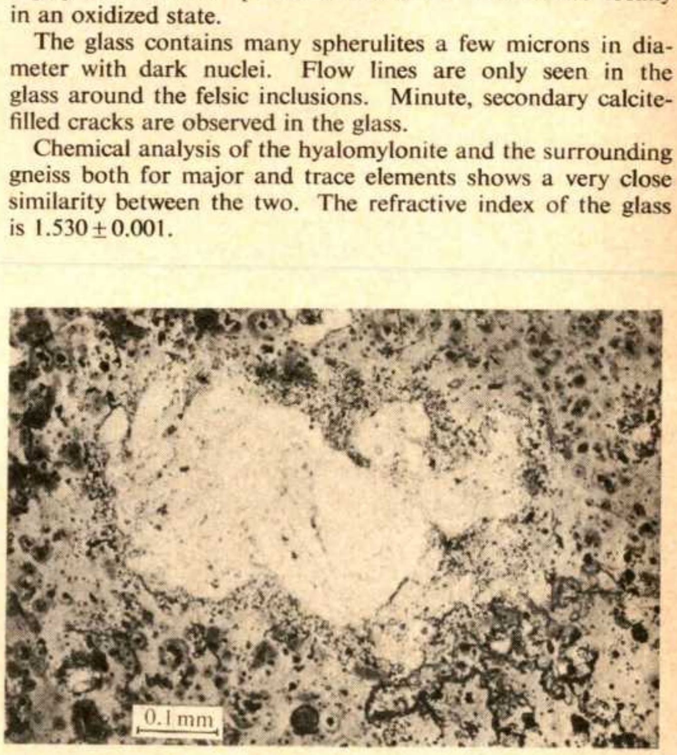

Fig. 2 Felsic grain enclosed in glass, viewed with plane-polarized light.

A K/Ar determination carried out on the glass gave an age of 3,070 ± 70 m.y.[6]. Only a very weak devitrification is observed locally, probably because of the dry conditions in the Isortoq complex as a whole[7], which would allow only thermal reconstruction, a very slow process, to occur[8].

The generally accepted age of the Nagssugtôqidian mobile belt is 1,790–1,650 m.y.[9], but several authors[5,10] believe that pre-Nagssugtôqidian rocks and structures are common in the area mentioned.

There is also a possibility that excess Ar is present, but because glasses are generally believed to be only weakly retentive to Ar and usually give low ages[11], further work is necessary to clarify the meaning of this unexpectedly old age.

The formation of the hyalomylonite vein is considered to be due to instantaneous movements in cold and rigid surroundings.

About 6 km from the most shocked area other hyalomylonites are found. Here the glass is enclosed in a mylonitic rim in contact with the gneiss, which is also severely crushed. Different types of recrystallization, partly devitrification and partly crystallization from a melt, are observed.

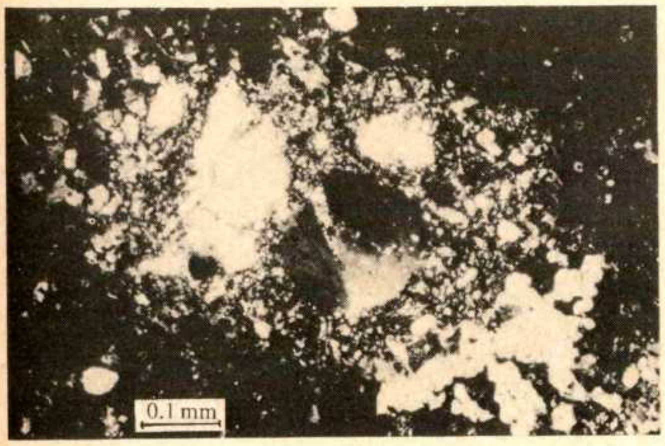

Fig. 3 Same as Fig. 2, but viewed through crossed nicols.

Different crush-rocks from tectonics are present in the Agto area, but the features discussed here are only seen in the vicinity of the shock metamorphic locality. Metamorphism giving rise to such features seems possible only as a result of meteorite impact (astroblemes[12]) and the observations around Tâterât seem indicative of an impact in early Pre-Cambrian time.

Detailed mineralogical investigations which have been carried out on the shocked minerals and hyalomylonites will be presented later.

The work was carried out under the auspices of the Geological Survey of Greenland (GGU) and Institute of General Geology, Copenhagen. Dr C. K. Brooks assisted with the preparation of the manuscript.

Quinacrine Staining of Chromosomes and Evolutionary Studies in *Drosophila*

PARTICULAR chromosome regions have been found to fluoresce intensely after staining with quinacrine and related compounds[1–16], and we have been studying the pattern of distribution of these regions in the chromosomes of various species and laboratory stocks from the genus *Drosophila*. We find that these patterns vary in interesting ways and that they are a characteristic of chromosomes that can be used in studies of evolutionary cytogenetics in much the same way as structural rearrangements[17–19]. The following are among our observations.

(1) *Drosophila melanogaster* differs consistently from its sibling species *D. simulans* in the pattern of the brightly fluorescent regions. The two species can be distinguished by the patterns of bright fluorescence of either the mitotic chromosomes of the neuroblasts or the polytene chromosomes of the salivary gland cells. In neuroblast metaphases of *D. melanogaster*, every chromosome has brightly fluorescing regions. In *D. simulans*, such regions are found on only the *Y* and fourth chromosomes of metaphase cells. In salivary gland cells of *D. melanogaster* (Oregon-R) there is always an intensely fluorescent region near the base of chromosome IIIR at approximately 81F; and, in some individuals, there is also a second brightly fluorescent region more distally at approximately 83D (see (5) below). *D. simulans* salivary gland cells have no brightly fluorescent regions on the third chromosome. In *D. melanogaster* (Oregon-R) there are two intensely fluorescent regions on chromosome IV: one near the base in region 101 and one in the middle of IVR at approximately 102D. In *D. simulans* salivary gland cells there is always a brightly fluorescent region at the base of the fourth chromosome near the chromocentre; there may be a second intensely fluorescent region at the tip of chromosome IV depending on the stock (see (2)). Dots of brightly fluorescent material not obviously associated with any chromosome are frequent within the chromocentre of both species. These observations suggest the usefulness of quinacrine staining for analysing genetic and evolutionary relationships among sibling species[20–23].

(2) Certain laboratory stocks of *D. simulans* differ with regard to the intensely fluorescent regions of the fourth chromosome. In individuals from three laboratory stocks (wild type stocks derived from populations in Honduras and Madison and a *vermilion* stock from the California Institute of Technology) such regions are found at both the base of the fourth chromosome adjacent to the chromocentre and at its tip. These two regions usually pair ectopically, and the whole chromosome then takes on a U shape. In cells from larvae of the fourth stock (*yellow*, *white* from the California Institute of Technology) only the base of the fourth chromosome fluoresces brightly after quinacrine staining. In this stock there is no noticeable ectopic pairing of the base with the tip of the chromosome, and the fourth chromosome is straight[24]. Because *D. simulans* is one of the three widespread species of *Drosophila* considered to be monomorphic with regard to chromosome structure[25], our observations indicate that quinacrine staining can reveal chromosome polymorphisms among and within populations that contain no gross rearrangements and are therefore classified as chromosomally monomorphic. All four stocks are classifiable as *D. simulans* on the basis of their male genitalia[26], and breeding experiments indicate no genetic isolation among them.

(3) A survey of a few of the principal species groups within the genus reveals that not all species have chromosome regions which fluoresce brightly after quinacrine staining and that the distribution of such species follows generally what is known of the taxonomic relations within the genus. Thus, *D. melanogaster*, *D. simulans* and *D. virilis* have fluorescent bands, while

D. hydei, *D. melanopalpa*, *D. repleta*, *D. peninsularis* and *D. tumiditarsus* do not. It will be interesting to correlate such cytological observations with information about the composition of DNA, especially satellite DNA, of the various species[27].

(4) A band that fluoresces intensely after quinacrine staining is found on the dot chromosome of the Hawaiian species, *D. hemipeza* but not in *D. grimshawi*, another Hawaiian species.

These observations open the possibility of comparing closely related species, including homosequential or nearly homosequential ones, found on these islands. Homosequential species[28-29] are morphologically distinct, reproductively isolated species with identical banding patterns along their polytene chromosomes. Differences in the fluorescence patterns of homologous loci may therefore indicate alleles which differ to an evolutionarily significant degree.

(5) In some individuals of one laboratory stock of *D. melanogaster* (Oregon-R) one of the salivary gland chromosome regions (approximately 83D) fluoresces brightly after quinacrine staining; in others it does not. In still other individuals only a small amount of brightly fluorescent material is seen at this region. The analysable salivary gland cells from any one larva are all the same in this regard. It is not clear that the gene or genes responsible for bright fluorescence after staining with quinacrine are located at those chromosome regions where it is observed. To classify the phenomenon as a polymorphism, we should therefore like to be able to demonstrate heterozygous individuals within the population. In several different salivary gland preparations from this stock we have observed a few cells in which there is asynapsis for an appreciable length of chromosome IIIR, including region 83D. In such cells large portions of each homologue of IIIR can be examined separately. In some individuals we have found cells that fluoresce brightly at region 83D in one homologue but not in the other. In other individuals we have found cells that have bright fluorescence at region 83D on each of the asynapsed homologues. In still others we have found cells that show no bright fluorescence at this region in either asynapsed homologue. There must therefore be some individuals in this population which are heterozygous for bright fluorescence at region 83D, and they are probably those with a small amount of brightly fluorescent material at this region.

Taken together, these findings, which we shall report in detail later[30,31], indicate that the property of fluorescing brightly after staining with quinacrine is a phenotypic character observable at the level of specific chromosome regions in evolutionarily interesting situations. Chromosome differences have until now been observable within and among populations chiefly on the basis of gross structural rearrangements which *de facto* involve changes in gene order. The quinacrine technique has the advantage of being able to reveal chromosome differences within and among populations in the absence of gross changes in gene order. We suggest that this technique is promising as a tool in the analysis of chromosome differences between, and chromosome polymorphisms within, both natural and experimental populations of *Drosophila* and quite possibly other plant and animal taxa as well.

We thank Dr Lynn H. Throckmorton for confirming our classification of all *D. melanogaster* and *D. simulans* stocks used in this study, and Dr Harvey A. Bender and Dr Ronald S. Ostrowski for confirming our identification of salivary gland chromosome positions. Dr Barr is the recipient of a US National Institutes of Health Research Career Development Award; Dr Ellison is a US National Science Foundation postdoctoral fellow. Chromatid Disjunction in Unfertilized Ageing Oocytes

AGEING mammalian oocytes, which have spent longer than the optimum time in the oviduct without being fertilized, may, after fertilization, give rise to abnormal embryos in which aneuploidy is frequent[1]. We have now observed a change in the organization of the chromosomes of ageing secondary oocytes of mice, which may account for the occurrence of aneuploidy at the second meiotic division.

As in most mammals, the first meiotic division is completed in the ovary, and the ovulated oocytes are propelled along the oviduct in a state of arrested meiosis at second metaphase until—and if—they are fertilized. In the second meiotic division, which is activated by sperm entry at fertilization, the chromatid pairs which constitute each chromosome of the haploid oocyte disjoin and move towards opposite poles, one of which is destined to become the second polar body. We have evidence that the disjunction of chromatid pairs sometimes occurs before fertilization, but after prolonged sojourn in the oviduct. Subsequent fertilization of an oocyte in such circumstances may lead to a viable zygote in which, however, the synchrony of the partitioning of the chromosomal elements is so disturbed that aneuploidy is more probable.

When we induced virgin mice, 5–8 weeks old, to superovulate by the administration of hormones, we noted after they had been killed, that the contents of their oviducts were variable, particularly with respect to cohesiveness and location of the cumulus-oocyte mass. The occurrence of premature chromatid disjunction, observed in the meiotic chromosome preparations[2] was more frequent when the ductal contents were characterized by dispersed cumulus, location of most of the oocytes in the subampullar region and the presence of some oocytes devoid of follicle cells (Table 1). Those conditions may be more accurately indicative of "ageing" oocytes than the lapse of time after administration of the ovulatory hormone because (1) the effects of exogenous hormones are superimposed on the endogenous hormonal state, variable in mature female mice, and (2) although the precise role of the cumulus mass in which the oocytes are ovulated has not been defined, it is known that the cumulus is dispersed and the coronae of follicle cells fall away as the oocytes are propelled along the oviduct[3].

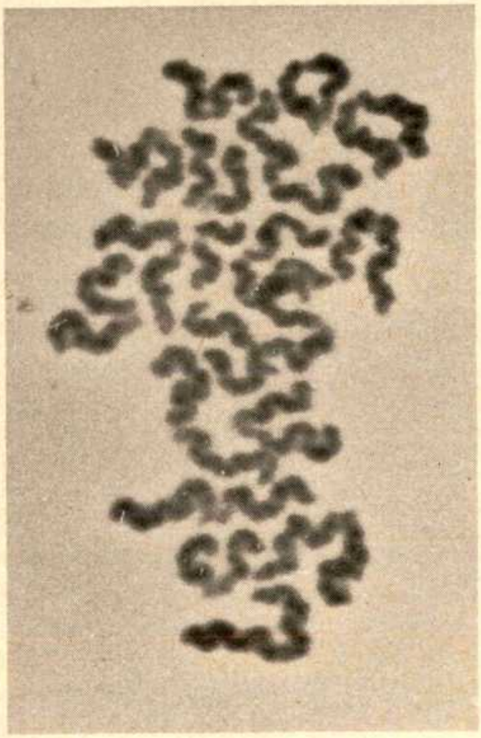

Fig. 1 Chromosome complement of secondary oocyte at second metaphase. All chromatid pairs are joined at their centromeres.

The relationship between anomalous development and experimentally induced delay in fertilization is well established[1]. Our observations, consonant with those of another investigator[4] who described morphological changes in the spindle assembly of mouse oocytes that had a prolonged stay in the oviduct, provide a cytologic basis for attributing those developmental abnormalities to impairment of the machinery of the second meiotic division. More important, they present a mechanism whereby the increased frequency of trisomy in offspring of older women may, as proposed, be due to the greater probability of delayed fertilizations.

It is significant that the type of chromosome alteration described here is not seen in the pathway of degeneration of the first polar body. Even in an advanced state of degradation, the polar body chromosomes remain as chromatid pairs, joined at their centromeres[2]. The disjunction of sister chromatids in unfertilized secondary oocytes appears, therefore, to be a characteristic of intraductal ageing rather than a non-specific type of change in degenerating meiotic chromosomes.

Table 1 Occurrence of Chromatid Disjunction in Unfertilized Secondary Oocytes in Relation to the State of the Intraductal Contents

* Oocyte-cumulus mass was cohesive, located in the ampullar region of the duct, and there were no separate oocytes, free of follicle cells. Chromatid disjunction was observed in 1.8% of the chromosome preparations.

† Cumulus mass fell apart in the saline solution in which the oviduct was sectioned, most of the oocytes were located in the subampullar region, and some oocytes, free of follicle cells, were present. Chromosome disjunction was observed in 15% of the preparations.

‡ Number of chromosome preparations in which the centromeres could be seen as either intact or divided in at least ten chromatid pairs.

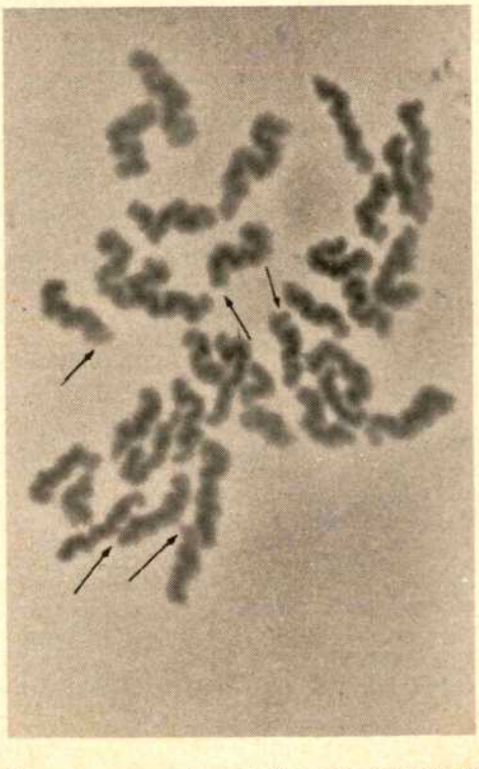

Fig. 2 Chromosome complement of secondary oocyte obtained from oviduct with "aged cumulus" (Table 1). Some sister chromatids have disjoined (arrows); others are still joined.

Sequential Activation of Clotting Factors during Blood Coagulation

THE existence of activated forms of blood clotting factors was suggested more than twenty years ago. Ware and Seegers[1], pointing out a difference between the plasma and the so-called serum factor V, postulated a partial modification of the clotting factor by thrombin, which resulted in more potent activity. After activation, procoagulant action rapidly declines[2]. Rapaport[3] described the activation of the anti-haemophilic factor VIII by traces of thrombin. Thus, it is likely that the first traces of thrombin, produced during coagulation, convert factors V and VIII into more active clotting factors (Va and VIIIa). These thrombin-activated factors accelerate the intermediate phases of coagulation, leading to a rapid generation of more thrombin, and subsequent formation of fibrin. One of the intermediate phases is the reaction of factor VIIIa with the activated form of factor IX (IXa). In the presence of phospholipid and calcium ions factors VIIIa and IXa convert factor X into an activated form[4], which in turn reacts with factor Va, phospholipids and calcium ions to give prothrombin-converting activity[5,6]. Factor IX is activated during the initial phases of blood coagulation, which involves activation of the Hageman factor (factor XII) as a result of contact with a foreign surface, and the activating action of the latter on factor XI[7].

So far the activation of clotting factors by thrombin has been studied only with more or less purified preparations. It seemed to us that a more physiological way of studying the activation of clotting factors would be to investigate the dynamic process of activation and inactivation in slowly coagulating, recalcified citrated plasma. In this way we were able to determine the thrombin activation of factors VIII and V, the generation of activated factors IX, X and of thrombin, the disappearance of the activated factors and the sequence of the reactions involved.

Normal human plasma was obtained by centrifuging citrated blood (1 volume of trisodium citrate 3.8%+9 volumes of blood), immediately after venepuncture, for 4 min at 12,000*g* at room temperature. The platelet-poor supernatant plasma was then centrifuged at 40,000*g* for 30 min at 0° C. To obtain plasma with a very slow and low thrombin generation, we had to work very quickly so as not to damage the platelets. Otherwise the activation of the clotting factors would have been too fast to be determined and the measurement of their activities would have been disturbed by the thrombin that was generated. The activities of clotting factors were measured by one-stage procedures[8–10].

We introduced an important modification to the assays for factors VIII and IX, because of the great lability of activated factor VIII. The diluted sample was omitted from the incubation mixture, but was added immediately after dilution, simultaneously with $CaCl_2$. The presence of fibrin monomers in solution was tested by the ethanol gelation test according to Godal[11]. The thrombin generated was tested with a normal plasma sample (0.1 ml. of incubation mixture added to 0.1 ml. of citrated plasma), the clotting time of this being a measure for the thrombin concentration. The amount of thrombin generated was calculated on a calibration curve, for the determination of which we used NIH thrombin and the same normal plasma as substrate.

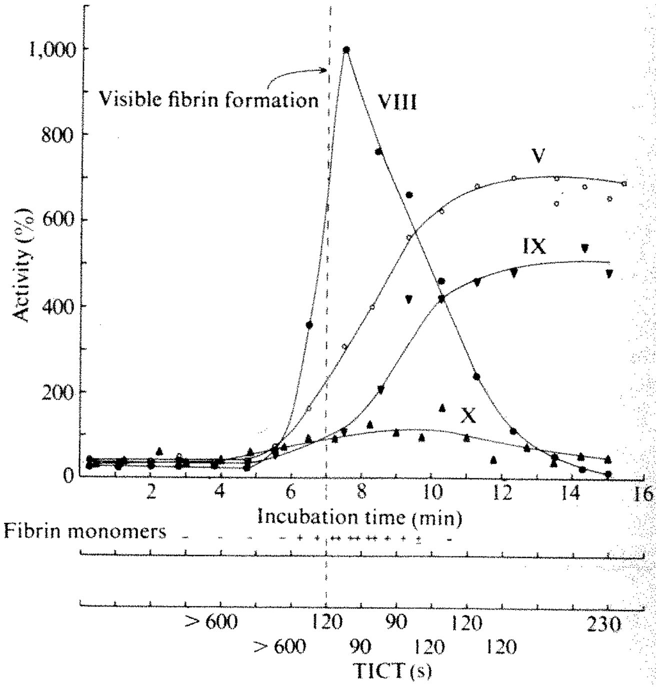

Fig. 1 Activation of clotting factors in a system consisting of equal amounts of practically platelet-free plasma, saline and $CaCl_2$, measured from the moment of recalcification. The formation of fibrin monomers, the appearance of a visible clot and the generation of thrombin, measured as the clotting time of normal plasma, are shown. □ TICT, Thrombin induced clotting time.

We investigated the activation of factors VIII, V, IX and X, the presence of fibrin monomers in solution, the appearance of the visible fibrin polymer (clotting of the mixture) and thrombin generation in a mixture of equal amounts of normal plasma, saline and $CaCl_2$ M/30, incubated at 37° C. The moment of recalcification was taken as zero time. At different times after recalcification, a sample was pipetted off, diluted 1 : 40 in Michaëlis buffer (pH $7.25 \mu = 0.15$) and simultaneously assayed for factor VIII, IX and V activity by three people. Thrombin generation was assayed in an undiluted sample. Immediately afterwards another sample of the incubation mixture was recalcified and assayed for factor X activity after dilution 1 : 10 in the same buffer. This procedure was repeated for the detection of fibrin monomers. The clotting time and thrombin generation curve were the same for all three incubation mixtures (combined results are shown in Fig. 1). The activity of the clotting factors was normal until 5 min after recalcification, when there was a large and rapid activation of factor VIII. We noted an activation from 28% to 1,000%, corresponding to a change in clotting time of the assay from 100 s to 71 s for a dilution of 1 : 40. Factor V was activated simultaneously; at the maximum the clotting time was shortened from 43 s to 20 s, corresponding to an activation from 42% to 700%. For the third factor which was activated, factor IX, there was a shortening of clotting time from 134 s to 92 s for a dilution of 1 : 40, corresponding to an activation from 40% to 500%. One minute before the coagulation of the mixture, fibrin monomers were detectable; visible fibrin formation lasted for 3 min, during which the test for fibrin monomers remained positive. Factor VIII activity disappeared from the clotted plasma very quickly, while high factor V and factor IX activities could be determined 2 h after clotting. In this clotting system the activity of factor X does not increase remarkably, the clotting time of a 1 : 10 dilution being shortened from 50 s to 40 s. The thrombin generation in this almost platelet-free plasma is very low. At the maximum of the thrombin generation curve only 0.3 U of thrombin/ml. are generated. This quantity of thrombin does not influence the determination of clotting factors, as blank tests proved.

The problem how the very first trace of thrombin, which initiates the autocatalytic activation of factors VIII and V, is generated, remains to be solved.

Interruption of SV40 Oncogenesis with Human Foetal Antigen

IMMUNIZATION of adult hamsters with irradiated foetal hamster or mouse cells produces strong immunity to SV40 cell challenge and simultaneously induces cytostatic (or C) antibody formation[1]. Furthermore, adenovirus 31 tumorigenesis can be interrupted by a single injection of hamster foetal cells if administered to neonatally infected hamsters 3 weeks after birth and before the appearance of the tumour[2]. SV40 viral oncogenesis could be similarly interrupted in male but not female hamsters[2]. This work provides support for the view that foetal and tumour cells share common antigens and that oncogenesis involves retrogenic activation of early foetal antigen genes in adult cells[3,4].

If the concept that ontogeny repeats phylogeny is applicable at the molecular level, early foetal proteins from different vertebrates should resemble each other more than adult proteins do. This would not be surprising, for the organizational problems of early foetal life are quite similar in different species, whereas the adaptation required for adult life may differ widely. Thus if viral oncogenesis involves activation of specific foetal genes, these may be expected to be immunologically similar in cells of widely different origin. Conversely, foetal cells of different species might be expected to immunize across species barriers against tumours produced by the same virus. This is important if conclusions drawn from animal model studies are to be applied to man and if vaccination or immunotherapy involving specific antigens is to be attempted.

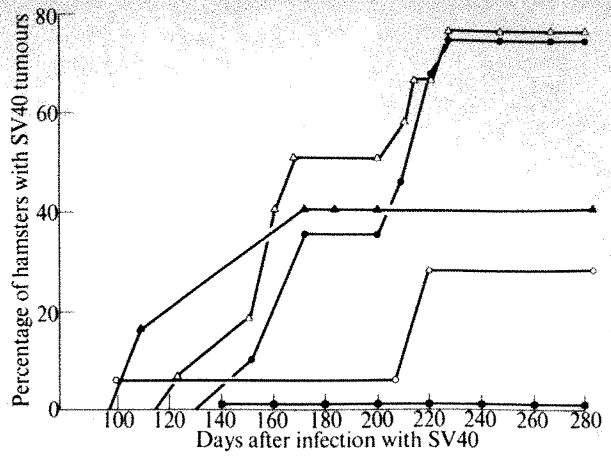

Fig. 1 Interruption of SV40 tumorigenesis by immunization with human embryonic kidney cells. △, No vaccine; ●, adult human kidney (5,000 r.); ▲, human embryonic kidney (5,000 r.); ○, SV40; ■, F5-1 SV40 tumour cells (5,000 r.).

Hamster, mouse, and human cells transformed by SV40 virus all exhibit a similar antigen capable of stimulating specific transplantation immunity against SV40-induced tumours in hamsters[5,6], supporting the concept of foetal antigen similarity. We now report cross immunization of adult hamsters against SV40 virus tumorigenesis by human foetal cell homogenates.

SV40 hamster tumour cells (F5-1 line) were cultured as previously described[7], and all experiments were done with the LVG hamster strain. C-Antibody levels were determined using implanted diffusion chambers containing SV40 tumour target cells[1,2,7,8].

SV40 virus (VA-45-54) was prepared in green monkey kidney cells (GMK) and had a titre of $10^{7.6}$ $TCID_{50}$/0.2 ml. in GMK. Hamsters were infected with 0.2 ml. of SV40 in the right subscapular space within 24 h of birth and palpated weekly for tumours after 4 weeks of age. Hamster foetal cell suspensions were prepared as previously described[1]. Lyophilized cells were prepared from washed suspensions of freshly harvested (trypsin) F5-1 tumour cells in HBSS. The cells were reconstituted in sterile distilled water to the original volume of liquid which had originally contained 5×10^6 viable cells/ml. Primary human embryonic kidney cells were purchased from Flow Laboratories, Rockville, Maryland. Foetal immunogens and control materials were exposed to 5,000 r. of X-irradiation before injection[1]. Five million trypan blue excluding cells were used for each immunization with all preparations except the lyophilized F5-1 cell vaccine.

Cytostatic antibody against SV40 tumour cells appears within 4 weeks after infection of neonate hamsters with SV40, persists in the peritoneal fluid and blood until several weeks before palpable tumour formation, then disappears[9]. SV40 tumours rarely appear in less than 90–100 days after infection. Neonatally infected hamsters were immunized with three injections of either SV40, irradiated SV40 hamster tumour cells, human embryo kidney cells, adult kidney cells, lyophilized SV40 tumour cells, 10-day gestation hamster foetal cells, or nothing. The results in Table 1 show that at 56–60 days after infection, non-immunized SV40-infected animals possessed a significant level of C-antibody, as previously reported[9]. Immunization of infected hamsters with SV40 virus, irradiated F5-1 tumour cells, primary human embryo kidney cells, or hamster foetal cells always increased the C-antibody level over that observed in control animals receiving no immunization. Adult primary human kidney cells, lyophilized SV40 tumour cells, or non-irradiated hamster foetal cells always diminished the C-antibody level below that observed in non-immunized SV40 virus infected control animals (Table 1). Lyophilized SV40 tumour cells, non-irradiated hamster foetal cells, or adult human cells failed to induce either immunity to SV40 tumour cell challenge or to interrupt SV40 oncogenesis. Fifty per cent protection against SV40 tumour induction was observed among hamsters immunized with irradiated human embryo kidney cells, and 62% protection was afforded by immunization of adult hamsters with SV40 (Fig. 1). Irradiated SV40 tumour cells gave complete protection. We have previously demonstrated that irradiated hamster foetal cells protect male hamsters against SV40 tumorigenesis[2].

Table 1 Potentiation of Diminution of Cytostatic Antibody Level to SV40 Hamster Tumour Cells using Human Foetal Cells as Immunogen in SV40-Infected Male Hamsters

Neonatal inoculation *	Immunogen †	Average No. of viable cells/ chamber‡	Inhibition§ (%)
Passage control fluid	None	626,000	Control

SV40	Adult human kidney cells	476,400	23
SV40	Primary human embryonic kidney cells	309,700	51
SV40	Lyophilized F5–1 (5,000 r.)	594,700	5
SV40	10 day hamster foetus (5,000 r.)	344,400	45
SV40	10 day hamster foetus (0 r.)	565,800	10

* Newborn hamsters were infected with SV40 within 24 h after birth or given noninfected cell culture control fluid.

† SV40 or irradiated cells (5,000 r.) administered intraperitoneally at 3 weeks of age, weekly for 3 weeks.

‡ Fifteen chambers originally inoculated with 18,000 viable SV40 tumour cells, implanted in immunized 56 day old hamsters for 5 days, and enumerated by trypan blue exclusion test.

§ Percentage inhibition of SV40 target cell growth in chambers observed between immunized control animals. All values given were significantly different from control at 1% confidence level as determined by Wilcoxon test.

The results show that injection of control tissues, lyophilized SV40 tumour cells, or non-irradiated hamster embryo tissues diminishes detectable levels of circulating antibody to the SV40 tumour target cells in the diffusion chambers. In contrast, human foetal cells and irradiated hamster foetal cells increase the level of circulating C-antibody, supporting the view that SV40-induced TSTA is the result of the retrogenic expression of a foetal or embryonic antigen gene.

Research was conducted under the joint NIH-AEC Molecular Anatomy (MAN) Program supported by the National Cancer Institute, the National Institute of General Medical Sciences, the National Institute of Allergy and Infectious Diseases, and the US Atomic Energy Commission.

Correlation between Humoral Antibody and Regression of Tumours induced by Feline Sarcoma Virus

Feline sarcoma virus (FSV) induces malignant tumours in cats[1–4], dogs[1,2,4], rabbits[1,4] and monkeys[4,5], and transforms cultured cells from several species including man[6,7]. Spontaneous regression of tumours induced by FSV has been reported[3]. We describe here a correlation between the presence of humoral antibodies to virus-associated cell membrane antigens and the failure of cats injected with FSV to develop progressive malignant tumours.

An indirect membrane immunofluorescence technique similar to that described for the detection of membrane antigens in murine leukaemia cells was used[8]. A lymphoblastoid cell culture derived from a feline leukaemia virus (FeLV)-induced tumour provided target cells. The derivation and maintenance of this culture, which produces FeLV in a steady state manner, has been described before[9]. Fluorescein-conjugated antiserum to cat IgG prepared in a goat (obtained from Dr Robert Holdenreid, National Cancer Institute, Bethesda), or rabbit (obtained from Dr Edwin Lennette, California State Department of Public Health, Berkeley) was used at a 1 : 20 dilution.

Bright and dense sectorial or ring fluorescence was observed in 90–100% of the cells at serum dilutions up to 1 : 128 with serum from certain regressor cats (Fig. 1). Two-fold dilutions of each serum sample were prepared, and fifty cells were examined at each dilution until fluorescence was no longer observed. The serum dilution at which the number of fluorescing cells had decreased to 50–75% usually was the same dilution at which punctate rather than ring or sectorial fluorescence was observed. We decided to designate end-point titres as the reciprocal of the highest dilution where 50% or more of the cells had distinct spots of fluorescence. The negative serum samples caused no such fluorescence even when undiluted. All samples were coded and read blind.

Serum samples were taken from cats before the injection of FSV and between 3 and 7 weeks later. Cats with progressive tumours usually died within 3–5 weeks after FSV inoculation and so later samples could only be obtained from regressor cats or those that failed to develop palpable tumours. Cats which were 0–1, 4, 13, 26, and 52 weeks old received 1.0 g equivalents of FSV prepared as previously described[3]. The inverse relationship between increasing age at the time of FSV injection and the incidence of progressive malignant tumours has been previously observed (S. P. S., manuscript in preparation), and the gross morphology and histopathology of progressive and regressive tumours has been described[3].

A distinct negative correlation was seen between the antibody titre 3–7 weeks after FSV inoculation and the development of progressive tumours (Table 1). Of three cats which were injected with FSV at 1 yr of age, two failed to develop palpable tumours and one developed a tumour which subsequently

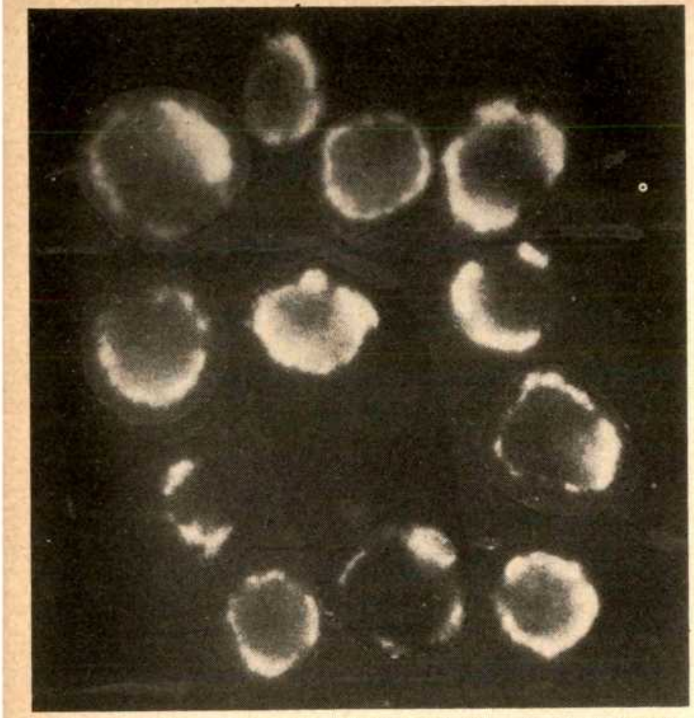

Fig. 1 Feline leukaemia virus-producing lymphoblastoid cells showing ring membrane fluorescence. The cells were exposed to serum (1 : 16 dilution) from a cat with a regressing FSV-induced sarcoma and sarcoma and subsequently to fluorescein labelled goat anti-cat IgG (1 : 20 dilution).

regressed. All three developed antibody titres which ranged from 16 to 256. The only kitten given FSV at 0–1 week of age which manifested tumour regression was also the only one in this age group to develop a significant humoral antibody titre. When all age groups are considered, nine cats developed tumours that were classified as progressive. Of these nine, none developed antibody titres above 2, and five had no demonstrable antibody. Twelve cats either developed no tumour or developed tumours which subsequently regressed. All twelve developed antibody titres of 4 or higher and eight had titres of at least 16 (Tables 1 and 2). Regressor tumours are defined as those which show a visible reduction in size before 7 weeks after FSV injection. Progressor tumours are those which show no visible or palpable regression, and which debilitate the host to the point of death. Kittens with progressive tumours were terminally exsanguinated to obtain serum. The reason for the presence of antibody titres in three of the twenty-one cats before FSV inoculation is not known, but the horizontal transmission of oncornaviruses in laboratory cat colonies has been reported[10], and since these three cats were either 13 or 26 weeks old at the time of testing, it is possible that they had been exposed to either FSV or FeLV.

Table 1 Titres of Antibody Detected by Indirect Immunofluorescence in Serum Samples from Cats of Different Ages Inoculated with FSV

Cat No.	Age in weeks*	Antibody titres-weeks† 0	3	4	5	7	Type of tumour response‡
1	52	0	128			128	regressor
2	52	0	4			128	no tumour
3	52	0	0			16	no tumour
4	26	0	16				regressor
5	26	16	64				regressor
6	26	0	2				progressor
7	26	0	32				regressor
8	13	0		0			progressor
9	13	8		64	256	256	regressor
10	13	0		2			progressor
11	13	8		8	32	16	regressor
12	13	0		0			progressor
13	13	0		1			progressor
14	4	0	4				regressor
15	4	0	4				regressor
16	4	0	4				regressor
17	0–1	0	0				progressor
18	0–1	0	1				progressor
19	0–1	0	4				regressor
20	0–1	0	0				progressor
21	0–1	0	0				progressor

* Age at time of FSV inoculation.

† Weeks following FSV inoculation.

‡ See text for definition of regressor and progressor.

Table 2 Summary of Antibody Response of Cats of All Ages According to Tumour Response and Antibody Titres

Type of tumour response	No. of cats with titres of 4 or over	No. of cats with titres under 4
No tumour	2	0
Regressors	10	0
Progressors	0	9
Total	12	9

The findings reported here clearly demonstrate an association between the development of antibody titres and either tumour regression or the lack of palpable tumour development. They also demonstrate a reaction between antibody associated with injections of FSV and a cell membrane antigen of cells that produce FeLV.

We thank Drs Edwin Lennette and Robert Holdenreid for fluorescein-conjugated antiserum, Harriet Blomquist and Sharon Beall for technical assistance, and Dr Leo Bustad for encouragement and criticism. This work was supported by fellowship awards from the Leukemia Society of America (M. E.) and the American Cancer Society (S. P. S.) as well as general support from the Special Virus-Cancer programme of the National Cancer Institute, the US National Institutes of Health and Public Health Service, the Swedish Cancer Society, the Jane Coffin Child's Memorial Fund for Medical Research, and the Harald and Greta Jeansson Foundation.

Inhibiting Effect of some Antimalarial Substances on Glucose-6-phosphate Dehydrogenase

COMPOUNDS with antimalarial activity are used as therapeutic agents in a number of disorders other than malarial infections. Our dermatological interest in these substances is two-fold. First, they are specific therapeutics for a number of autoimmune disorders with cutaneous manifestations[1] and, second, the use of these substances in malarial therapy or prophylaxis often causes adverse cutaneous side effects[1].

It has been known for some time that individuals with an erythrocytic glucose-6-phosphate dehydrogenase (E.C. 1.1.1.49) deficiency (favism) have an increased resistance to malaria[2]. These individuals also have a high incidence of haemolytic anaemia when given antimalarial drugs prophylactically[2]. These observations suggest that antimalarial drugs inhibit erythrocytic glucose-6-phosphate dehydrogenase (G6PDH) in malaria. Analogously, they may inhibit the G6PDH activity of the reticulo-endothelial system in their capacity as immunosuppressants, and that of the skin in their production of cutaneous manifestations. An essential first test of such an hypothesis is to see if these compounds are capable of such inhibition *in vitro*. We have therefore tested a range of antimalarial substances on purified yeast G6PDH from Sigma and on whole tissue extracts of erythrocytes and skin.

The usual commercial forms of the antimalarial substances were dissolved and filtered before use. Enzyme was assayed at room temperature by following the formation of NADPH fluorimetrically (exitation 340 nm, fluorescence 460 nm), or spectrophotometrically when difficulties from quenching were experienced. The general details of the assay have been described by Halprin and Ohkawara[3]. The reaction mixtures used are given in Table 1.

Table 1 Reaction Mixture for Testing Inhibitors of Glucose-6-phosphate dehydrogenase

	NADP 0.002 M in buffer (ml.)	G6PDH 10^{-3} mg/ml. in buffer (ml.)	Buffer 0.05M Tris (*p*H 7.5) $+5\times10^{-4}$ M EDTA $+0.03$ M $MgCl_2$ (ml.)	Inhibitor 10^{-3} M in buffer (ml.)	G6P (diNa) 0.014 M in buffer (ml.)
1	0.10	0.10	1.60	0.10	0.10
2	0.10	0.10	1.69	0.10	0.10
3	0.10	0.10	1.69	0.10	0.01

Before calculating the results it was observed that the inhibition could be reversed completely in most cases by excess NADP, that is, the inhibition was competitive for NADP. Therefore the following equation was used to calculate the K_I values

$$K_I = \frac{V_I}{V_0 - V_I} \times \frac{Km \quad [I]}{Km + [S]}$$

where V_I is the initial reaction velocity in the presence of the inhibitor, V_0 the initial velocity of the reaction in the absence of inhibitor, $[I]$ the final concentration of inhibitor, Km the Michaelis–Menton constant, K_I the inhibition constant and $[S]$ the concentration of substrate (NADP). This equation was derived by dividing the normal Michaelis–Menton equation by the equation for a competitively inhibited reaction and rearranging to give K_I.

In normal Lineweaver–Burk plots, the Km for glucose-6-phosphate and NADP were found to be 6.9×10^{-5} M and 1.43×10^{-5} M respectively. The enzyme was specific for NADP, which could not be replaced by NAD, and the reaction was inhibited by NADPH. The results of the inhibition studies are shown in Table 2.

Table 2 Inhibition of G6PDH by Antimalarials

Inhibitor	% inhibition at low [NADP]	% inhibition at low [G-6-P]	% inhibition at high [NADP] + [G-6-P]	Approximate K_I	Method used
Paludrine	30	—	—	1.1×10^{-4}	Fluorimetric
Daraprime	36.4	—	—	8×10^{-5}	Fluorimetric
Mepacrine	17.2	—	—	1.8×10^{-3}	Spectrophotometric
Primaquine	28.1	—	—	1.2×10^{-3}	Spectrophotometric
Chloroquine	47.5	—	—	5.14×10^{-4}	Spectrophotometric

The antimalarial compounds also inhibited the G6PDH reaction in skin and erythrocyte extracts to a similar extent. Gold salts were found to inhibit skin G6PDH noncompetitively and streptomycin to inhibit competitively for glucose-6-phosphate. Both of these compounds have a similar therapeutic application and range of side effects as the antimalarials proper[1].

It is interesting to consider the consequences of such an inhibition to the metabolism of the cell. G6PDH is the rate limiting point of entry into the pentose phosphate shunt which is the sole producer of extramitochondrial NADPH and also produces riboses for nucleic acid synthesis. Obviously inhibition of this enzyme and pathway will have far reaching effects, particularly in subjects such as favists who have a reduced G6PDH activity in the first place. It would also be of great interest to know if subjects who experience lichenoid skin eruptions as a side effect of antimalarial therapy have a skin-specific deficiency in this enzyme. We are currently carrying out such investigations.

We thank Professor J. W. H. Mali, Dr P. D. Mier and Dr R. C. A. Sengers for helpful discussions.

Effect of Infection with Trypanosomes on the Development of Experimental Allergic Neuritis in Rabbits

DATA obtained from hospitals in western Nigeria[1] have shown that rheumatoid arthritis is uncommon in that region and, when the disease occurs, it is clinically milder than in Europeans, involving few of the expected immunological changes[2,3]. Other conditions in which auto-immune processes are thought to be involved were also found to be rare, and Greenwood suggested that repeated exposure to parasitic infections might be responsible, at least in part, for the infrequent occurrence of these auto-immune diseases. Infection with the rodent malaria parasite *Plasmodium berghei yoelii* delayed the onset of haemolytic disease in 4 week old NZB mice and prevented the development of renal disease in (NZB×NZW) F_1 mice at the same age[4]. The severity of adjuvant arthritis in rats was also reduced by simultaneous inoculation of *P. berghei yoelii*, which produces a very mild infection, but not by infection with a more virulent strain of *P. berghei berghei*[5]. We are investigating the effects of trypanosome parasites on the development in rabbits of experimental allergic neuritis (EAN), a demyelinating paralytic disease[6], the genesis of which is primarily a cell-mediated type of immune response (manuscript in preparation), and the preliminary results are reported here.

Adult New Zealand white rabbits of both sexes were infected by intraperitoneal inoculation of blood from mice infected with trypanosome parasites; five received *Trypanosoma brucei brucei* (Serial No. LUMP 143) which is maintained as a stabilate[7], and seven received a *T. brucei* parasite (strain S 427 supplied by Dr L. G. Goodwin and now maintained as stabilate LUMP 231). Parasitaemia was estimated by examination of fresh blood preparations by phase contrast microscopy (×40 objective) every 2–3 days. The rabbits infected with *T. b. brucei* LUMP 143 were cured 24 days after inoculation of parasites by treatment with 'Berenil' (10 mg/kg given intramuscularly). Five of the seven animals infected with *T. brucei* S 427 were cured in the same way 59 days after inoculation; the other two developed severe EAN signs and had been killed and autopsied by this time.

Extraneous fat and connective tissue were removed from human sciatic nerve obtained at *post mortem*. The nerve was cut on a freezing microtome and the "brei" produced was homogenized with saline. An equal volume of Freund's complete adjuvant was added and a stable water-in-oil emulsion prepared by further homogenization. 0.2% of phenol was added to the antigen which was stored at −20° C. 0.2 ml. of antigen were injected intradermally into the left hind foot pad of each rabbit. Further details of antigen preparation and injection procedure are given elsewhere[8].

The antigen was injected into nine uninfected rabbits and into the twelve trypanosome-infected animals 19 or 21 days after inoculation of parasites. After the injection of EAN antigen, animals were examined by two observers at 2 day intervals for signs of functional disability. Autopsy was carried out at 55 days after antigen challenge or earlier when necessitated by the onset of severe paralysis. Rabbits were killed by intravenous injection of 'Nembutal'. For preliminary histological survey, dorsal lumbar roots were removed and fixed with osmium tetroxide. Teased preparations were made from these nerves as previously described[8].

Live parasites were seen in all rabbits during the period between inoculation of trypanosomes and injection of EAN antigen. Since the levels of infection at this stage were so low (one to ten trypanosomes per fifty microscope fields), no importance was attached to the apparent length of the latent period; the shortest was 3 days and the longest was 14 days, the average being about 7 days. *T. b. brucei* LUMP 143 infections had reached a level of one to fifteen parasites per microscope field by day 24 and were therefore treated, but *T. brucei* S 427 was less virulent.

EAN signs were assessed on a three point scale. Early and mild cases (denoted by +) showed features such as weakness of hind limb(s), poor "displacement reflex", some ataxia, some sliding of fore limbs and poor "withdrawal reflex".

In later stages (+ +) these features became more pronounced and more frequent. Severe cases (+ + +) showed additional signs such as extended flaccid limbs, great difficulty in walking, flailing of limbs, total limb paralysis, incontinence, loss of appetite and weight and laboured breathing (for more details of EAN signs see Allt, Evans and Evans[8]).

In the "EAN+trypanosomiasis" group (twelve rabbits) seven animals were alive 55 days after EAN antigen challenge. Five of these had shown no overt EAN signs. Of the "EAN alone" group (nine rabbits) only one remained alive at 55 days after injection of EAN antigen, and it had previously shown unambiguous EAN signs. The remaining rabbits of this group developed marked (+ +) or severe (+ + +) EAN signs and had to be killed (Table 1).

Spinal roots are especially vulnerable to demyelination in EAN and lumbar dorsal roots were chosen for preliminary

Table 1 EAN Signs (Severity, Duration, Onset) and Histopathology

* Rabbits showing (*a*) severe paralysis (+ + +), (*b*) marked paralysis (+ +), together with respiratory difficulty, were killed.

† Difference in survival between the two groups is significant, that is, greater than two standard errors (s.e. 0.22) or $P<0.05$.

‡ Four point scale for extent of demyelination/remyelination derived from teased preparations: + + +, "extensive"; + +, "moderate"; +, "occasional"; t, "trace".

§ See text for grading of EAN signs.

examination. Teased preparations of osmicated nerves from paralysed rabbits revealed focal, segmental myelin loss characteristic of EAN. Various stages of myelin breakdown could be observed, ranging from the replacement of a part of an internode by several large myelin ovoids, through many droplets of myelin, to totally denuded axon segments[8]. Remyelination, in the form of short, intercalated internodes, was evident in animals which had recovered from EAN. Unlike the adjacent undamaged myelin, such internodes had thin myelin sheaths.

Table 1 correlates the severity of EAN signs and the extent of histological changes. Generally, the greater the paralysis and ataxia the more extensive the demyelination. Occasionally marked paralysis was accompanied by only sparse demyelination. The explanation for this may be either: (*a*) inadequate histological sampling, or (*b*) that demyelination is not the only important histopathological effect. Comparisons of the time of onset and the duration of EAN in control rabbits and in those trypanosome-infected animals which were affected showed no significant differences between the two groups.

In this series of experiments, all the control animals developed unequivocal signs of the disease whereas a significantly smaller number of the trypanosome-infected animals did so. It seems probable therefore that the presence of the parasite caused a marked suppression of EAN. We cannot say at present what the mechanism of this suppression is but it might have an immunological basis since EAN induction is primarily a cell-mediated immune response (manuscript in preparation). The effects of trypanosome infections on such responses have not to our knowledge been investigated, but Goodwin *et al.*[9] have examined the antibody response to sheep erythrocytes in mice and rabbits infected with *T. brucei*. There was a pronounced depression of the anti-sheep red blood cell response in the infected mice and immunodepression was also demonstrable in some of the trypanosome-infected rabbits. The response in other rabbits was very difficult to interpret, however, because of the appearance during the infection of heterophile antibody which reacted with antigen of the sheep erythrocytes (Goodwin and Voller, personal communication). They suggested that the presence of the trypanosomes seemed to make it difficult for the rabbit to produce antibody to "large" antigens which may require to be processed by macrophages before antibody forming cells can be stimulated.

It is interesting that the trypanosome infection suppressed EAN in some of our rabbits but was ineffective in others in terms of the time of onset and duration of EAN symptoms and the histological reactions. These variations in response to EAN were not related to the strain of parasite used and could not be correlated with any observed feature of the trypanosome infections. Thus suppression was not obviously related to the overall level of parasitaemia or to "peaks" of infection such that the results might be explained in terms of antigenic competition due to the number of parasites present. It is important to remember that the trypanosome is a tissue parasite[10] and that there are likely to be many more trypanosomes in the extravascular spaces than in the peripheral circulation. We are investigating the effect of varying the time of parasite infection in relation to antigen injection on the subsequent development of EAN.

^{13}C NMR Spectra of Lecithin Vesicles and Erythrocyte Membranes

UNLIKE proton nuclear magnetic resonance (NMR) spectroscopy, ^{13}C NMR has the potential advantages in studies of macromolecular systems of a wider range of chemical shifts ($\sim$200 p.p.m.) and of reduced resonance broadening in structures with restricted molecular motion. Thus we have been able to observe ^{13}C NMR spectra of unsonicated lecithin and erythrocytes, which do not yield high resolution proton spectra. We also report T_1 relaxation times for ^{13}C nuclei in the polar headgroup of the lecithin molecule and at both ends of the alkyl chains, in sonicated vesicles in D_2O buffer and in deuterochloroform. The results are consistent with increasing chain motion towards the terminal methyl group of the alkyl chains for both systems, in agreement with relaxation data for stearic acid derivatives specifically labelled with ^{19}F nuclei in lecithin vesicles[1], and with the results of similar spin label experiments of Hubbell and McConnell[2].

Dipalmitoyl lecithin was obtained from Koch Light, and human erythrocyte membranes were prepared as described previously[3]. Lecithin (230 mM) was sonicated in D_2O buffer containing 45 mM NaCl, 30 mM Na acetate and 5 mM Na phosphates (pH 7.4) in glass vials under nitrogen at 50° C until translucent, and transferred into 12 mm NMR tubes under nitrogen. The ^{13}C NMR spectra were obtained by the Fourier transform technique[4] on a Varian XL 100–15 spectrometer at 25.1 MHz locked onto deuterium in the solvent (D_2O or $CDCl_3$), and accumulated in a Varian 620i computer. Chemical shifts were corrected to a dioxan internal reference. A pulse method similar to that of Vold *et al.*[5] (π–t–$\pi/2$ pulse sequence) and modified by Freeman and Hill (private communication) was used to measure T_1 relaxation times, where t is the delay in seconds between the π and $\pi/2$ pulses. The T_1 measurements were made on lecithin in D_2O buffer thoroughly deoxygenated with nitrogen, and $CDCl_3$ degassed by repeated freeze–pump–thaw cycles. Proton NMR spectra were obtained on a Varian HA100–15 spectrometer.

The ^{13}C spectra of dipalmitoyl lecithin dissolved in $CDCl_3$ and a fully sonicated sample in D_2O buffer are shown in Fig. 1 *a*, *b*. The alkyl chain carbons were assigned by analogy with the published spectra of fatty acids[6], and the other resonances by comparison with the spectra of the model compounds choline, choline glycerol phosphate, and phosphatidic acid. All the resonances in both systems are relatively sharp and even the signals from the alkyl chain carbons remain well resolved in the vesicle bilayers. This enabled T_1 measurements to be made on most of the observable nuclei in the molecule and the results are shown in Table 1; values shorter than 0.1 s were inaccessible in the present experiments. In both systems T_1 increases along the alkyl chains towards the terminal methyl

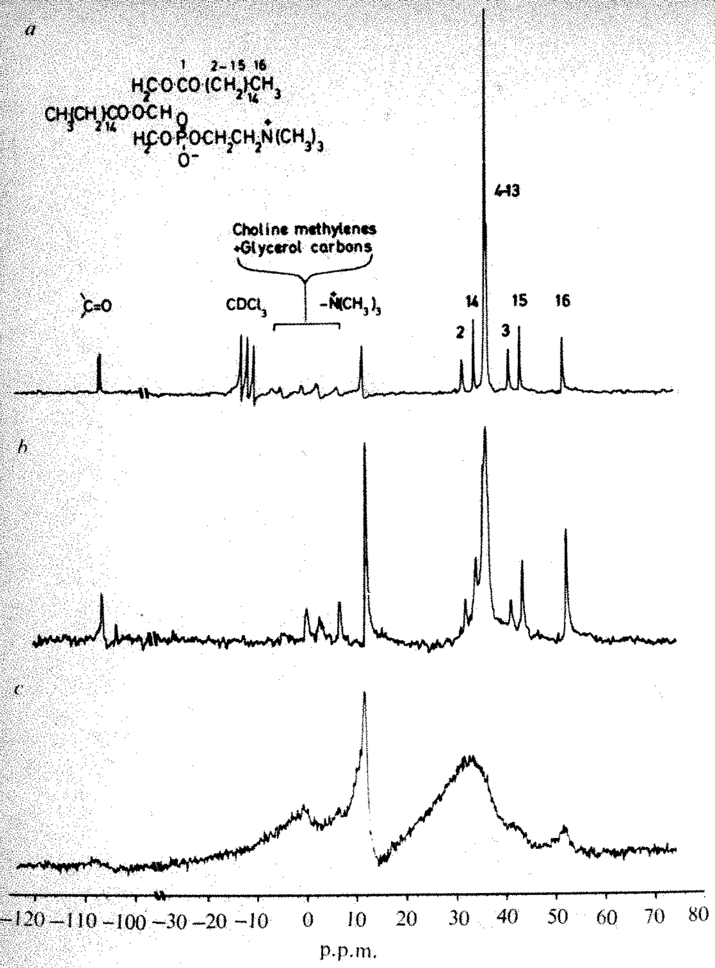

Fig. 1 The ^{13}C NMR spectra of dipalmitoyl lecithin. *a*, 290 mM lecithin in $CDCl_3$ at 28° C. Shifts are corrected to an internal dioxan reference of zero p.p.m. *b*, Fully sonicated and *c*, unsonicated lecithin (230 mM) in D_2O buffer at 52° C. (The unsonicated sample also contained 26 mM palmitic acid to prevent coagulation of the suspension; the palmitic acid did not affect the spectrum of the same sample in the sonicated state.)

group although there are significant differences in the gradation of the changes. A striking difference between the two systems is the very short T_1 value for the $\overset{+}{N}-(CH_3)_3$ carbon nuclei relative to the $(CH_2)_n$ resonance envelope in $CDCl_3$. The spectra after delays of 0.1 and 1.0 s between the π and $\pi/2$ pulses show this difference clearly in Fig. 2, in which the $-\overset{+}{N}(CH_3)_3$ resonance has almost disappeared in $CDCl_3$ after 0.1 s but is still relatively large compared with the $(CH_2)_n$ resonance in the D_2O buffer. We suggest that the short T_1 for the $-N(CH_3)_3$ nuclei in $CDCl_3$ may be due to the formation of a micellar structure with the polar headgroups restricted in motion by being at the centre of the micelle with the alkyl chains exposed to the $CDCl_3$ solvent. In contrast, in the bilayer structure formed in water where the headgroups are exposed to the D_2O solvent, we expect relatively free motion of the $-N(CH_3)_3$ group and a longer T_1 value. In both systems we attribute the changes in T_1 along the alkyl chain to increasing chain motion towards the terminal methyl group. By appropriate substitution in the alkyl chain of stearic acid, for example, with a single fluorine atom, or by the introduction of a double bond, at least twelve of the eighteen carbon nuclei can be resolved. Some of these extra resonances are resolved in egg lecithin containing unsaturated chains. Relaxation measurements on synthetic lecithins incorporating substituted and unsaturated fatty acids will be reported elsewhere.

Fig. 1*c* shows the ^{13}C spectrum of unsonicated lecithin in which both the $-N(CH_3)_3$ and terminal methyl resonances remain relatively narrow in contrast to the main methylene envelope which is broadened approximately eight-fold. In

Table 1 T_1 Relaxation Times of Carbon Nuclei in Dipalmitoyl Lecithin in D_2O and $CDCl_3$

Carbon	T_1 (s) D_2O (52° C)	T_1 (s) $CDCl_3$ (28° C)
2	0.10	0.19
3	0.52	0.28
4–13	0.55	1.04
14	1.14	2.20
15	1.76	2.65
16	3.34	2.88
$-\overset{+}{N}(CH_3)_3$	0.57	0.19

Palmitic acid carbons are numbered from the carboxyl group (1) to the terminal methyl (16).

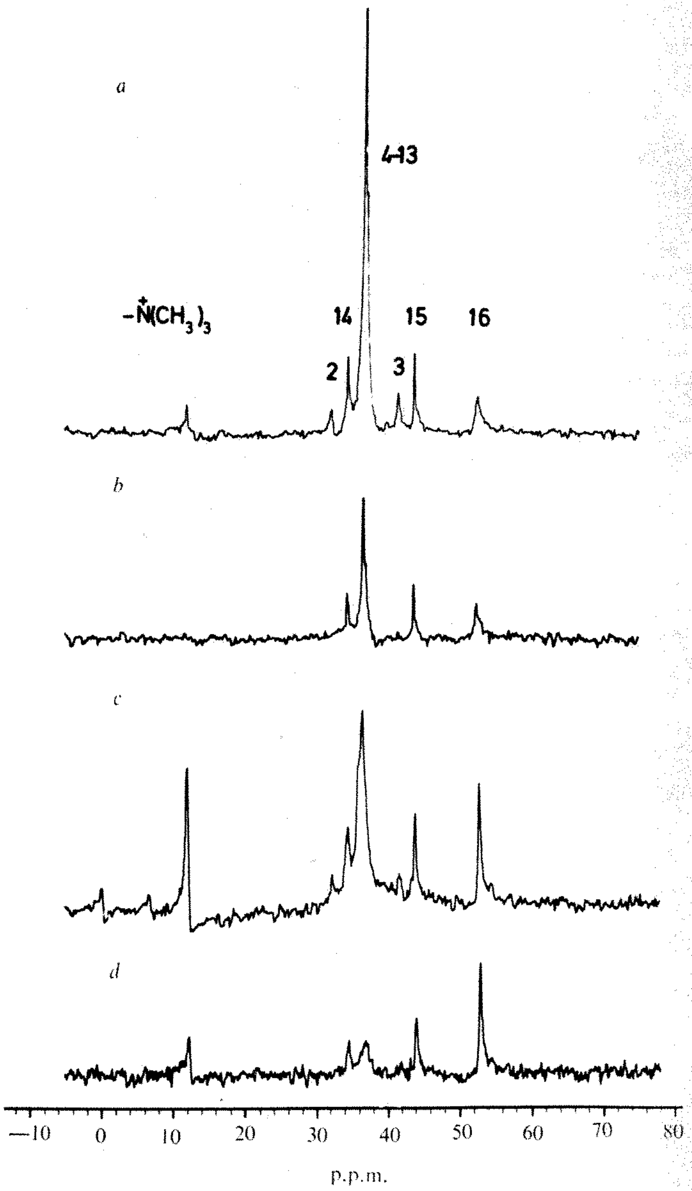

Fig. 2 The ^{13}C NMR spectra of dipalmitoyl lecithin with a pulse sequence $(\pi - t - \pi/2 - t_1 - \pi/2)$ where t is the delay between π and $\pi/2$ pulses and t_1 is a long delay (~20 s): the observed signal is the difference between the signals resulting from the $\pi/2$ pulses. With this pulse sequence, the shorter the T_1 value for a nucleus, the faster the decrease in amplitude of its resonance as t increases. 290 mM lecithin in $CDCl_3$ at 28° C: *a*, $t=0.1$ s; *b*, $t=1.0$ s. 230 mM lecithin in D_2O buffer at 52° C: *c*, $t=0.1$ s; *d*, $t=1.0$ s. Note the very short T_1 of the $-\overset{+}{N}(CH_3)_3$ resonance relative to the $(CH_2)_n$ resonance in $CDCl_3$, compared with the similar T_1 values of these two resonances in D_2O buffer (see also Table 1).

spite of this, the methylene carbons at the terminal methyl end of the chains can be detected superimposed on the main envelope. Preliminary experiments suggest that the main envelope is broadened mainly by chemical shift differences rather than by any major differences in T_1 values for the same carbon nuclei in the sonicated and unsonicated states. No high resolution proton NMR spectrum could be obtained from the same unsonicated sample.

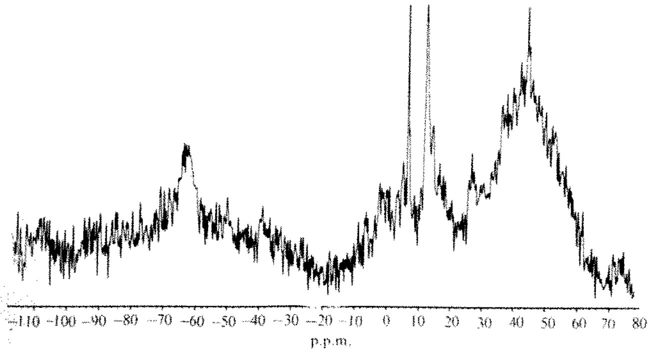

Fig. 3 The ^{13}C NMR spectrum of human erythrocyte membranes (10% w/w) in D_2O buffer at 28° C. The relatively sharp resonance at higher field (13 p.p.m.) is tentatively assigned to the $-\overset{+}{N}(CH_3)_3$ carbons of lecithin in the membrane; the sharp resonance at lower field (~7 p.p.m.) is possibly due to Trisious bound during the preparation of the membranes.

The observation of a spectrum from unsonicated lecithin suggested that biological membranes might yield ^{13}C spectra without sonication. The spectrum of 10% erythrocyte membranes in D_2O buffer at 28° C showed several broad envelopes of resonances, although the membrane suspension was extremely glutinous (Fig. 3). We will determine whether the broad envelopes of resonances result from many chemically shifted signals rather than from very short relaxation times, by selective ^{13}C enrichment of lipids biosynthetically incorporated into the membrane. If sharp resonances can be obtained from identified membrane components then ^{13}C NMR will provide detailed structural information about the membrane.

Release of Calcitonin from Thyroid Granules

THYROID parafollicular cells contain calcitonin in a granular form. Reduction in numbers of granules and vesicles occurs during induced calcitonin secretion *in vivo*[1], and from thyroid slices[2]. Particulate fractions with the biological activity of calcitonin have been derived from homogenates of pig, calf and rat thyroid glands[3,4]. We have prepared calcitonin containing particulate fractions from pig thyroid and have studied the properties of the isolated granules.

Sub-cellular fractions were prepared from pig thyroid glands by a modification of the method of Bauer and Teitelbaum[4]. Fresh glands were homogenized in 0.25 M sucrose with no additives. The effluent from the celite column was recentrifuged at 100,000*g* for 1 h, omitting the sucrose density gradient centrifugation, and was resuspended in barbital buffered saline (*p*H 7.2) containing 5 mg/ml. of bovine serum albumin. Calcitonin concentration was measured by radioimmunoassay. Tracer was prepared from synthetic porcine calcitonin and it was incubated with a guinea-pig antiporcine calcitonin serum prepared in this laboratory, at a final concentration of 1 : 15,000. The assay detects 50 pg of calcitonin in the 0.5 ml. incubation volume. Recoveries of calcitonin added to the granule fractions were 94–102%. Inhibition of binding by the fractions was parallel to the inhibition by standard, and there was close correlation between bioassay and immunoassay. The sub-cellular fractions were examined morphologically and biochemically. Granule fractions were comprised of dense granules and vesicles 50–200 nm diameter, some endoplasmic reticulum, ribosomes and occasional mitochondria. Beta glucuronidase[5] and malic dehydrogenase[6] concentrations relative to calcitonin were respectively 4.2 and 8.1 in the homogenate and 6.5 and 1.5 in the granule fractions.

Supernatant was separated from particulate calcitonin by centrifuging 1 ml. samples of the granule fraction at 0.8×10^6 g min. Greater centrifugal forces produced no further decrease in supernatant calcitonin concentration. Total and supernatant calcitonin were assayed in duplicate at two dilutions, and the fraction in particulate and supernatant pools was calculated.

Calcitonin was released into the supernatant with sonication, repeated freezing/thawing and with alterations of *p*H to 4.2 and 8.6 (Table 1). Filtration of granule suspensions through a 1.2 µm sartorius membrane filter did not remove particulate calcitonin. No spontaneous release of calcitonin into the supernatant occurred over 24 h at 0° C and 22° C, but at 37° C there was some release. This was not modified by the inclusion of 50 mM potassium chloride, 5 mM magnesium chloride, 5 mM calcium chloride or dibutyrylcyclic 3′5′ AMP in the incubates (Table 2).

Table 1 Calcitonin (%) in Supernatant after Various Stresses

Stress	Before	After
Sonication	33	85
Sonication	28	78
Freezing/thawing	19	48
Freezing/thawing	46	71
*p*H 3.5	46	69
*p*H 8.5	22	70

These results are consistent with the report that sonication increases calcitonin biological activity in particulate fractions of pig thyroid[4]. Freezing/thawing releases catecholamines from nerve storage granules[7], alteration of *p*H releases catecholamines from adrenal[8] and nerve granules[7], and granules containing catecholamine are heat labile at physiological temperatures[7,8]. Calcium and dibutyrylcyclic 3′5′ AMP which release porcine calcitonin *in vivo*[9,10] and from thyroid

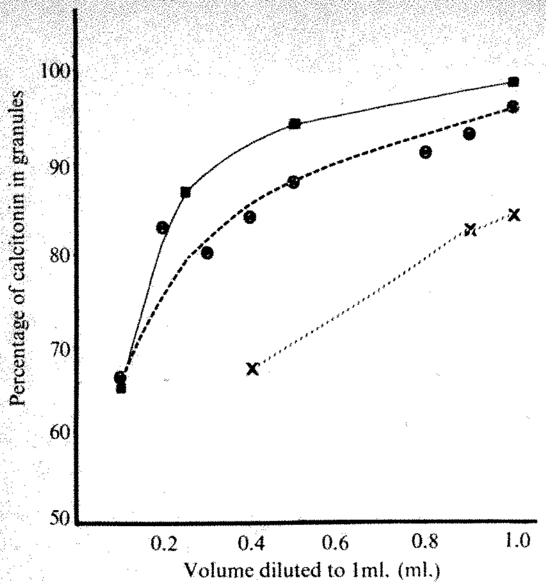

Fig. 1 Increasing volumes of granule suspension in buffer (0.025 M barbital, *p*H 7.2, 0.1 M saline, 5 mg % bovine serum albumin) were diluted in this buffer and incubated for 15 min at 4° C before separation of sedimentable from supernatant calcitonin. The percentage of calcitonin in the sedimentable fraction is shown as a function of dilution in three separate experiments.

slices[11] did not affect release from isolated granules; calcium has been shown to induce release of catecholamines from adrenal medullary granules in some electrolyte media[12].

As the granule suspensions were diluted in isotonic buffer release of calcitonin occurred (Fig. 1). For a ten-fold range of dilution, the percentage of particle-bound calcitonin decreased from 90–95% to 20–30%. This release was independent of bovine serum albumin concentration in the buffer over the range of 0.5–10 mg/ml.

Release of hormone on dilution in isotonic buffer occurs from histamine containing granules of mast cells[13] and adrenal chromaffin granules in the presence of calcium[14].

Table 2 Calcitonin (%) in Supernatant in Buffer with and without Addition of Ions and Dibutyrylcyclic 3′5′ AMP

	0	1 h
Control	22	41
Calcium 5 mM	22	28
Magnesium 5 mM	29	42
Control	48	62
Calcium 5 mM Potassium 50 mM	38	46
Calcium 5 mM Magnesium 5 mM	41	50
Calcium 5 mM Magnesium 5 mM Potassium 50 mM	36	64
Control	20	50
Dibutyrylcyclic 3′ 5′ AMP 0.2 mM	19	31
Dibutyrylcyclic 3′ 5′ AMP 0.2 mM Calcium 5 mM Magnesium 5 mM	—	46

Medium consisted of 0.025 M barbital, *p*H 7.2, 0.1 M saline, 5 mg % bovine serum albumin.

Release of calcitonin on dilution in isotonic buffer is consistent with the intra-cellular release of hormone from storage granules that von Euler has proposed for chromaffin granules[15]. Calcitonin release may be mediated at the cell membrane and intra-cellular stores repleted from the storage granules as the intracellular concentration falls.

Significance of Surface Potential Measurements on Lipid Monolayers during Action of Phospholipase A on Lecithins

STUDIES on the action of enzymes on lipids and proteins of model membranes are aimed at identifying the relative position and orientation of the hydrophilic groups of the various membrane constituents[1,2] so that models of the molecular organization and surface topography of membrane structures can be built.

Following discovery[3] of the action of phospholipase A on films made of egg lecithin, Colacicco and Rapport described the phospholipase A action of two snake venoms on monolayers of two lecithins: phosphatidyl choline from egg and from beef heart[4]. The disappearance of lecithin and the appearance of lysolecithin in the film resulting from the action of phospholipase A are revealed by a decrease of surface potential: at neutral *p*H, the presence of fatty acid has little effect on the magnitude of the surface potential of lysolecithin[4]. It has been assumed[1-4] that the fall in surface potential is proportional to the number of lecithin molecules transformed into lysolecithin, provided that the reaction products remain in the film. This is supported by two observations[4,5]: first, thin-layer chromatography of film material showed that most of the lysolecithin was in the film; second, in conditions in which low protein concentrations (0.1 μg/ml. *Naja naja* venom) would not interfere with surface pressure and surface potential measurements, loss of reaction products would be accompanied by a considerable decrease in film pressure, which, however, was not seen[4,5]. In contrast, when *Naja naja* venom (3.6 μg/ml.) was injected under high pressure films of ^{32}P-labelled yeast lecithin, surface radioactivity was lost rapidly and more than 80% lysolecithin was found in the subphase, and Dawson argued[6] that the reaction products left the film. This has thrown doubt on the assumption of Colacicco and Rapport[7].

The conflict is traceable to basic differences in experimental conditions. Colacicco and Rapport used egg lecithin, the lysolecithin in which remains in the film at low pressure[4,5]. Dawson used yeast lecithin[6], the lysolecithin in which leaves the film readily at high pressures (near 30 dynes/cm). Some of the differences are examined here, and the surface potential measurement is shown to be an accurate method for determining the kinetics of the phospholipase A action on lecithin monolayers.

Yeast lecithin was obtained from Dr M. M. Rapport[8]. Dipalmitoyl lecithin and dimyristoyl lecithin were purchased respectively from Mann Research Laboratories, New York, and LaMotte Chemical Laboratories, Chestertown, Maryland. Preparations of egg lecithin and hydrogenated egg lecithin have already been described[2]. Before use, lipids were purified by column chromatography on 'Unisil', from which the lecithins were eluted with chloroform–methanol mixtures. Fractions which were homogenous by thin-layer chromatography and gave a satisfactory analysis for phosphorus and esters were used[9]. Chain length and unsaturation of the egg lecithin and yeast lecithin used are known[10]. The technique for bringing lecithin and enzyme into contact has already been described; the rectangular trough was used[4]. The lecithin monolayer was spread at zero pressure on 0.04 M phosphate buffer, containing 58 μM CaCl$_2$ (*p*H 7.0) 25° C, and 0.2 μg/ml. *Naja naja* venom. The film was compressed rapidly (10 s) to the desired film pressure, and the changes in film pressure and surface potential were monitored as a function of time. Details of these and other techniques have been described[1,2,4]. Surface pressure was determined by the Wilhelmy method; surface potential was measured with the use of a radioactive (^{226}Ra) air electrode[4]. Unless it is otherwise specified, the rate of fall of surface potential is identified with the rate of hydrolysis of lecithin. The identity was established by the concomitant measurement of the relative quantities of substrate and product in collected lipid films[4].

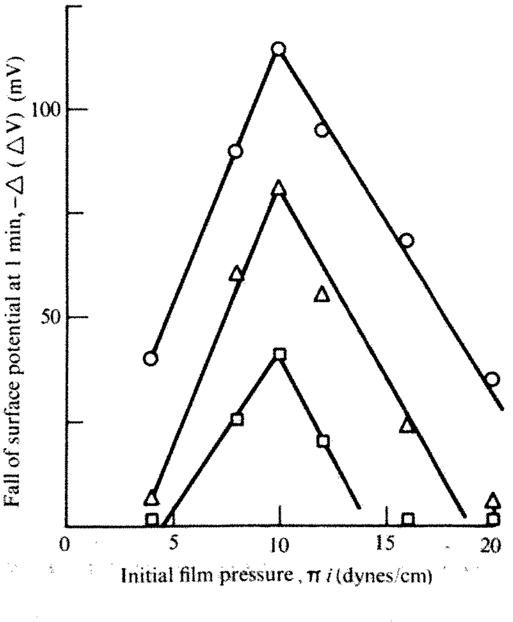

Fig. 1 Influence of initial pressure of lecithin film on decrease of surface potential, $-\Delta(\Delta V) \equiv$ hydrolysis, caused by action of phospholipase A in first minute. ○, Yeast lecithin; △, dimyristoyl lecithin; □, dipalmitoyl lecithin. Egg lecithin and hydrogenated egg lecithin are not shown: the curve of the first, with an optimum of 12 dynes/cm, was between the curves of yeast and dimyristoyl lecithins; the curve for the second was below that of dipalmitoyl lecithin. Temperature, 25° C.

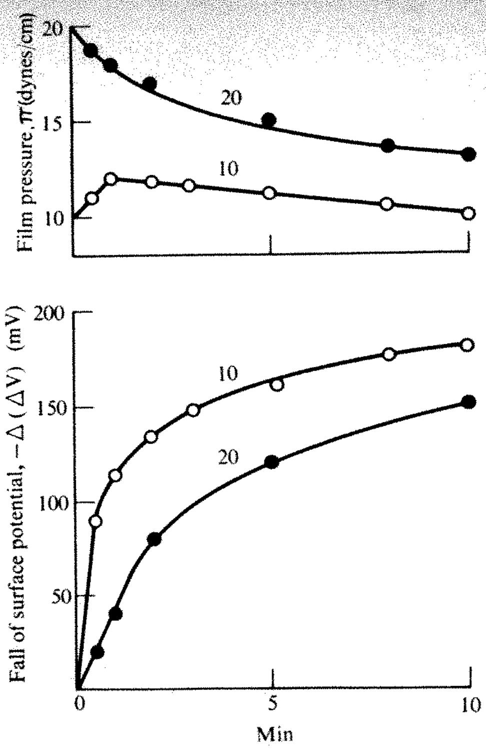

Fig. 2 Pressure-time (upper) and Δ(ΔV)-time curves during the action of *Naja naja* venom on monolayers of yeast lecithin at two initial film pressures: 10 dynes/cm and 20 dynes/cm. The temperature was 25° C.

Decrease of surface potential, $-\Delta(\Delta V)$, in the first minute is related to the initial pressure of the lipid film (Fig. 1). The data show unequivocally, first, that all three lecithins—yeast, dimyristoyl and dipalmitoyl—displayed an optimal reaction at a film pressure of 10 dynes/cm; second, that with a given chain length (C$_{16}$), phospholipase A action is favoured by unsaturation (hydrolysis of monounsaturated yeast lecithin, which consists predominantly of dipalmitoleyl lecithin[10], is markedly faster than that of fully saturated dipalmitoyl lecithin); and third, that of two saturated lecithins the one with shorter chains (dimyristoyl) is attacked more rapidly than the one with longer chain (dipalmitoyl).

The question of the conditions in which lysolecithin leaves the film is illustrated in Fig. 2 by the kinetic curves of the lipase action on monolayers of yeast lecithin. At the optimal film pressure of 10 dynes/cm, most of the lysolecithin remains in the film in the first 10 min as indicated by the little change in film pressure. Thin layer chromatography of films collected on a platinum guaze[4] confirmed that 95% of lecithin was hydrolysed and more than 90% of it was in the film. At moderate film pressures, therefore, yeast lysolecithin does not leave the interface. But when the monolayer of yeast lecithin had an initial pressure of 20 dynes/cm, loss of film pressure and escape of lysolecithin from the film are so rapid that measurements of surface potentials past 2 or 3 min have to be regarded only as qualitative. Thin-layer chromatography of materials in the film and in the aqueous phase indicated that after 10 min only 70% of lecithin was hydrolysed and about 60% of it was in the hypophase. The rapid loss of pressure following the action of the venom on high pressure films of unsaturated lecithin is consistent with the pressure-time curves reported by Shah and Schulman in the action of *Naja naja* venom (0.05 μg/ml.) on monolayers of highly unsaturated soybean lecithin[5].

The ejection of lysolecithin from the film is far from quantitative, so that the measurement of surface radioactivity loss is inadequate for the description of enzyme kinetics; it is restricted to the high pressure films and highly unsaturated and very short chain lecithins (Fig. 2 and ref. 5). We therefore conclude that surface potential is the only method which

Pure Chemistry Library

reveals instantaneously the transformation of lecithin into lysolecithin. Even in conditions in which lysolecithin is ejected from the film, the initial rate of fall of surface potential (for example in the first minute) truly reflects the enzyme kinetics. Concurrent determination of the reaction products either by surface radioactivity measurements and better by thin-layer chromatography and/or scintillation counting of aliquots from the hypophase[2] really establishes the validity of surface potential measurements. In contrast, measurement of surface radioactivity at low film pressure is useless if lysolecithin does not leave the film, and so also at high pressure in the known cases in which ejection of lysolecithin is not quantitative[4-6].

Systematic studies can shed some light on the structural requirements of the lipid for hydrolysis of film lecithin by phospholipase A (as in Fig. 1) and ejection of lysolecithins, and in turn help to define the film pressure of biological membranes. Because the criteria used are not rigorous, the arguments in favour of low film pressure[11], for example 10 dymes/cm are as valid or liable as the arguments in favour of high film pressure, for example 30 dynes/cm or more[12]. For given unsaturation and chain length of the membrane lecithins, ejection of lysolecithin after action of phospholipase A could become a criterion for establishing the film pressure of biological membranes.

Perceptual Fading of a Stabilized Cortical Image

AN image that is physically fixed on the retina rapidly seems to fade[1], and if the stabilization is good enough it never reappears[2,3]. We have some evidence that this process of fading is not entirely retinal, but is partly central, for we have noticed that an image free to move over the retina, but "stabilized" on the visual cortex, also becomes less distinct.

Neurones of the visual cortex in cat and monkey respond best to line-shaped targets, black or white bars, of a particular orientation and often of a certain width[4,5]. Many of them have quite large receptive fields on the retina and respond to the same sort of image anywhere within them.

There is psychophysical evidence that human visual systems also have this sort of organization, and that the neurones are central[6-10]. So presumably if we look in the middle of a pattern of black and white stripes (a grating), it is "stabilized" in our visual cortex. Within limits, wherever we move our gaze over the pattern, the same set of cortical neurones, specific for the orientation and width of the stripes, should be constantly stimulated. If our cortical cells show the same sort of attenuation of response that many sensory neurones suffer, then the activity aroused by such a pattern should gradually wane.

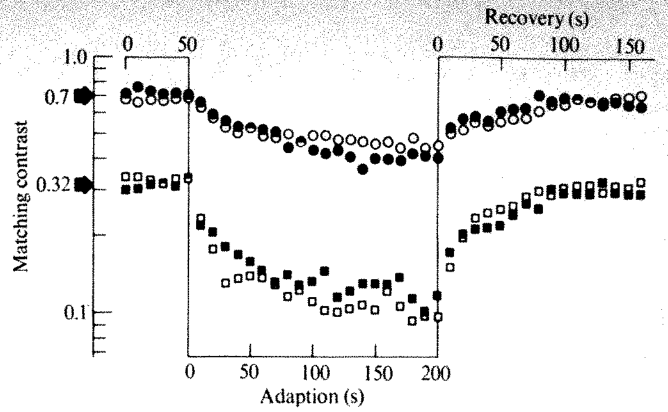

Fig. 1 Every 10 s the subject matched the contrast of the lower grating, shown on the ordinate, to that of the upper. Each symbol, open for one subject, solid for the other, is the mean of four settings made in separate experimental sessions. The average standard error of these means is only about 0.02 log units. For the circles the test grating on the upper screen had a contrast of 0.7, the same as that of the adapting pattern. For the squares the test grating had a contrast of 0.32. Contrast= (I max−I min)/(I max+I min) where I max I min are the maximum and minimum luminances in the grating. ● ■, J. M.; ○ □, C. B.

We have found that as one looks at a grating its apparent contrast declines and the pattern becomes less and less distinct. We arranged two oscilloscope screens, one above the other, each one subtending 4° in width and 3° in height. The gap between them was 24′ and in the middle of it there was a luminous horizontal fixation bar. We generated on the screens vertical dark and light stripes, with sinusoidal luminance profile[11], and the experimenter could alter the spatial frequency (number of cycles of the grating per degree of visual angle) and contrast of the two patterns independently, and turn them on and off without changing their mean luminance, which was 4.8 cd m^{-2} for both screens.

Throughout the experiment the observer held his gaze on the fixation bar and his only task was to turn a logarithmic potentiometer to match the contrast of the pattern on the lower screen to that on the upper one. He pressed a button to print out his contrast setting. Every 10 s a test pattern of 5 cycles/degree appeared and the subject adjusted the contrast of the lower grating to match the upper one as quickly as possible. In between these settings the gratings on both screens were turned off. After the sixth such setting, the lower pattern disappeared but the upper one was replaced by an adapting grating of 5 cycles/degree at a contrast of 0.7. So now the subject was adapting the upper part of his visual field to the grating, while the lower part remained merely light adapted.

Every 10 s the original test grating appeared above and a comparison pattern below. The subject matched the contrasts quickly and the adapting situation was restored for a further 10 s before the next setting. After twenty such settings, with constant adaptation between each, the upper pattern was also extinguished between readings as we followed the time course of recovery.

The open and solid symbols in Fig. 1 show the results for two subjects. The contrast setting on the lower screen is plotted on the ordinate. For the circles, the test grating was identical in contrast (0.7) to the adapting pattern; for the squares the test grating had a contrast of only 0.32. In both

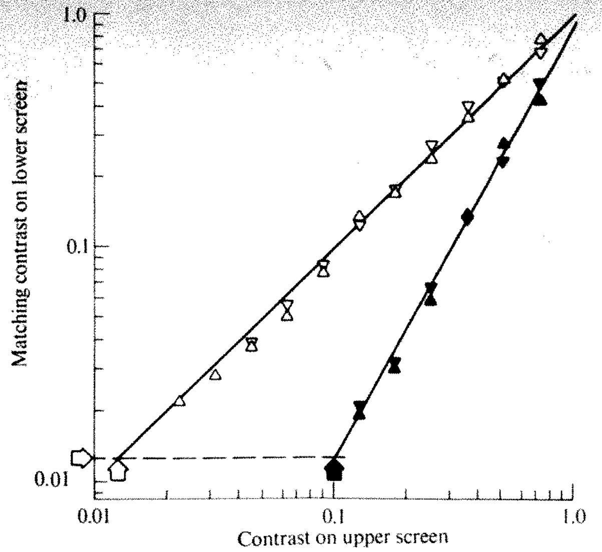

Fig. 2 The subject adapted constantly to a grating of 5 c/degree at a contrast of 0.7 on the upper screen. Every 10 s it was replaced by a test grating the contrast of which was varied from trial to trial. Each solid symbol is the mean of six settings of the contrast on the lower screen. A regression line (method of least squares) is fitted through them. The open symbols show the results for an identical series of contrast matches but with no prior adapting pattern on either screen. These points fit the expected line with a slope of +1. The open arrows indicate the threshold contrast before adapting ($N=6$; subject C. B.) and the solid arrow shows the elevated threshold on the upper screen after adaptation ($N=6$; C. B.). ▽ ▼, J. M.; △ ▲, C. B.

cases there is a clear reduction in apparent contrast, with a time constant of about 30 s, but it is much greater for the lower contrast test grating.

Having seen that adapting to a high contrast grating can cause an apparent reduction in contrast that varies with the contrast of the test pattern, we performed the following experiment. The subject made a series of contrast matches for test gratings of 5 cycles/degree at various contrast levels: in between each setting both screens went blank. In Fig. 2 these unadapted settings are plotted as open symbols for the two subjects. The abscissa and ordinate are the contrasts on the upper and lower screens respectively. Not surprisingly, the open points lie near the expected function with a slope of +1.

Now the subject adapted constantly to a 5 cycles/degree grating at a contrast of 0.7 on the upper screen for 3 min, to allow the adaptation to build up to a maximum (Fig. 1). Then, as before, a test grating appeared on the upper screen with a comparison grating on the lower one and a match was made. At least 10 s of re-adaptation to the 0.7 contrast grating on the upper screen were allowed before the next pair appeared.

The contrast of the test grating was varied from trial to trial and the results are plotted as solid symbols in Fig. 2. Obviously, adapting to a contrast of 0.7 causes a reduction in apparent contrast at all test contrasts, but the magnitude of the effect is greatest at low contrast levels. Open arrows on the abscissa and ordinate mark the threshold contrast level for the stripes to be just distinguishable, before adaptation, and the solid arrow shows the new threshold contrast on the upper screen measured after adaptation. As Blakemore and Campbell described, the threshold is grossly elevated by prior adaptation[10]. Indeed elevation of threshold can be thought of as a special case of reduction in apparent contrast.

Fig. 2 shows an interesting point. Although at every contrast level the apparent contrast is reduced during adaptation, the slope of the function is steeper than +1. So the amplification or gain of the visual system for changes in contrast is actually increased by adaptation, although the absolute signal is smaller at all contrast levels. This increase in gain seems to be the first potentially beneficial consequence of spatial adaptation that anyone has reported. If one looks at a grating, or presumably any other contour-containing pattern, one becomes more sensitive to changes in its contrast, like those effectively produced by fast eye movements, for example.

Finally, we have been able to use this new technique to measure the selectivity of human visual mechanisms for orientation and spatial frequency, at suprathreshold levels. If the adapting grating is replaced, not by a grating of identical orientation and spatial frequency, but by one that is markedly different, then the apparent contrast of the test grating is not reduced. This implies that the adapting and test gratings are handled by different neural channels. We shall be able to define the specificity of these channels and compare them with those revealed by threshold elevation[8-10].

Iridescent Corneas in Fishes

DURING the course of underwater studies of fishes in the English Channel, Mediterranean and Indian Ocean, it was noticed that a coloured iridescent layer was often present on the inner surface of the cornea extending over the pupillary area (Fig. 1). Iridescence has been observed in a variety of animal tissues[1,2] and is caused by regular multilayer structures stacked in a medium of different refractive index. Iridescent tissues already known in fish include the tapetum in which the principal material may be guanine[1] or collagen[3] and the silvery iris and scales of teleost fish where the principal material is guanine[4].

Walls[3] noticed that in a few fishes including the gobies and particularly the Plectognaths (which include the Balistidae and Tetraodontidae) the corneal substantia propria exhibits a complex lamination with histologically peculiar intercalated layers. Iridescence is the rule among the groups Walls mentions and the iridescent layer can be seen by examination of the live fish to be situated at the inner surface of the cornea, so that it is reasonable to assume that the layers in the substantia propria are responsible for iridescence. In addition a similarly placed endothelial layer in the strongly iridescent cornea of the serranid fish *Nemanthias carberryi* possesses regular laminations that could well cause iridescence (personal communication from Locket).

Corneal iridescence has received scant, if any, attention in the scientific literature and should not be confused with the iridescent iris found in many fishes[4]. In the past corneal iridescence may have escaped notice since it is normally only

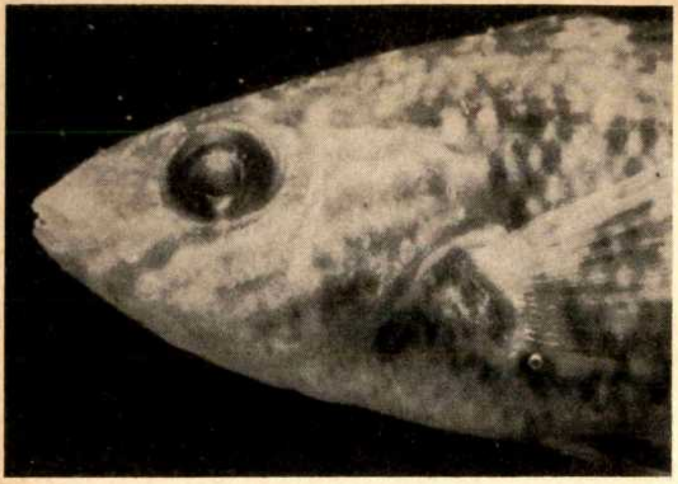

Fig. 1 *Crenilabrus melops* illuminated by electronic flash from above, showing corneal iridescence. The fish is alive, healthy and is in water. The cornea is green in colour, having a maximum reflectance in the region 520–550 nm.

visible when most of the illumination comes from above. This is the case in the natural environment[5] but is less common in aquaria.

Corneal iridescence is common in members of the Tetraodontidae (puffer fishes), Balistidae (trigger fishes), Siganidae (rabbit fish), Scaridae (parrot fish), Gobiidae (gobies) and Labridae (wrasse). It has also been observed in the Cottidae and Serranidae. The colour varies from an unsaturated red in *Epinephelus merra* through yellow–green (*Arothron citrinella*) to a saturated blue–green (*Cottus bubalis*). There is, however, no obvious correlation between the colour of the iridescence and the colour of the water in which the fish lives.

Fishes with iridescent corneas often, but not always, possess yellow filters[6] at some point in the optical pathway. Thus of the fishes with iridescent corneas mentioned here, ***Arothron citrinella*, *Crenilabrus melops*, *Cottus bubalis*** and ***Balistapus undulatus*** have yellow corneas; *Xanothon bipallidus* and *Callyodon viridifucatus* have yellow lenses. No yellow coloration has been observed in the lens or cornea of *Epinephelus merra* or *Siganus stellatus*. The aqueous or vitreous humours were clear except in the case of a yellow vitreous humour in *Siganus rostratus*. The cornea of *Nemanthias carberryi* was clear but the lens was not examined.

The data that follow were obtained from fishes collected by the use of explosives at the Royal Society's Research Station on Aldabra in the Indian Ocean. Immediately after the charge was detonated, three divers entered the water; one to collect fish, one to watch for sharks and one to study iridescence of the collected fishes.

The fish, killed by the explosion one to two minutes previously, was clamped to a plastic writing board with an inclinometer attached at the lower left hand corner. The inclinometer consisted of a glass sphere open at the bottom and marked with lines of latitude and longitude. A metal rod was fastened inside the sphere in such a way that its tip marked the geometric centre of the sphere. Underwater the sphere filled with water; a small air bubble was then introduced and this indicated the vertical. The direction of view was obtained by noting the locus on the surface that aligned with the centre of the sphere. Observations were made as near noon as possible at 15–25 m. depth. In this way the direction of maximum downwelling radiance corresponded with the vertical within the limits of experimental error.

The apparatus was held level with the eye so that the anterior/posterior axis and the axis between the eyes was horizontal. In *Callyodon*, *Xanothon* and *Balistapus* corneal iridescence was visible in this position. In *Nemanthias* the fish had to be slightly below the level of the observer's eye. The apparatus with fish attached was then rotated around the anterior/posterior axis (roll) and then around the axis joining the eyes (pitch). The angles of pitch and roll through which iridescence was visible are listed in Table 1. When iridescence is visible under natural conditions the entire corneal area is affected. When a small artificial light source is used as in Fig. 1, the sector of the cornea shaded from the light does not appear iridescent. The fishes were then viewed from different directions, keeping the anterior/posterior axis and the inter-eye axis horizontal. When viewed from below and somewhat from in front, no iridescence was visible (Fig. 2).

Table 1 The Angles of Pitch and Roll through which Corneal Iridescence is Visible

	Pitch		Roll	
(*A*) *Nemanthias carberryi*	−25°	+25°	−0°	+66°
(*B*) *Balistapus undulatus*	−61°	+54°	−49°	+59°
(*C*) *Xanothon bipallidus*	−51°	+32°	−10°	+68°
(*D*) *Callyodon viridifucatus*	−66°	+44°	−25°	+66°

The angles are measured from the vertical. Negative pitch is when the head is in the up position; negative roll is when the back of the fish is tilted away from the observer.

It is now well established that the silvery iridescent scales and iris of fish act as a camouflage device underwater[4] and it might seem natural to ascribe the same function to corneal iridescence. To the diver, however, corneal iridescence often shows up extremely brightly underwater and is rarely the same colour as the head; for instance, corneal iridescence in *Nemanthias* is blue–green whilst the head and body is golden orange. Furthermore, the cornea is not iridescent in silvery sided pelagic fishes where the black pupil may be the only visible part of a fish swimming in open water[4].

It is too early to speculate on the role of the yellow optical filters and the iridescent cornea on selective spectral absorption of light from different directions, but all the fishes so far known

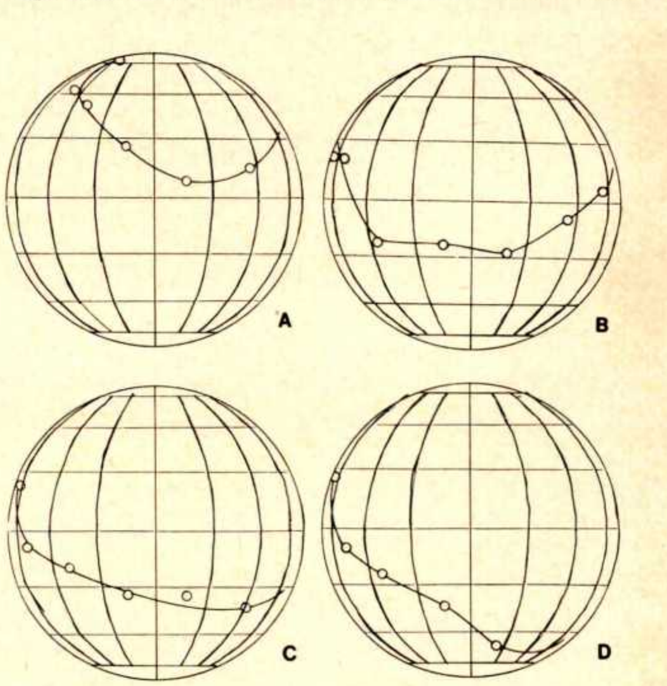

Fig. 2 Direction from which corneal iridescence is visible. The diagram represents the curved surface of a cornea oriented in the same way as in the fish in Fig. 1. The angle of view is indicated by the locus on the sphere's surface which aligns with the centre of the sphere. The line joining the circles indicates the direction of view at which the entire surface of the cornea appears iridescent. Iridescence ceases to be visible when the direction of view is from below the line. *A*, *Nemanthias carberryi; B, Balistapus undulatus* (trigger fish); *C*, *Xanothon bipallidus* (parrot fish); *D*, *Callyodon viridifucatus* (parrot fish).

to possess this iridescence live and feed near the bottom and it may be that the iridescence acts as a sophisticated sunshade designed to reduce by reflexion the bright light arriving from the upper hemisphere, whilst allowing the much less bright light entering from the direction of the sea bed to pass without significant loss.

I thank the staff of the Royal Society Research Station and my co-divers, Mr J. A. Stevenson, Dr W. R. A. Muntz and Mr A. J. Young for their support and help.

Titration of Oral Nicotine Intake with Smoking Behaviour in Monkeys

SEVERAL studies have indicated that nicotine is an incentive in smoking. Johnston[1] found that heavy smokers reported a pleasurable sensation when given nicotine, whereas non-smokers reported an unpleasant effect. Lucchesi *et al.*[2] showed that intravenous administration of nicotine diminished the number of cigarettes smoked by heavy smokers. Jarvik *et al.*[3] found that oral nicotine administration produced a very small but significant decrease in the number of cigarettes smoked but because humans were used, they[3] were not able to use large doses of nicotine which might have produced larger decrements in smoking. Previous work in this laboratory with monkeys trained to puff cigarette smoke showed that mecamylamine, a nicotinic-blocking agent, reduced their smoking[4], and the work reported here was conducted to establish more definitely that orally administered nicotine could substitute for nicotine derived from smoking.

Four mature rhesus monkeys were trained to puff cigarette smoke. Only one (Phoebe) had served as a subject in the previous study with mecamylamine. Puffing behaviour was instilled initially by making the monkeys suck on a tube in order to drink. The mouthpiece of a cigarette smoking apparatus[5] was then substituted for the water tube. The smoking apparatus allowed a monkey to smoke lit cigarettes by automatically lighting each cigarette, spacing the cigarettes over time, and sensing changes in pressure as the monkey puffed. When the monkeys had learned to puff, they were so trained that they had to puff but were allowed to choose between smoke and air[6]. This procedure was developed to reduce the large variability from subject to subject inherent in free puffing.

A smoking apparatus was attached to a 'Plexiglas' panel covering a 36 cm square opening in the door of each monkey's home cage. Two tubes, one delivering cigarette smoke and a "dummy" tube with access only to air, were also mounted on the panel. A water solenoid was mounted between the smoke and air tubes. A puff on either the smoke or air tubes preset the solenoid and would release a small amount of water when the monkey touched the solenoid spout. A light mounted above the solenoid signalled the availability of water. A fixed ratio (FR) contingency was added, so that a monkey could be required to puff a specific number of times to obtain water.

The monkeys received all their water during a daily 4 h puffing session. Thirty cigarettes were loaded into the smoking apparatus each morning and the test was started at 1030 h. A new cigarette was automatically lit every 7.5 min. The positions of the smoke and air tubes were interchanged each morning so that side preferences would not develop. Initially, water could be won with a single puff on either the smoke or air tube. The number of puffs for a reward of water was then increased to five, ten, twenty and finally to thirty. The FR 30 schedule was then maintained. Puffs were recorded on Sodeco counters.

All four monkeys preferred smoke to air; that is, although they could get water by puffing on either the smoke or the air tubes, they reliably took more puffs on the smoke tube than on the air tube. When puffing rates on the FR 30 schedule stabilized, the nicotine experiment was begun (except for the monkey used in the previous mecamylamine experiment[4]; the present experiment was started 2 months after completion of the previous experiment).

Various quantities (50 mg to 200 mg) of nicotine tartrate were dissolved in the water which each monkey obtained through puffing. The amount of nicotine on a given day was always dissolved in 700 ml. of water although the monkeys would usually consume only 300–400 ml. during a puffing session. Increasing dosages of nicotine were self-administered in this way with at least 4 days between successive nicotine trials. Each dose was repeated two or three times before starting a higher dose.

The results obtained from such oral nicotine administration are shown in Table 1. The data on days immediately preceding oral nicotine days were used as control data in paired *t* tests. For each monkey, doses of oral nicotine were found which significantly decreased and in some cases reversed the smoke–air preference without significantly affecting the overall puffing rate.

Table 1 Changes in Smoke Preference induced by Oral Nicotine

	Phoebe		Alex		Ivan		Dot	
Dose (mg)	Total puffs	% pref.	Total puffs	% pref.	Total puffs	% pref.	Total puffs	% pref.
Control	6,103	88.7	4,844	86.4	2,786	87.2	4,322	91.1
50	6,509	87.5			2,594	87.0	3,666	88.3
75	6,466	91.0	5,191	90.0	3,465	87.0	4,437	86.0
100	6,440	92.0			3,453	75.0	4,754	81.5
125	5,784	64.1*	4,798	91.9	2,589	41.7*	4,308	14.8*
175			4,973	75.0				
225			4,623	56.7*				

* Significantly less than control at $P<0.05$.

One additional drug trial was conducted with one of the monkeys. Because previous work had shown that mecamylamine inhibited monkeys' smoking, it was of interest to determine whether mecamylamine would antagonize the inhibition of smoking by orally administered nicotine, that is, whether the combination would depress smoking behaviour less than either treatment alone. For this purpose, the monkey used in the previous mecamylamine experiment as well as the more recent oral nicotine experiment was used again. A dose of 125 mg of nicotine tartrate was administered orally as already described. In addition, a dose of 0.8 mg/kg of mecamylamine was given intramuscularly 15 min before the beginning of the same puffing session. This combination was repeated twice. Thereafter, two administrations of the mecamylamine alone were conducted. The results are shown in Table 2. All three treatments—oral nicotine alone, mecamylamine alone and the combination—produced significant inhibition of smoking behaviour. Only mecamylamine alone and the combination significantly decreased overall puffing. Most surprising, however, was the finding that the inhibition of smoking produced by the combination was significantly greater ($P<0.05$) than that produced by either drug treatment alone.

Table 2 Changes in Smoke Preference of Phoebe induced by Oral Nicotine (125 mg) and/or Mecamylamine (0.8 mg/kg)

	Total puff	% pref.
Control	6,055	88.2
Nicotine	5,784	64.1*
Mecamylamine	4,842*	65.5*
Nicotine + mecamylamine	3,358*	33.5*

* Significantly less than control at $P < 0.05$.

These results raise interesting questions about the role of nicotine in smoking. If oral nicotine depressed smoking by providing a greater than optimal level of nicotine, such that additional nicotine derived from smoking was aversive, then mecamylamine should have antagonized rather than potentiated this effect. However, different central actions of nicotine may have been responsible. Perhaps the aversiveness produced by the large oral nicotine doses was a function of nicotinic blockade rather than of activation[7]. Blockage of nicotinic activating, presumably rewarding, actions of nicotine by mecamylamine would then allow non-rewarding blocking actions to predominate. Clinical studies are being conducted in this laboratory to evaluate the therapeutic significance of this hypothesis.

Effects of Cyprenorphine Hydrochloride on Sensory Reinforcement in the Rat

In a previous study[1] of the morphine antagonist cyprenorphine hydrochloride (M 285), we examined the possible hallucinogenic effects of this analgesic compound on the light-reinforced behaviour of rats. Control animals receiving saline injections showed typically increased response rates during test sessions in which response–contingent light (RCL) was available, whereas M 285 (0.3 mg/kg) depressed this light reinforcement (LR) effect. The drug had no effect on operant or non-reinforced responding, and so we postulated that it had its principal effect in relation to the relative significance of the stimulation to the animal. More specifically, this drug (in common with other hallucinogenic agents) may raise the arousal level of an animal that is relatively deprived visually, so that it needs very little further stimulation.

We report now a further test of the hypothesis that M 285 has a direct sensory effect. A response–contingent light offset (RCLO) situation involves sensory reinforcement, just as in the RCL onset situation, but the sensory conditions are reversed. If the visual stimulation is hallucinogenically intensified by injection of M 285, then the drug group should respond more than the saline group in order to turn the light off for a short period.

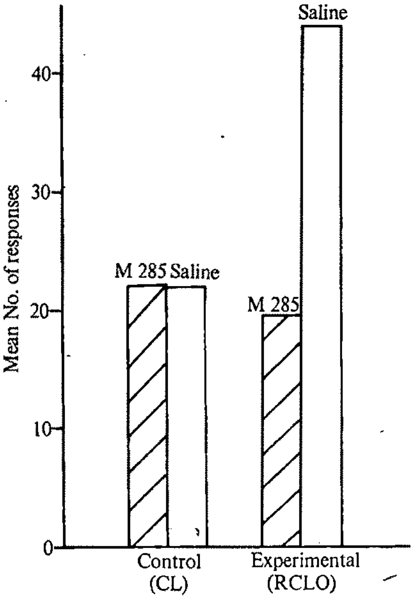

Fig. 1 Effect of M 285 (0.3 mg/kg) on reinforced (RCLO) and non-reinforced (CL) responding in rats. Response rates were recorded from a 60 min test session on day 2. All four groups ($n = 9$) were matched for mean baseline response rates in a 30 min CL session on day 1.

Thirty-six female hooded rats, 80–90 days old, were tested in the six sound-insulated, light-proof Skinner boxes described in the previous study[1]. Each rat was placed in a response box with the end ('Perspex') wall dimly illuminated constantly throughout an initial 30 min baseline session. A response (lever press) produced no change in the stimulus condition. After this "constant light" (CL) period, the thirty-six rats were matched in four groups of nine on the basis of their average operant response rate during this first CL session. On the following day, two groups received 0.3 mg/kg of M 285 intraperitoneally in 0.9% saline solution. The other two groups were injected with saline. Ten minutes after injection the rats were placed in the same response boxes with constant dim illumination. One drug group and one saline group were run in the experimental condition, in which a lever press switched off the light for as long as the lever was depressed (RCLO). The two control groups (drug and saline) were run under constant light (CL) as on day 1, and their responses produced no change in the stimulus conditions. The control (CL) and experimental (RCLO) sessions on day 2 lasted for 60 min.

Fig. 1 shows the response rates of the four groups during the test sessions on day 2. In the experimental (RCLO) condition there is a very significant difference between the drug and saline animals ($t = 4.9$; d.f. $= 16$; $P < 0.001$). The saline group shows a typical sensory reinforcement effect, since the mean response rate was twice that of the control (CL) group. Response rates of experimental animals injected with M 285, however, were no different from those of the control groups.

We have thus replicated, in a different experimental situation (RCLO), the finding that M 285 (at a dosage of 0.3 mg/kg) selectively depresses a sensory reinforcement effect without affecting non-reinforced operant responding. This result, however, contradicts the expected increase in responding of the experimental M 285 group, predicted from the hypothesis that visual stimulation is hallucinogenically intensified. A more likely explanation is that the sensory change is the critical stimulating and reinforcing factor, irrespective of whether this change involves onset or offset[2]. Thus, RC changes in sensory stimulation would be less rewarding for animals whose arousal level has been raised by M 285 than for saline animals.

We thank Reckitt and Colman for supplies of M 285, and Dr A. L. A. Boura for advice and assistance. The work was supported by a grant from the Medical Research Council.

Characterization of the Principal Steroidal Saponins of the Starfish *Marthasterias glacialis*: Structures of the Aglycones

Steroid glycosides with surface active properties have been isolated from extracts of the starfish, *Marthasterias glacialis*, by gel filtration and ion exchange chromatography[1,2]. These saponins induce avoidance reactions in the mollusc, *Buccinum undatum*, and may play a part in reducing predation by the starfish on this mollusc and other marine organisms. Mackie[3] has discussed the possible significance of this type of interaction in relation to pollution studies. Partial characterization of one of the major glycosides showed it to be a mixed conjugate of a Δ^{24}-23-ketocholestane derivative[2]. In this communication we discuss the composition of the glycoside mixture and evidence for the nuclear structure of the aglycone.

Crude starfish extracts were hydrolysed with hydrochloric acid and the water-insoluble aglycone was purified by chromatography on silica gel. Although homogeneous by thin-layer chromatography in several solvent systems, the aglycone was resolved into three components (ratio approximately 1 : 5 : 4, varying slightly with different batches of animals) by gas chromatography. The major components were then separated by preparative layer chromatography using continuous development in benzene–ether (24 : 1 v/v). The more polar of these, now called marthasterone, contained the Δ^{24}-23-ketone system previously characterized[2] (λ_{max} 240 nm; ν_{max} 1,690 cm^{-1}), while the other component exhibited no selective absorption in the ultraviolet and its carbonyl stretching frequency appeared at 1,715 cm^{-1}. This, together with its nuclear magnetic resonance (NMR) spectrum, suggested that it was the 24,25-dihydroderivative of marthasterone, and the relationship was confirmed by selective hydrogenation (Pd/C, 1 atmosphere, 1 h) of the side-chain double bond of marthasterone, which yielded the other major component. Further structural work was then carried out on this material, melting point 167°–169° C, now called dihydromarthasterone.

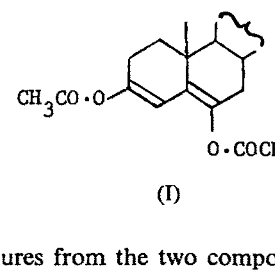
Dihydromarthasterone ($C_{27}H_{44}O_3$, M$^+$ 416.3289 (required 416.3290)) showed a mass spectral fragmentation pattern analogous to that of marthasterone, with the major cleavage (at C_{20}–C_{22}) involving loss of the six-carbon fragment containing the ketone function (*m/e* 316, 301, 299, 298, 283, 265).

Previous work indicated that the nuclear substituents of the aglycone consisted of a double bond and two hydroxyl groups[2], and spectral data established conclusively that the trisubstituted nuclear double bond was not attacked in the above conditions. Prolonged catalytic hydrogenation (50 h) was required to reduce the nuclear double bond, as shown by the disappearance of the olefinic proton signal at τ 4.68. In the resulting tetrahydromarthasterone, the C_{19} angular methyl group showed a large upfield shift (10 Hz), while the C_{18} angular methyl had moved downfield (2 Hz). Zürcher's rules[4] indicated that this was in accordance only with the presence of a $\Delta^{9(11)}$-olefinic bond in the substrate. Other trisubstituted double bonds produced markedly different effects on the positions of the angular methyl group resonance frequencies. (Hydrogenation of the side-chain double bond had no significant effect on these resonances.)

Epoxidation of the nuclear double bond, using monoperphthalic acid in ether, was accompanied by loss of the olefinic signal at τ 4.71 and the appearance of a broad one-proton doublet at τ 6.83 ($J = 6$ Hz). In addition, downfield movements of the C_{19} (14 Hz) and C_{18} (5 Hz) protons were noted. Similar changes occurred in the positions of the angular methyl proton signals following the epoxidation of a number of model $\Delta^{9(11)}$-compounds ($\Delta^{9(11)}$-tigogenin acetate, $\Delta^{9(11)}$-pregnanolone acetate, and so on). There is thus strong evidence that the nuclear double bond of marthasterone occupies the 9,11-position.

The locations of the two nuclear hydroxyl groups were next investigated. Oxidation of marthasterone with chromic acid in acetone gave a triketone (λ_{max} 239 nm, $\varepsilon = 10,120$; ν_{max} (KBr) 1,715 and 1,680 cm^{-1}). Its NMR spectrum showed downfield shifts (C_{19}, 15 Hz; C_{18}, 5 Hz) for the angular methyl groups, and the olefinic proton at C_{11} had also moved 16 Hz to lower field. This indicates that the keto-groups are relatively close to the C_{19} angular methyl group and the $\Delta^{9(11)}$-bond, but more remote from the C_{18} angular methyl group. Chemical shifts for the angular methyl protons calculated from literature values[4] were in good agreement for 3 and 6-keto groups, as were the observed values for the triketones obtained by similar oxidation of dihydro and tetrahydromarthasterone. Further evidence for this assignment was obtained by oxidation of 3β,6α-dihydroxy-5α-cholestane to 5α-cholestane-3,6-dione. This was accompanied by downfield shifts of 13 and 4 Hz, respectively, for the 19 and 18-protons. Other positions for the two nuclear oxygen functions were excluded by reference to literature compilations[4,5].

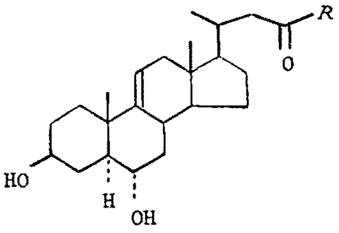
Attempts to confirm the 3,6-relationship of the new keto-groups by dehydrogenation to the conjugated Δ^4-3,6-dione system using selenium dioxide were unsuccessful. Treatment of the triketone with isopropenyl acetate, however, produced a diacetate mixture having λ_{max} 244.5 nm ($\varepsilon = 3,430$). The corresponding product mixture from 5α-cholestane-3,6-dione had λ_{max} 245 nm ($\varepsilon = 3,450$). This absorption corresponds to that of an heteroannular diene chromophore of type (I). The acetylated mixtures from the two compounds were shown by gas–liquid chromatography to consist of similar mixtures of components, resulting from the various enolization pathways open to the diketones. The major products appear to be the $\Delta^{3,5}$ and $\Delta^{2,5}$-dien-3,6-diol diacetates.



(I)

The broad nature of the C_3 and C_6 proton signals in the original aglycones and their diacetates indicate that they are both axial; hence the hydroxyl groups are equatorial, and occupy the 3β and 6α positions.

NMR spectral data on this series of compounds accord with the A/B-*trans*-ring junction, rather than the A/B-*cis*-junction, and hence the structures proposed for the major aglycones present in the *Marthasterias* saponins are 3β,6α-dihydroxy-5α-cholesta-9(11),24-dien-23-one (marthasterone, II) and its 24,25-dihydro-derivative (III).



[II; $R=CH=C(CH_3)_2$]

[III; $R=CH_2CH(CH_3)_2$]

Two structural features of these molecules are of biogenetic interest. First, the keto-groups at position 23 are unique, oxygenation at this position in the side chain having only previously been encountered in nature in the case of 23ξ-hydroxylanosterol. This was isolated from the common fungus, *Scleroderma aurantium*, by Entwistle and Pratt[6,7]. The nuclear hydroxylation pattern occurs in the cactus sterols, peniocerol[8] and macdougallin[9,10]. Second, starfish sterols are characterized by the presence of a Δ^7-bond[11], as are those of sea cucumbers. The latter, however, also produce toxic steroidal saponins (the holothurinogenins) possessing a $\Delta^{7,9(11)}$-diene system[12,13], and $\Delta^{9(11)}$-derivatives[14].

Recent work[15,16] shows that echinoderm sterols are partly dietary in origin and partly biosynthesized by the animals. Incubation of starfish with 2-^{14}C-mevalonic acid gave heavily labelled lanosterol, although cholest-7-enol, the principal sterol component, was only weakly radioactive.

Synthetic work to confirm the structures proposed is in progress in this laboratory, as well as further work on the location of the conjugating groups in the original saponins, and characterization of the minor component.

Lead Accumulation by Wild Oats (*Avena fatua*) in a Contaminated Area

THE input of lead into the environment has increased during the last two decades[1-4], especially with the development of lead-containing gasolines[2]. The body-burden of lead is now much greater in man than in his modern ancestors[5] and as one source of lead is food, its acquisition, mobility and effects in plants and animals, as well as its partitioning among the air, soil, water and biotic fractions, must be understood.

The Benicia-Vallejo area, 25 miles north-east of San Francisco, is a unique site for such studies because it has been continuously contaminated with lead from a nearby smelter for approximately 70 yr[6]. The area includes both agricultural and urban uses of land. Between early 1969 and early 1970 thirteen Appaloosa horses died while grazing in a winter pasture in the area and their deaths were correlated with a high body-burden of lead. Since then we have carried out an intensive sampling and analysis of native vegetation.

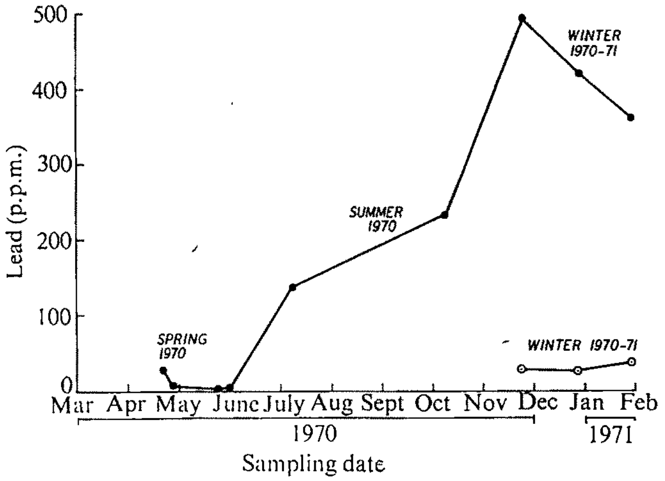

Fig. 1 The concentration of lead (p.p.m. of dry weight) in the above-ground portion of *Avena fatua* as a function of sampling date. ●, 1969–70 growing season; ○, 1970–71 growing season.

The aerial parts of various plants were analysed for lead by atomic absorption spectrophotometry[7]. Tests on two dates indicated no detectable difference in lead concentrations between washed and unwashed samples. Fig. 1 summarizes the analysis of *Avena fatua* samples. Initially, during the period of rapid growth and heading out (April–June), the lead concentrations decreased, but then increased substantially during ripening until autumn, when the plants were completely air-dry. The increase continued, accelerating after heavy rain in October and November when the new season's growth began, and reached a peak in December. Late November to late January was also a period of heavy rain. Lead contamination in the new growth was similar to that observed in the early samples of the 1970 season.

The shape of the curve in the early months of the year may reflect growth dilution. The plants are growing and are constantly absorbing lead from either the soil or the air, and a decrease in concentration might be expected. As the plants senesce and desiccate the lead concentration would increase because, although input may remain constant, the mass of the plants, is no longer increasing. Later in the season, however, when the plants and soil are dry, the transfer of lead from the soil to the shoots would presumably cease. The observed continuation of the accumulation of lead probably, therefore, derives from atmospheric inputs.

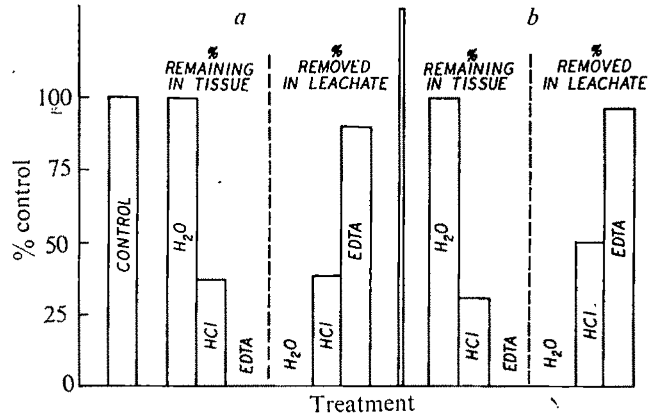

Fig. 2 Leaching for (*a*) 4 and (*b*) 24 h of ground plant material by various solutions. The results are expressed as percentage of lead in control, represented by untreated straw. Treatments consisted of H_2O, 0.01 N HCl and 0.01 M NH_4-EDTA (*p*H 6.5).

An alternative interpretation is suggested by the work of Mitchell and Reith[8] who discovered that as plants began to senesce the lead they contained was mobilized, substantially increasing in concentration in the shoot. But the pasture in which their study was conducted, unlike that reported here, was a perennial association and the plants were still viable in October when the increase occurred. Subsequent lack of growth due to the low winter temperatures, and the continued translocation of lead may have caused the late autumn and winter increase. The onset of spring growth would have then diluted the lead concentration. My own greenhouse experiments with *A. fatua*, and other reports[9,10], suggest that very little lead is translocated in representative grasses of the Benicia-Vallejo area, so that such an explanation for the increase there is unlikely.

A final alternative could be that the increase resulted from a substantial reduction in dry matter of the plant, with no loss of the associated lead. To account for the observed increase, however, a dry matter loss of at least 95% would be required but only a 10–20% dry weight loss actually occurred. This suggests that there is indeed a continuous input of lead into the system, presumably from the atmosphere, much of which is actively retained by plant material. Acting as a store in this way the plants may serve to regulate, at least partially, the cycling of lead within the system.

If the accumulation of lead results from the settling of superficial dust and atmospheric particulates on the surface of the vegetation, it might be expected that with the onset of the winter rains, significant quantities would be removed. In fact, the loss of only small amounts was detected. To investigate the effect of rain, a series of leaching experiments was conducted on dried straw collected during November.

The material was ground to pass through a 20-mesh screen, and 0.1 g samples were placed in flasks with 25 ml. of either H_2O, 0.01 N HCl, or 0.01 M NH_4-EDTA (*p*H 6.5) for periods of 4 and 24 h. The material was then filtered, washed several times and the leachates were combined. Both the residual material and the leachate were analysed for lead. The results of these experiments are presented in Fig. 2. The EDTA treatment was very efficient in removing lead, the acid less so, and the water leaching removed very little lead from the plant tissue. These data indicate the tenacity with which lead is retained by the dried plant material and to some extent confirm that rainfall can be expected to be ineffective in removing it.

The accumulation on the surface of the vegetation during the summer, therefore, is possibly followed by a binding of the lead by the dried plants. As very little rain falls in the area during the summer, only negligible amounts of surface lead would be removed, and there would be an extended period of contact during which such binding could take place. Straw consists almost entirely of cell wall remnants and heavy metals are known to be bound by such tissues in both roots and leaves[11,12]. Analyses of the surface litter reveal lead concentrations of 700–1,000 p.p.m., indicating a further concentrating effect.

The phenomenon described here has important implications for management and surveying in contaminated areas. The California Department of Public Health, in cooperation with the Air Resources Board, has carried out a comprehensive survey of lead in the Benicia-Vallejo region by sampling *A. fatua* over a large area. Because of the propensity of the grass to accumulate lead throughout the season, this may be a suitable method for monitoring the atmospheric input on a large scale. Management could be instituted to reduce the intake by stock of the previous season's contaminated plants. Because only small amounts of lead seem to be taken up from the soil[9,10], residual old growth could be ploughed in. Grazing practices might also be altered to avoid the use of contaminated pastures until most of the total feed available is represented by the current season's growth which contains only low concentrations of lead.

I thank Hector Schoo, Shirley Kunisaki and Catherine Rains for technical assistance, and Sydney Thornton and Dr R. G. Burau for their contributions.

Effect of an RNA-rich Extract on Acquisition of a One-way Avoidance Response in Rats

Two recent approaches to the biochemistry of memory have involved, respectively, the measurement of molecular changes after training, and attempts, using brain extracts, to transfer trained behavioural tendencies between animals. Zemp *et al.*[1] have reported differences between experimental and yoked-control mice in the synthesis of both nuclear and cytoplasmic RNA after a training session in which they learned to jump onto a platform to avoid foot shock; subsequent work[2] suggested that the change in RNA synthesis during learning is a function of the learning experience and not of stimulation, sensitization or other non-specific factors. The "memory transfer" effect was discovered in our laboratory and has now been replicated successfully in at least twenty others[3–5]. We had now attempted to interrelate these two approaches by studying the behavioural significance of substances synthesized after acquisition of the same response used by Zemp *et al.*, as measured by their effects when injected into a second animal.

RNA-rich extracts were obtained from the brains of trained animals, untrained controls, and yoked-shock controls (that is, animals receiving the same shocks as trained donors but prevented from learning the avoidance response). Animals receiving injections of extract from these three sources were compared on rate of acquisition of a jump-up avoidance task.

Forty-three 100–150 day old, male albino rats were housed in individual cages and given food and water freely throughout the experiment. An automated one-way avoidance chamber[6] was used to train animals to avoid a 0.6 mA shock by jumping onto a platform. The conditioned stimulus was the retreat of a wall that had barred access to the platform. Shock followed 10 s later. Thirty seconds after shock onset the wall returned, pushing the rat onto the grid for another trial. A correct trial was scored if the rat jumped to safety before shock onset.

Experimental donors were trained intensively to establish the learning experience firmly. They received ten trials a day for 5 days. Recipients, on the other hand, received three trials a day for 6 days. The difference in procedure reflects the fact that animals receiving ten trials a day mastered the task readily, often reaching asymptotic performance on the second day. Limiting practice to three trials a day made acquisition of the avoidance response more difficult for recipient animals, so that enhanced acquisition could more easily be measured.

The yoked-shock donors were placed in the apparatus for the same time as the experimental donors. Each yoked-shock donor received the same number, duration, and spacing of shocks as an experimental donor; but the 'Plexiglass' wall was always advanced to prevent any learning of escape or avoidance responses.

All rats were handled for about five minutes each day for 10 days before the first day of training. Fifteen of the rats served as donor animals and were assigned on a random basis to an experimental ($N=5$), control ($N=6$), or yoked-shock control ($N=3$) group. One animal was used for chemical assay of the donor material; the remainder of the animals were assigned to three corresponding recipient groups. Members of one group ($N=10$) received extract from the pooled brains of experimental animals. Members of a second group ($N=12$) received pooled extract from the brains of the control group. Members of a third group ($N=6$) received pooled extract from the yoked-shock group.

Within one hour of the last training session, donors were decapitated, and their brains, excluding cerebellum and olfactory lobes, were removed to a beaker of dry ice, where they were kept at −20° C. RNA was obtained by cold phenol extraction[7].

Twenty to twenty-six hours before its first post-injection test session, each recipient animal was injected intracranially with 0.15 ml. (0.5 brain equivalent) of extract from a trained or untrained donor[8].

The mean number of avoidances during the eighteen trials was 6.25 for animals receiving control group RNA, 5.83 for animals receiving yoked-shock control group RNA, and 10.5 for animals receiving experimental group extract. Individual rats receiving control group material ranged from four to nine avoidances, while rats receiving experimental material ranged from nine to thirteen. These individual scores were ranked and submitted to a Mann–Whitney U test. The resulting statistic was highly reliable ($U=0$, $P<0.001$). Yoked-shock recipients ranged from three to ten avoidances. When these scores were ranked against the experimental recipient scores, the resulting test statistic was again highly significant ($U=3$, $P=0.001$). When the yoked-shock and control scores were ranked against each other, however, the resulting statistic was not significant ($U=26$). Fig. 1 presents the mean number of avoidances on each of the training days. As can be seen, the group receiving "trained" extract displayed higher performance on every day after the second.

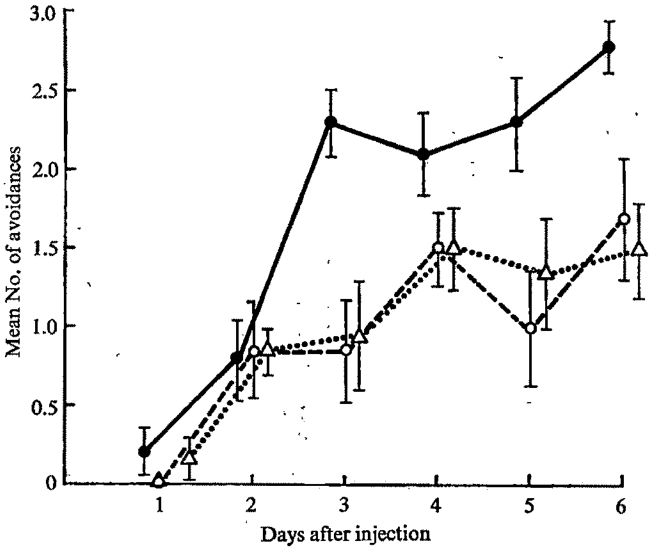

Fig. 1 Mean avoidances of experimental, control, and yoked-shock recipient groups on each of 6 days following injection of RNA-rich brain extract. (The vertical bars at each data point represent one standard error of the mean.) ●—●, Experimental; ○----○, yoked-shock; △----△, control.

The enhancement of avoidance by extracts from trained donor brains is open to several interpretations. The chemical changes in trained animals responsible for this effect might reflect learning, or they simply might reflect general stimulation such as shock trauma, violent activity, of mere exposure to the experimental apparatus. The total ineffectiveness of extracts from yoked-shock donors argues against the latter conclusion. But we did not control for all conceivable sources of stimulation, such as being pushed off the platform. It should also be noted that the cold phenol extract contained many impurities[7], in addition to RNA. Thus it is not certain that the enhancement was due entirely to RNA.

BOOK REVIEWS

Pioneers

Sex, Career and Family. By Michal P. Fogarty, Rhona Rapoport and Robert N. Rapoport. (George Allen and Unwin: London, 1971.)

THE initial research of Rapoport, a sociologist–psychoanalyst, Rapoport, a social anthropologist, and Fogarty, an economist, aimed to understand the problems of women in top jobs. However, as the work progressed it became clear to them that one could no longer look at women and work as isolated variables. Rather, as their book *Sex, Career and Family* has so convincingly demonstrated, work patterns and family relationships must be re-examined together in the light of changing social mores, aspirations, motivations and opportunities. The single-role stereotypes—the father as provider, the mother as child-raiser-homemaker—have changed. With each passing decade the number of women who work increases, with the greatest increase being among educated women. The more education a woman has, the more likely she is to be employed. For example, in the United States more than 70 per cent of women who have completed more than five years of college are in the labour force. But when we ask how successful they have been in the work they are doing, the picture darkens; this book demonstrates dishearteningly that unless society is willing to undertake major changes in the way jobs are defined, family roles assigned and attitudes challenged, we shall continue to send a double message to young women—"Aim high, but not too high". Given the same intellectual endowment and educational achievement as the men with whom she attended university, the young woman can look forward to a position somewhere in the second rank of any given profession or organization. The world abounds with women whose titles are prefaced by "Assistant".

The authors make it clear that to understand how this down-grading happens to women one must shift emphasis from women alone to men and women together. From there a short step leads to the exploration of society's legitimization of the relationships between men and women, the family and work. The authors consider family patterns and sex roles as they affect job and career potential for women and, at the same time, open up the crucial psychological issues of self-definition and interpersonal expectations. All of these are examined in the context of changing attitudes toward work and the impact of industrialization and urbanization on social and psychological processes. This matrix of interlocking variables necessarily complicates methodological structure although the authors' struggle to achieve a sensible research methodology is one of the book's important contributions.

The men and women who work out new patterns of relationship between work and family to facilitate the wife's pursuit of an effective career and still maintain a family are pioneers in several dimensions simultaneously. To break the lockstep of man breadwinner and woman homemaker which is so accepted by our social institutions, both the women and men (the dual career families) involved must also change their view of women as the weaker partners. This "creative minority", as the authors call them, are distinctly on the move, spurred by unanticipated social and technological changes.

A reason for this book's excellence, besides the vast spectrum of data drawn upon, is its awareness that one cannot blueprint how or what will be the result of a social, psychological or technological change. Events that seem unconnected emerge as forces to be integrated by these pioneers into the different family, work and personal patterns they definitely predict. As one surveys the rapidity of change in our society, it is hard to fault their insight. Who could have predicted a few years ago the almost universal militancy for equal rights of underprivileged groups which now affects the women's rights movement so directly? Or, as more cogent examples, who could anticipate how definitely one discrete technological advance could change sexual mores and another the roots of sexual identity?

It is unlikely that the puritanical Henry Ford ever thought he would be the father of America's sexual revolution. His interest was in transportation—mechanical not emotional. Yet he provided America's first bedrooms on wheels, thereby changing sexual behaviour to a greater extent than we can measure. It was a technological achievement external to individuals which began by changing social vistas and eventually reshaped psychological responses.

Now we are in a new era . . . that of the pill. Like Henry Ford, the steroid chemists (were they all men?) were attempting to solve a technological problem . . . how to provide a better method of contraception. To a large extent they have solved the technical challenge . . . for millions of women the pill is a miracle. What was unanticipated and as yet only dimly perceived, are its social–psychological side-effects. Chemists set out to develop safe, cheap, readily available contraception. Once the means to that end came into being, it turned out that the achievement of this seemingly straightforward goal necessitated broad revisions of society's attitudes toward such specific matters as contraception, conception, copulation and consent. On a more abstract level but in the long run probably more salient in determining our attitudes and behaviour will be the revision of our sexual identity.

For example, in any sexual encounter before the pill, the woman had to be protected. Concrete evidence for this assumption is provided in the name of a proto-diaphram patented as early as 1846 . . . "The wife's Protector". She could protect herself from the spectre of unwanted pregnancy, could ask the man to or could expect it of him as (to drift into the Victorian for a moment) a gentleman. Now the pill is taken along with vitamins, orange juice and morning coffee, separate from and unrelated to the act of going to bed or to the person she might be sleeping with.

The pre-pill perception of the woman was in part that she was weak, fragile and vulnerable. Can anyone imagine that this persistent image of a woman in this most basic act does not influence men and women's view of themselves and others? If the idea that she must be cared for becomes integrated as part of her sense of self, it also implies that she must be protected from the man who might be careless, that is potentially harmful. As the impregnators, men develop from the same experience similar views of themselves and women. The interaction of these intrinsic sexual identities reinforce each other and the weak–strong dichotomy is maintained. Hence, attitudes derived from the sexual act can affect the way in which children are treated from birth; they can be extrapolated to a general equation describing men and women's roles and functions. She requires protection and pays for it in status. But now she no longer needs the protection—she has it. One can see how in a society pressing towards egalitarianism, the pill would have a definitive impact on that social and psychological equation.

The above oversimplified analysis of the potential impact of the pill on sex, career and family life would probably arouse little disagreement at the nearest cocktail party or at the course, *Women in Society*, recently spawned at the local university. Does that mean we are adapting psychologically and sociologically to the coming change?

Not necessarily. The authors show how little prepared we are individually or as a social group to cope with change despite our awareness that it must come.

Their studies of highly qualified British women graduates of 1960 show that only one per cent of those now married with children definitely intend not to work and that four out of five intend to be in part or full-time work when their children are grown. These findings are similar to those in the United States, where the Labor Bureau reports a marked upswing in the percentage of young women college graduates continuing to work after the birth of their first child. Some of the technical problems associated with this are obvious. How much should be spent on "improved housing, neighbourhood service and provision of nursery schools?" Less obvious are the challenges faced by employers. If it is necessary to re-cast their recruitment and promotion practises to take into account women's different life-cycles, can the community be expected to meet some of the costs coming out of the adaptations which will pay for maternity leaves and relaunching programmes? The authors present evidence that "these programmes can be operated only if there is broad social support from the community and its formal representatives, the law and the government". Industry cannot afford and has little inclination for pioneering. This broad social acceptance and support is necessary at all levels if women are not just to be allowed in as assistants but are to reach their capacity at the top of their professions. For, although many women plan to work, the most depressing statistic presented is how few women go far or rise high whether it be in Great Britain, Eastern Europe or the United States.

Thus the change throughout must be in the potential not simply for acceptance but for status: from aspiring for auxiliary roles in work, protection in sexual encounters, or help in the house to expecting an equal opportunity to be leader, sex partner, or non-housekeeper if and when they so choose. This book offers an informed, scholarly approach to new intra-familial relationships which, while not for everyone, would offer a positive direction for families to move in—all within the definition of the family.

DOROTHY S. ZINBERG
NORMAN E. ZINBERG

Men at War

War and the Human Race. Edited by Maurice N. Walsh. (University of California, Los Angeles, Faculty Lecture Series, 1968.) Pp. 95. (Elsevier: Amsterdam, London and New York, 1971.) £2.25.

THE editor claims for this small volume that it represents an inter-disciplinary approach to the problem of war. Unfortunately it does not. The fact that the contributors are drawn from six different disciplines, and that no attempt was made to integrate their conclusions—not even in the "Summary and Conclusions"—scarcely justifies the editor's interdisciplinary claim for it. Dr Maurice Walsh, the editor, is a practising psychoanalyst with a gift for misquotation even to the misspelling of common proper names, and a style so banal that it is calculated to confer mediocrity on the most promising of subjects. The book would have benefited from the omission of his "Editorial Introduction", his lecture, "Psychic Factors in the Causation of Recurrent Mass Homicide", and his "Summary and Conclusions", all of which repeat one another, and the principal theme of which is a "new" theory of war.

The theory is that since wars take place at an average interval of 19.6 years, which is the time of the psychic stresses of late adolescence, the period without voting rights and susceptibility to the aggressive propaganda of charasmatic leaders, coupled with the intense murderous hostility of the older for the younger males (oedipus complex), the result is recurrent mass homicide (war).

As a true believer Dr Walsh has a properly idolatrous regard for the catchwords of psychoanalysis, which is not, in the end, helpful. We must, however, be grateful to him for the passionate plea he makes for more research, and for having gathered together these interesting lectures.

Dr Bernard Brodie, a political scientist, discusses "Theories on the Causes of War", illuminatingly disposing of the usual theories as to the causes of war, such as munitions makers, big business, innate aggression, arms races, neurotic leaders, and the like. Herbert Friedmann, a biologist, in "Animal Aggression and Its Implications For Human Behaviour", clarifies some of the confused issues in which the term "aggression" is used, carefully distinguishing between the "aggressive" behaviour of other animals and that of man, a very necessary distinction because it has become popular, as Dennis Chitty has recently remarked, to blame our animal ancestors for some of the distressing things we do to each other. Regrettably, when Professor Friedmann writes that man "has innate aggressive tendencies", the statement remains declarative, and no evidence is provided for it.

Dr John G. Kennedy, an anthropologist, writes on "Ritual and Intergroup Murder: Comments on War, Primitive and Modern". This is an excellent contribution and provides a sound overview of conflict and restraint among nonliterate peoples, as well as a fine analysis of their causes, functions, and meaning.

The historian, Jere Clemens King, offers a brief survey of "The Role of Warfare in History", and a journalist, Walter Wilcox, in "The Loneliness of the Long Distance Soldier", provides a first-hand examination of what makes the infantryman run, usually, in the direction in which he is ordered.

ASHLEY MONTAGU

Pesticide Journal

Pesticide Biochemistry and Physiology: An International Journal. Edited by R. D. O'Brien. Volume 1, Number 1. Pp. 122. (Academic: New York and London, March 1971.) $30.00.

THE most important question to be directed at a new scientific journal is the quality and rigour of the editorial scrutiny that will be applied to the papers proffered. No one would question the capacity of the editorial board listed in this journal: it is to be hoped that they will have the time to spare for the work.

In the first issue four of the eleven papers are from laboratories of members of the board. In general the standard attained is good. However, one paper on resistance in fungi is not related to the effects of a pesticide. The others include four papers dealing with metabolism by insect gut or microsome preparations. The mode of action of a fungicide on a fungus is described in biochemical terms and that of dieldrin on insects in neurophysiological terms. The metabolism of insecticides in resistant insects is referred to in two papers, one of which suggests that the resistant insect metabolizes one of the new "low toxicity" organophosphorus insecticides like the insensitive mammal. The binding of anticholinesterases to prevent access of meotine or decamethonium to sensitive sites is the subject of another paper. To the reader used to mammals, perhaps the greatest surprise is the explanation of why *Rhodnius* "wets its pants" when exposed to some insecticides.

If this journal can attract high quality papers describing work on the comparative effects of pesticides on target and non-target species it will provide useful background information for the eventual design of more selective but effective pesticides.

For journals whose contents cross the lines of several basic disciplines the titles of the papers are particularly important to enable the appropriate abstracting services to bring them to the attention of others. In this respect this issue is good.

It will be interesting to review this journal again in two or three years time to see whether the editorial aspirations have been maintained. By then one may probably anticipate that the price will have risen above the present £3 for 120 pages and library committees will probably still be looking critically at their budgets. J. M. BARNES

Pharmacological Methods

Methods in Pharmacology. Vol. 1. Edited by Arnold Schwartz. Pp. xiv+585. (Appleton Century Croft: New York, January 1971.) $26.50.

THE title of this book is rather misleading as are the headings of many of the chapters. For example, it is surprising to find that a chapter entitled "The Use of Microelectrode Techniques in Muscle" is concerned with microelectrodes and oxygen electrodes in cardiac muscle, not skeletal or nonstriated muscle. In fact, the book concentrates heavily on cardiovascular pharmacology, the remaining chapters being less coherent.

The sections also vary between comprehensive and useful accounts of techniques, such as those on ATPase and on the sarcoplasmic reticulum, to more restricted accounts of personal research having less general interest. The overall effect is that while much of the volume has interest for the experimental pharmacologist, it can hardly become the place to turn to for a comprehensive account of pharmacological methods. For this purpose the well known texts edited by Laurence and Bacharach and by Siegler and Moyer remain unrivalled. A. S. V. BURGEN

Phase Transitions

Phase Transitions. (Proceedings of the Fourteenth Conference on Chemistry at the University of Brussels, May 1969.) Pp. xi+256. (Wiley-Interscience: London and New York, March 1971.) £6.

IN 1952 there was an international conference in Paris on *Changements de Phases*. In 1969 the same title was chosen for the Solvay Conference in Brussels, although in the published proceedings this has been translated into English. At least ten people (including myself) took part in both meetings and to us, at least, it is instructive to see how far we have come in seventeen years.

At both meetings the emphasis was on theory. The only exact result known in 1952 was Onsager's recently obtained solution of the two dimensional Ising model in zero field. There is, alas, little more to report now. There are a few further results, notably those of E. Lieb, who reviews this topic, but these have not been so fruitful a source of inspiration as that of Onsager. On the other hand, we have now an immense amount of numerical information on both two and three dimensional lattices. This has been obtained in two principal ways.

First, we have series expansions of the partition function, usually in powers of $1/kT$, and the examinations of these series for singularities by the method of Padé approximants. The start of this work was described in 1952 by Rushbrooke; its most extensive practitioners have been Domb and his group in London, but this work was not described at Brussels.

Second, computers have arrived. These can be used to undertake calculations impossible in 1952, as, for example, the use of the matrix method for semi-infinite lattices, described here by A. Bellemans. Their greatest success, however, has been to act as a "laboratory" in which experiments on simple continuum models can be carried out by Monte Carlo or molecular dynamic methods. Virtually all we know about the melting of a system of hard spheres or about the whereabouts of the critical point of a Lennard-Jones system comes from computer simulation. L. Verlet describes this work. Our purely theoretical knowledge of continuum systems remains in a primitive state, although both J. E. Mayer and S. A. Rice sketch possible lines of attack.

The critical point is always with us. By 1952 the classical description of van der Waals was no longer accepted (at least by chemists) but there was no agreement about what should take its place. Now the nature of the singularities in the thermodynamic functions is known, if not understood, and much of the interest has passed to the less easily measured transport properties. G. B. Benedek and P. Résibois describe recent progress which has been aided by the advent of the laser, which allows us to study the spectrum as well as the intensity of the scattered light.

The remaining papers delivered at Brussels dealt with more complex systems where experiment rightly still takes precedence over theory. A. R. Ubbelohde spoke on melting and crystal structure (and was also chairman of the conference), G. Busch on liquid metals and S. Lifson on transitions in chain molecules. This welcome book contains also the discussion; some of it rather elliptic, but it may contain as many seeds of future advances as the formal papers. J. S. ROWLINSON

Band Theory

The Electron Band Theory of Solids. By G. C. Fletcher. Pp. xv+260. (North Holland: Amsterdam and London, 1971.) £6.30.

THERE are already a number of advanced texts devoted to the electron band theory of solids, but for some time there has been a need for a treatment of this particular specialization from first principles, that carries the subject to a level from where the reader can easily tackle the advanced literature, which deals with the technicalities involved in actual band theory calculations. This book adequately fulfils this need.

The basic principles of the subject are introduced, in the first few chapters, in a way that should be easily understood by the average graduate, without demanding a wide command of mathematical skills (several later chapters are devoted to mathematical techniques), yet without recourse to tedious methods nor with loss of rigour. In this section of the book the author very briefly discusses the validity of the one-electron treatment, although this is dealt with in much greater detail in the appendix. Crystal and reciprocal lattices are discussed adequately, and the appendix compliments these topics by providing a useful set of figures illustrating the Bravais lattice types and corresponding Wigner cells and Brillouin zones. Density of states and related matters are dealt with briefly, and a chapter is devoted to the problems of choice of realistic initial potentials, discussion being confined to those of "muffin-tin" type. Discussion of the exchange term occurring in these potentials is relegated to the appendix. Two chapters dealing with the free and nearly free electron approximations conclude what I would regard as the introductory section of this book. These two topics are used to provide useful illustrations of the restricted and unrestricted zone schemes, and of the formation of energy gaps.

A considerable portion of the book is devoted to an introductory review of some of the more important methods adopted for solving the one-electron equation. These methods are returned to, a few chapters later on, after ideas of symmetry and degeneracy have been discussed and it is then shown how the methods of group theory can be used to facilitate the obtaining of solutions at points of high symmetry. A chapter deals briefly with relativistic effects, too briefly I suspect, for most readers at whom the book is aimed and consultation of works listed in the reference section at the end of the chapter will probably be necessary. Other topics considered in the remaining chapters include the pseudopotential method and various semi-empirical and interpolation techniques.

An extensive appendix is provided and apart from items already mentioned, topics include the principles of numerical integration, Legendre polynomials and other mathematical functions encountered in the main text, and Lowdin's expansion. There is additional work filling in on the Green's function method and proofs connected with the theory of group representations.

In conclusion, this is a generally well-written book with its subject matter crisply presented. It should not be omitted from lists of recommended texts for postgraduate courses in solid state physics and metallurgy. It clearly fulfils the author's avowed aim to provide a primer for people wishing to carry out actual band theory calculations and to give guidance for the assessment of the reliability of such calculations.

M. GUMBRELL

Complex Permittivity

Complex Permittivity: Theory and Measurement. Compiled by B. K. P. Scaife, W. G. S. Scaife, R. G. Bennett and J. H. Calderwood. Pp. vi+170. (English University: London, 1971.) £3.45.

THIS monograph on dielectric materials consists of three separate chapters, the first, by B. K. P. Scaife, is on the theory of dispersion in polar dielectrics, the second, by W. G. S. Scaife, discusses the effects of hydrostatic pressure on the properties of dielectrics, and the final chapter, by J. H. Calderwood and R. G. Bennett, deals with experimental methods for the measurement of complex permittivity.

The first chapter gives a most readable account of the theory of dispersion. An initial section on the macroscopic approach has the fluctuation–dissipation theorem as the central theme, and a link between microscopic and macroscopic considerations follows in the next section. Details of the microscopic treatment follow, and include inertial and dipole–dipole coupling effects. A new method is described for plotting experimental results when inertial effects are important. This has the advantage that the complex plane plots are still circles, whereas the Cole–Cole ε'' against ε' plots give more complicated curves when inertia becomes important.

The next chapter, on pressure effects, briefly reviews the theory for non-dipolar fluids, and then describes the experimental techniques which have been used, with some discussion of the results obtained. Sections on crystalline solids and on polar fluids follow; in both the emphasis is on the interpretation of experimental results in the light of theory. There is a final section on dipolar relaxation processes in solids.

The final chapter on experimental techniques gives a clear and straightforward account of the principles and basic theory of a number of different experimental methods, from bridges through resonance methods to waveguides, thus covering a wide range of frequencies. Particular emphasis is placed on sources of error and practical convenience, and the influence of the computer on experimental method has not been overlooked. There are a few blemishes. No suggestion is made, for example, about sub-millimetre wave measurements, yet the first chapter contains a proposed new method for analysing experimental results in this region of the frequency spectrum, so crucial to the inertia effects which occupy so much of the book. There is no mention of resonant cavity techniques, yet the transformer ratio-arm bridge is described separately in chapters two and three.

This book will undoubtedly be useful to specialists in this field, and can be recommended. It must be understood, however, that it is a collection of three related review articles, rather than a comprehensive treatment of all aspects of dielectric materials.

A. L. CULLEN

Lasers Applied

Lasers and Their Applications. By M. J. Beesley. Pp. xii+234. (Taylor and Francis: London, July 1971.) £5.

THE author's stated aim in writing this book is "to explain the mechanism of laser action . . . and to describe some applications of the laser . . .", but it is not clear, on reading the book, to whom it is directed.

The level of the material included is highly variable — for example, it assumes that the reader will need help with the most elementary algebra but that a casual reference to free-space mode densities suffices. The initial parts of the book suffer from too extreme condensation, which has resulted in many half truths or misleading statements—for example, "for most atoms and molecules . . . the first level above (the ground state) is separated by a gap of 1.25 eV". Fortunately this does not hold for the ammonia molecule, description of which follows the above rather sweeping comment. From the text it may appear that the inversion mode is the only possible vibration mode for NH_3.

The description given of the beam focuser supplies a lot of irrelevant detail but nowhere describes why or how the system works. It is implied that the amplitude of a lightbeam reflected at a plane surface at non-normal incidence is independent of the state of polarization of the light. One can unfortunately find all too many examples of this kind of obscurity and matters are not always helped by carelessness in the exposition. (Thus the onus is on the reader to deduce whether the expression "direction of plane-polarized light" refers to propagation or electric vector.)

The author's practical experience with lasers is reflected in the brief descriptions of laboratory procedures. These parts of the book are more successful and really it looks as though the author has written the wrong book. The average scientific paper tends to contain a simple diagram showing arrays of, for example, mirrors or other optical devices. It is not uncommon for newcomers to the field to have to spend a lot of time gaining experience in this area and the ideal solution—to work under the guidance of an "old hand"—is not always possible. (This is of particular relevance in the laser field, where applications are possible in areas where no optical experience exists.) It does seem that, if the author had addressed himself specifically to this problem, a far more satisfactory result could have been achieved.

The selection of applications chosen for description is well made and gives an excellent view of the potentialities of the laser in a variety of fields. Unfortunately, as in the earlier part of the book, some of the descriptions lack the clarity required for the unfamiliar reader. Sufficient references allow further exploration of the topics described.

O. S. HEAVENS

CORRESPONDENCE

Six Years for a PhD

SIR,—The impression exists among many students of college age and earlier, and among their families, that three years is a "normal" length of post-baccalaureate time for a PhD. Many university faculty expect their graduate students to finish in four, or perhaps five, years. Those who spend six years or more in graduate study are often asked why they took so long. As we shall see here, however, six years is about the median time for a PhD at both Harvard and Caltech.

Fig. 1 shows the distribution of time between first degree and doctorate for all students receiving PhDs at Harvard University in 1969. The first degree is always used although, especially in the case of foreign students, it was not always a BA or BS. No adjustments were made for interrupted or part-time study. Obviously most of those taking over ten years were not in graduate full-time for the entire period. The curve for mid-year degrees, which at Harvard are dated "March", is shifted left by six months to provide a better fit.

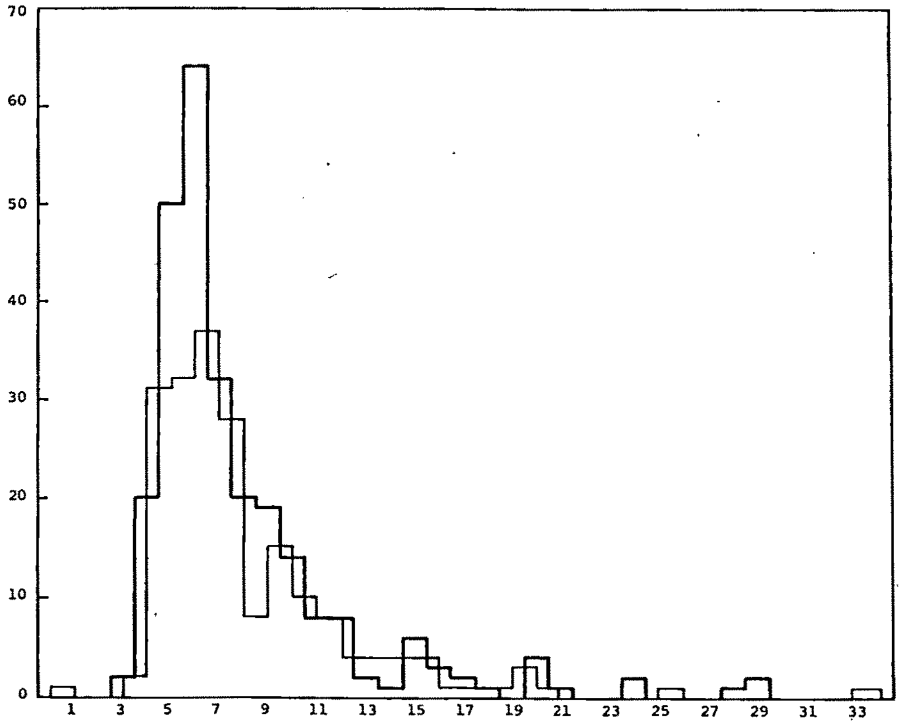

Fig. 1 Number of years between first degree and PhD for those receiving degrees at Harvard commencement in 1969. The dark line is June degrees; the light line is March (mid-year) degrees.

The curves, which are drawn to the same absolute scale, agree in the form of the distribution, which peaks at five through seven years. The average length of time spent before receiving the 262 June 1969 degrees at Harvard was 7.9 years, with a median of 6 years and a mode of 6 years. The average for the 459 total degrees was 8.9 years, with a median of 7 years. There is a long tail, gradually extending out to approximately 30 years. The number who receive PhDs in the traditional three years or less is negligible: less than one per cent.

The curves for mid-year and June degrees agree also in absolute numbers for the wings; additional recipients of June degrees are clustered at 5 and 6 years. The sharp drop thereafter probably represents the effect of the existence of deadlines, not only departmental rules but also psychological pressure felt by the individuals, both students and advisers.

The California Institute of Technology is a more specialized institution, and the 117 PhDs awarded in June 1971 were all in scientific subjects. Yet the distribution (Fig. 2) is very similar to that for all Harvard degrees, peaking at 5 and 6 years with a long tail that extends out to 16 years.

The average length of time of post first-degree enrolment before receiving a Caltech PhD is 6.4 years, with a median of 6 years and a mode of 6 years.

Clearly, the fact that so many students take more than five years for a PhD reflects more than individual delays, and must result partly from the design of

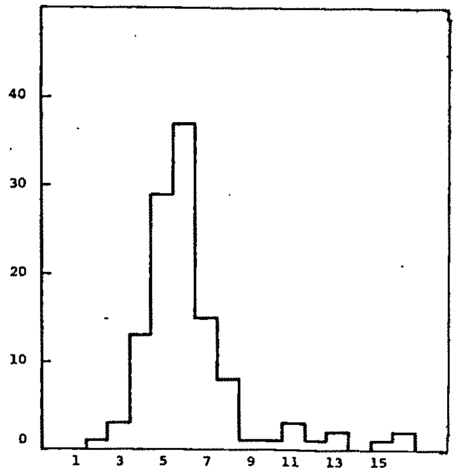

Fig. 2 Number of years between first degree and PhD for those receiving degree at California Institute of Technology commencement in 1971.

requirements laid down by the departments, including minor theses, qualifying examinations, and supplemental research projects.

Bird Navigation

SIR,—Two points appear to be misleadingly used to indicate that domesticateal *Columba livia* does not require sun-azimuth for route-finding when your correspondent on the homing sense in pigeons (*Nature*, **232**, 86; 1971) stated: "Recent evidence that this ("map" mind of the homing bird) can operate effectively even after many days' imprisonment away from the home loft . . ." I published elsewhere[1] examples of very long memory in pigeons including the following: a Hollywood (USA) pigeon which raced up to 500 miles, 1931–4, sold to Huntington (California) which returned on escape after kept "prisoner" 8 years; one lost racing Rennes (France) to Manchester, 1926, which returned home 1931, after presumably being stolen and kept prisoner; an Australian pigeon lost racing 550 miles Benallo–Melbourne, 1944, which returned in 1948, and another which returned 400 miles to France 2 years after sale to Newcastle, where it was kept prisoner a year. I have known pigeons lost up to a year return to their old nest-boxes, among many inside a breeding loft, and fight the new owner for occupation. As the breeding season approaches, more lost birds home than otherwise.

In all such cases which could be investigated, the birds were kept as "inside" prisoners without sky-views. Where transported birds are kept prisoner a week or more in outside, mesh-wire "aviaries", they "resettle" to the new territory. Young birds (6 months old) have thus been resettled in 1 week, exceptionally in 4 days; but older birds usually require 8 to 10 days. My operational birds in the British Army Pigeon Service in the 1939–45 war were sent forward in baskets (to be flown back to their lofts) with the instruction "it is important that birds should be so placed that it is impossible for them to see their immediate external surroundings", and that unused birds should not be kept in delivery or stock baskets for more than 4 days (in trench-baskets, 3 days), but returned for replacements. This was to avoid birds "seeing" and "remembering" the new temporary release-point.

Visual recognition of their external surroundings (e.g. sky and landscape was used to resettle birds to "home" to new loft-sites in place of old ones, using outside aviaries or baskets on top of the loft for at least an hour daily. I allowed my loftmen a minimum of a fortnight to settle pigeons to a new loft-site, but preferred 5 weeks (longer still for distances over 30–50 miles). We once settled thirty-four birds to "home" to a new loft site in 10 days. I have no evidence of birds settled to fly to a new loft-site by "inside" imprisonment, without external views, excepting the "nomad" type of training where a pigeon homed to a marked mobile loft, or basket, by recognition of the mark used also when feeding it.

While ability to home is known to be inherited (an untrained 2-months-old pigeon still squeaking homed 40 miles to one of my lofts, where it was bred) the homing territory is acquired after birth—pigeon eggs taken 100 miles to be hatched and reared "home" to the loft where they were reared, not where the eggs were laid. Pigeons returning to Scotland continued through the longer light of Scottish summer nights to arrive earlier than birds roosting in the darker English night before reaching English lofts. Pigeons liberated in fog distinct from merely ground-mist, are delayed, presumably by waiting for visibility to clear.

The more remarkable test of astral and sun navigation is not this long delayed homing of pigeons, but the annual return to the same breeding and wintering territories by trans-equatorial migrants, particularly the purely marine southern petrels and shearwaters, whose journeys cover seas with no landmarks.

Black Hole to the North?

SIR,—I read with extreme interest the editorial observation that, over the past ten years, "the population in the extreme North of Britain decreased, with Lancashire, Cumberland and Northumberland all returning figures lower than in 1961 . . ."[1] thus confirming the fears of those of us who dwell beyond the pale in the thirty-one counties of mainland Britain on the wrong side of Hadrian's Wall, that in fact we really do have no existence and that contracting population acting like some contracting stellar body has pulled the land mass with it leaving a "black hole" to the north of Carlisle.

Or perhaps the statement showed a trace of Anglo-Chauvinism in confusing the land of the English with the island of Great Britain?—an inauspicious error in a journal dedicated to the objective accuracy of science.

Unfair to Scientists

SIR,—During the period when the pay of civil service scientists has been the subject of public debate most of us concerned with the matter have felt the reports in *Nature* to be well balanced and to fairly state the case of both sides. Your conclusions have represented a fair assessment of the merits of the case. But, then, we could expect you as a serious commentator on scientific affairs to recognize what enormous damage would be done to the scientific community at large by the Civil Service Department's ludicrous pay offer to its scientific staffs. I should like, however, to emphasize the following points.

Regrettably, the arbitration tribunal has done nothing to resolve the basic problem. Anyone trying to reconcile the irreconcilable is likely to produce a nonsensical result. That was bound to be the outcome of trying to bring together "fair comparisons" and internal relativities. The Civil Service Department at least recognized the problem. They acknowledged that there were special circumstances affecting the pay of scientists but argued that they were irrelevant and, in any case, could not be measured. Thus, for them, there was no conflict. We were not prepared, and are not now, to have scientists treated as poor relations of their civil service colleagues in the technological field, nor yet of those in administration.

We will not take part in another pay research exercise and we are determined to get a joint review to establish a proper basis for future pay reviews for scientific staffs. We will press for early action on all of the structure aspects of Fulton, including the point which you rightly make about the need for scientists (and other specialists) to move across to more general administration. In part, of course, the point can be met by proper systems of accountable management but there will remain a need to move away from science for those who are going to get right to the top.

Neither this alone, nor in combination with your other point of allowing greater freedom to leave the civil service (a subject on which we are currently in discussion with CSD) will resolve the main problem. This remains the need to provide the great majority of scientific staffs—who will not become Chief Scientists or Permanent Secretaries—with a pay and career structure which matches that of those of their colleagues whose job weight, background and qualifications is unquestionably in no way superior to their own. That is not the case now; we are quite determined that it shall become so.

All this is far removed from your suggestion that we may become "entirely lost in detailed quibbles", or that we are taking an insufficiently radical view of what is needed. I should have thought that our aims are precisely those which would result in scientists assuming their rightful position in the Service. As you have recognized, it will be a sorry day for science and scientists generally if we fail. We do not intend to fail; there is too much at stake.

Yours faithfully,

CYRIL COOPER

Deputy General Secretary

History of "Plasmas"

SIR,—There has been speculation as to the basis for Irving Langmuir's use of the word "plasma" to describe a particular region of an electrical discharge in a gas. I was working for Langmuir when he made this innovation about 1927, and, much later, described it in a letter to a friend at the General Electric Research and Development Center, dated April 20, 1967. The pertinent extract from this letter follows.

"Meanwhile word had come down from on high that we had better do something about mercury-arc rectifiers and converters, which were the big new things in the electrical engineering world, although at that time they were all in glass bulbs. So Langmuir began to study mercury vapor discharges. He shortly invented his probe, I did the experimental work and most of the mathematics, and we soon accumulated a lot of data about ion densities and velocity distributions in the mercury arc columns, in the positive columns of Geissler tubes, and in gas-filled thermionic tubes.

"We noticed the similarity of the discharge structures they revealed. Langmuir pointed out the importance and probable wide bearing of this fact. We struggled to find a name for it. For all members of the team realized that the credit for a discovery goes not to the man who makes it, but to the man who names it. Witness the name of our continent. We tossed around names like 'uniform discharge', 'homogeneous discharge', 'equilibrum discharge'; and for the dark or light regions surrounding electrodes, names like 'auras', 'haloes', and so forth. But one day Langmuir came in triumphantly and said he had it. He pointed out that the 'equilibrium' part of the discharge acted as a sort of sub-stratum carrying particles of special kinds, like high-velocity electrons from thermionic filaments, molecules and ions of gas impurities. This reminds him of of the way blood plasma carries around red and white corpuscles and germs. So he proposed to call our 'uniform discharge' a 'plasma'. Of course we all agreed.

"But then we were in for it. For a long time we were pestered by requests from medical journals for reprints of our articles. This happens to me this day. The scientific world of physics and chemistry looked askance at this uncouth word and were slow to accept it in their vocabulary. The engineering world treated it as a GE trade name. Then all of a sudden, long after I had left the laboratory, to my pleased surprise, everybody started to talk about plasmas. This happened not long before they became thermonuclear and so government subsidized. That finally put the seal of respectability on plasmas."

Yours faithfully,

NATURE Volume 233 SEPTEMBER 24 1971

Why Not to Test Cannikin

THE United States Administration seems bent on making everybody wait until the last minute before knowing whether there will actually be an underground explosion of a five megaton weapon in the Aleutians in October. Both the Department of Defense and the Atomic Energy Commission have said that they see no reason why the Cannikin test should not take place, but President Nixon is wisely determined to make the final decision himself. After all, it is he and not the designers of the warheads for the Sprint ABM rocket who will have to travel to Alaska two weeks from now to spend an afternoon with the Emperor of Japan. He or the Department of State, and not the technical people, will also be the first and principal recipients of any trouble which may come from the way in which the Cannikin test is likely to offend the Soviet Union and disturb the SALT negotiations in Helsinki. And finally, of course, with the Atomic Energy Commission and the Department of Defense in constant trouble on issues as various as the proper siting of nuclear power stations and the continuing war in Vietnam, it is understandable that President Nixon should find it necessary either to fortify a decision to go ahead with Cannikin by the prestige of his own office or—perhaps—to abandon the project at the highest level.

In all the circumstances, the arguments against the Cannikin test need to be appreciated for what they are—chiefly political and diplomatic but also technical. After all, the Cannikin explosion will amount to five megatons. In previous underground explosions, the AEC has moved gingerly towards one megaton. The most powerful underground explosion so far under American auspices, the Milrow test carried out in the Aleutians in 1969, was, to be sure, a fairly reasonable sign that Cannikin will do very little damage. It is improbable that the event will trigger off tsunamis. It is also improbable that the worst fears of the protesters will be realised and that earthquakes will follow the explosion. But there is a greater risk of a leakage of radioactive material from the site. No doubt the cautious fellows at the AEC have done all they can to ensure safety, but it is only as recently as December 1970 that a miscalculation led to a leakage of radioactivity from an underground explosion in Nevada. That was only a small test, but even so it stopped the weapons testers in their tracks for close on half a year. Can they now be sure that the much larger undertaking in the Aleutians planned for October will be safe? And are they in a position to predict what diplomatic fall-out there will be if radioactive material should find its way either to the Soviet Union or to Canada?

Another and more serious issue is the extent to which such an obvious test of a warhead for an ABM may upset the negotiations at Helsinki. It is true, of course, that the issue is by no means simple. In the past few weeks it has begun to seem as if an agreement on the mutual limitation of anti-ballistic missiles would be the chief component of an agreement between the Soviet Union and the United States on the limitation of strategic weapons. The fact that a comparatively small item in the package, the agreement that there should be an improved method of instant communication between Washington and Moscow based on a communications satellite, was made public prematurely last week is a sign that there are serious difficulties in reaching a more comprehensive treaty. In circumstances like these, to be sure, it may be entirely appropriate that one potential signatory or the other should be seen to be pushing vigorously ahead with preparations for defence—if the Soviet Union earnestly desires an agreement on ABMs, testing by the United States may help to encourage an agreement. The difficulty, unfortunately, is that the Russians have been talked into believing that ABMs are bad. A show of obduracy may therefore be more a provocation than a pressure in the right direction.

It is possible, of course, that President Nixon has made an exactly similar calculation and that he intends, at the last minute, to call a halt to the Cannikin test. In that case no lasting harm will have been done. But if the explosion goes ahead as at present planned, it will be a great misfortune if the managers of the AEC are able to persuade themselves and the Administration, as they have done before (see page 230), that opposition to this event is entirely unfounded.

Creating a Professional Labour Market

THERE is in Britain a remarkable coincidence of view emerging about the steps which need to be taken to bring the output of the universities and other institutions of higher education more accurately into line with the demand. In the past few months (see page 225), pure mathematicians have been told by the Science Research Council that they must modify postgraduate courses in such a way as to produce graduates who are at once more broadly based than in the past, by which the Science Research Council implies a greater awareness of the fields of study in which pure mathematics can be profitably applied. The fact that some mathematicians are up in arms about this advice, and are pleading that such instructions entail an infringement of academic freedom, should be no surprise. This, after all, is what physical scientists said when the Science Research Council first embarked on its policy of increasing the proportions of students on short advanced courses in the entire population of postgraduates. To some extent, the mathematicians who protest will no doubt learn a lot to their discomfort in the report, issued this week, of the Working Group on Biological Manpower (see page 224), which comes out with an endorsement of the Science Research Council's old policy which is in turn endorsed by no less a person than Sir Frederick Dainton. On the face of things, at least, the Science Research Council will have no difficulty in winning its case. That, however, is only half the battle. It is also important to understand just why these policies are now in vogue.

The first thing to be said is that universities are by no means in scorn of academic ideals if, for some reason or another, they seek to educate students in ways which are considered a preparation for life in the outside world. It is, however, important that such a concern does not imply that higher education should consist of what is more commonly known as vocational training. Indeed, it should by now be apparent to all concerned that many of the difficulties which science graduates are experiencing in finding jobs are simple consequences of the narrow base of their education, however academic its character. Indeed, the university curriculum in science has over the years become a strange amalgam of education in the broadest sense, and training in techniques which are essential preparations for careers in professional science. The result, quite understandably, is that a great many scientists are hampered by their training from moving easily from one branch of science to another. The implications of this state of affairs for the labour market in professional science, clearly defined by the Working Group on biological manpower, are profound.

Jobs in professional science, in teaching, research or development, are bound in a relatively stable society to increase at a measured pace. The numbers of people employed in research, for example, are unlikely to grow much faster than the Gross National Product although, of course, there will be variations from one industry to another. To be sure, the pace of expansion in fields such as medicine may grow with great speed as a result of policy decisions to invest more social capital in health, but these are exceptional circumstances. And it is beyond dispute that all societies are likely in the next few years to want to increase their commitment to higher education as quickly as their commitment to any other form of expenditure. The consequence, of course, is either that courses of higher education which are vocational or partly vocational in character will grow less quickly than the universities as a whole, or that they they will keep pace with the general rate of expansion, but turn out graduates unable to find jobs. The figures for British higher education are striking enough. The output of graduates of all kinds was in the late sixties growing at 23 per cent a year at a time when the conventional demand for biologists, one of the most buoyant parts of the labour market in science, was growing at only 10 per cent a year. It has been conventional wisdom for several years to say that the growth of secondary education entails changes in the school curriculum, particularly in the sixth form. So far as undergraduate education is concerned, the only novelty in the present situation is that the same effect has been translated into higher education.

By good luck, or perhaps even by good judgment, there have in the past few years been some important experiments in the design of broader university courses of a kind likely to turn out graduates who are likely to be comparatively flexible in their choice of a career, either within science as a whole or in such a way that a scientific background is considered an important part of a general education. Without in any sense decrying the value of the boldest experiments of all, the attempts to introduce into universities thoroughly liberal courses of scientific study, much must be said in favour of more arbitrary marriages between courses of different kinds—physics and economics, for example. To be sure, in these respects British universities and other institutions of higher education are still much more narrow than their counterparts elsewhere, especially in the United States, but there is at least a chance that some of the new courses being tried out may have the advantages of breadth, and of the discipline that goes, or is supposed to go, with depth. Although in the past, universities (especially in Britain) have been inclined to think that new courses or combinations of courses can be launched after a sufficiently long period of committee meetings within the faculty, the truth is that much remains to be done before there is an objective appreciation of the advantages of different methods of educating science undergraduates more broadly. All those who pronounce on the subject, the Science Research Council and the Working Group on biological manpower included, have an obligation to say as much and, when they have the power, to spend money on this cause.

The issue of postgraduate education is more complicated. For four years, the declared policy of the Science Research Council has been to maintain in postgraduate courses a constant proportion of those taking first degrees in science and engineering, but to ensure that increasing proportions of the postgraduate students will follow courses of advanced study lasting one or two years. In other words, although the numbers of PhD graduates will continue to increase, the proportion of first degree graduates completing PhD courses will at the same time decline. It is of course important that this policy has been linked with the deliberate attempt by the research councils to divert science students towards practical studies and with the policy of selection and concentration by means of which some departments in certain universities have been encouraged to develop in directions in which they excel. Those pure mathematicians who are now protesting might equally well have cried scandal at any time in the past five years, for the intentions of the Science Research Council have been declared policy all along. Moreover, the question asked about them is not whether they entail an infringement of academic freedom whatever that may mean, but whether they are in the best interests of students and of society at large.

There is at least some reason to believe that the attitudes towards PhD courses which are now becoming conventional are too draconian. To be sure it is easy enough to argue that if undergraduate courses in British universities have a dangerously strong vocational flavour, then PhD courses, which prepare people for research and virtually nothing else, are even more restrictive. This is one of the reasons why the Science Research Council has come down strongly in favour of postgraduate courses which last for only one or two years and, with such a pattern, it is of course easy to see how the selection of PhD students might be carried out in such a way as to provide cohorts of young men and women even more dedicated to research and the ivory tower than they are at present. The flaw in the argument is of course the assumption that a long postgraduate course consisting to a large extent of original research is exclusively a preparation for a career in research or academic life. To be sure, it is remarkable that in the past few decades, even such a narrow preparation has made it possible for growing proportions of the PhD population to work at other tasks. Moreover, if a scientific education may be a good intellectual preparation for a general career, may not a properly organized PhD course be still better? This is one question that should be answered objectively before too much is done to concentrate PhD courses still more narrowly on the needs of research and the universities, for that will only create a set of circumstances in which the assumptions underlying the new policy become self-justifying. And as at the undergraduate level, so in the graduate schools, nobody knows what kinds of curricula would exploit these opportunities most efficiently. In short, those committees which are inclined to follow the Science Research Council and the biological manpower committee in asking for smaller proportions of PhD students should first of all apply themselves to learning more about the functions of postgraduate education.

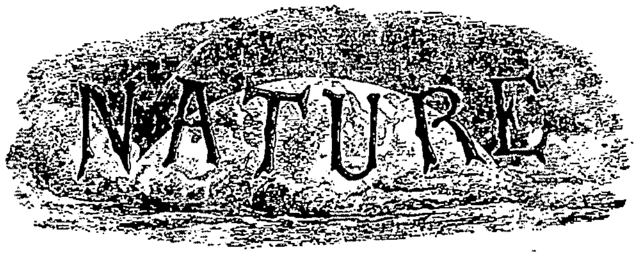
Pugwash Joins the Establishment

As the years go by—there have been fifteen of them so far—the Pugwash conferences have become respected and even respectful. The twenty-first conference, held at Sinaia in Romania at the end of August, seems to have been one of the most sober and constructive so far. Certainly the document now published by the Pugwash Continuing Committee is much more closely argued than many of its predecessors. For what the declaration of a private group of people is worth, the document also serves to bridge many gaps which have on previous occasions been contentious issues in Pugwash and elsewhere. On this occasion, for example, it seems to have been widely agreed that anti-ballistic missiles should be abandoned by the nuclear powers and that indeed the SALT agreement should not merely limit the possession of ABMs by the United States and the Soviet Union, but should actually abolish them. The conference appears to have taken a cheerful view of the decision to ban biological weapons, and the throng of signatories to the Geneva Convention in the past few months, but in pleading that governments should not therefore be diverted from the search for an agreement on chemical weapons, the delegates to the Pugwash meeting appear to have been divided—as indeed their governments are—on the need for on-site inspection. Sensibly enough, the meeting has reaffirmed its belief in a comprehensive test-ban treaty as well as its scepticism about the supposed economic benefits of nuclear explosions for peaceful purposes.

The surprising familiarity of these views does not of course imply that Pugwash has ceased to be a valuable institution. Over the years, it has demonstrated that it can at times of stress serve as a valuable channel of communication between East and West. It is a fact, even if now a comparatively old fact, that Pugwash helped enormously in the negotiation of the partial test-ban treaty in 1963 and 1964. As it has developed, the organization is no doubt regarded by all governments as a valuable listening post, to say nothing more of it. In the circumstances, however, it may not be surprising that Pugwash has fallen into one or two familiar traps, at least as far as can be told from its latest declaration. In Romania this year, there seems to have been a general feeling that political circumstances now favour an international conference on European security along the lines of the proposal being canvassed by the government of Finland. The notion is that there should be to begin with a mass renunciation of the use of force and of tendencies to interfere in other people's internal affairs, and the recognition of boundaries, renegotiated as necessary. The latest statement includes a string of detailed proposals about the regulation of tactical nuclear weapons in Europe that might be a sensible basis on which to construct a more permanent agreement. Outside Europe, on the other hand, the statement of the Continuing Committee consists largely of hand-wringing over the war in Indo-China and the renewed threat of war in Korea. But is this not too Western a view of what needs to be done to make the world a safer place in the decades ahead? Pugwash is wise not to chase some of the hares which used to distract its attention, but is there not a strong case for keeping permanently on its agenda the search for the issues which may replace the threat of a European war in the seventies and eighties? Should not, for example, Pugwash be working hard at the design of international institutions likely to help with such things as the regulation of fish or telecommunications, two obviously contentious issues? Another trap into which there is a danger that Pugwash might fall—the latest statement from Romania skirts carefully around the edges—is the tendency to repeat clichés about the environment.

---

100 Years Ago



When ocean cables were first submerged, various apprehensions of probable injury were entertained, some of which have proved to be well founded, and others less so. It was supposed that worms or mollusks would burrow in the substance of the envelope, and ultimately penetrate to the centre of the wires; or, again, that the attachment of barnacles, mollusks, or other marine animals on the exterior would invite the attacks of the sharks, rays, and other fish of powerful jaws, and induce them to subject the bunch of matter to such a mastication as should produce serious harm to the cable. To what extent any accidents have happened from this source it is perhaps difficult to say; but we now learn from *Harper's Weekly* that the Florida cable between Punta Rosa and Key West has been injured in numerous places, as supposed by sea-turtles biting through or crushing it in their teeth, to such an extent as to destroy its continuity. It is, perhaps, a question whether the turtle be chargeable with these operations; and we think it is quite as probable that, under the circumstances, some ray or other fish has attacked it, and for the reasons already suggested.

From Nature, 4, 436, *September* 28, 1871

OLD WORLD

ENVIRONMENT

Global Watch

from a Correspondent

Canberra, September

A FRUITFUL meeting in Canberra on September 1–3 has ensured that several ambitious and promising proposals for putting global environment monitoring on a firm scientific footing will be put to the Stockholm Conference on the Human Environment in June 1972. The proposals, prepared by working groups of the Special Committee on Problems of the Environment (SCOPE) of the International Council of Scientific Unions (ICSU), were adopted at SCOPE's first general assembly here. The chief proposal is for a world-wide monitoring system aimed at helping to detect significant and potentially harmful changes in the environment early enough to take preventive action, and eventually to predict harmful trends before they occur. To back this up, a SCOPE committee is examining methods of analysis for major pollutants in air, water and biological tissue and hopes to make recommendations on the best methods for measuring each pollutant by the end of 1972.

The proposals were prepared at the request of Mr Maurice Strong, the Secretary-General of the Stockholm Conference, who was an invited guest at the meeting. They call for the regular collection of data from a global network of a hundred or more selected areas exposed to minimal, medium and intense human impact. Every nation is being urged to set up a national monitoring office to integrate its own monitoring effort and to contribute to international coordination. Also existing monitoring activities would be fed into the system.

The working group listed three sets of problems which deserve the highest priority for global monitoring: potentially adverse climatic changes resulting from human activities; potentially adverse changes in biota and man from contamination by toxic substances; and potentially adverse changes in biological productivity caused by improper land use. Highest priority is given to atmospheric measurements of turbidity, carbon dioxide, surface solar radiation and standard meteorological variables; monitoring mercury, lead cadmium, DDT and polychlorinated biphenyls in air, water, soils and biota; keeping check on a variety of data reflecting the state of human health; and implementing studies of vanished or endangered ecosystems and vertebrates and of the population size and distribution of birds. The documents say that research activities and pilot studies are essential for defining and evolving detailed monitoring programmes where necessary, and recommend the establishment of internationally funded and staffed laboratories in at least three monitoring areas subject to minimal human impact.

Mr Strong told the assembly there had been a gratifying response to requests for contributions to the conference from governments, United Nations agencies and scientific organizations. He predicted that the main constraints on necessary environmental projects after Stockholm would be political unwillingness on national levels, not a lack of sufficient ingredients for action. Mr Strong also said that another conference, similar to that at Stockholm, might be needed within three or four years, and argued a case for continuing and consolidating the present organization for Stockholm—in effect advocating a new UN agency for the environment. This proposal runs counter to the views of the existing UN agencies with fingers in the environmental pie (for example, UNESCO, FAO, WHO) and the scientific unions, who see it as, on the one hand, a threat to their existing responsibilities and, on the other, as an unnecessary proliferation of international bureaucracies. In pressing his case, Mr Strong said "I don't think we are at a sufficient state of readiness in terms of knowledge and particularly political willingness, to do all the kinds of things that are going to be necessary".

BIOLOGICAL MANPOWER

Broadening the Base

PROFESSIONAL biologists are the latest to be told that their education should be broader and that they must be more ready to change disciplines in mid-career. The *Report of the Working Group on Biological Manpower* (HMSO Cmnd Paper 4737, £0.85), published this week, also echoes previous declarations by, for example, the Swann committee (of which it is a descendant) that qualified scientists must broaden their concept of what constitutes a professional job as the output of the universities and other institutions of higher education grows so as to outstrip what is at present considered to be the demand. The working group, the chairman of which is Dr Richard D. Keynes, director of the ARC Institute of Animal Physiology at Cambridge, is, like other bodies, anxious that university departments and grant-giving bodies should in future discriminate more carefully between graduate students who can make proper use of a PhD course and those who have less aptitude for original research.

Sir Frederick Dainton, chairman of the Council for Scientific Policy, is one who plainly finds the group's recommendations to be acceptable. In his introduction to the report, he says that "much of the report could be applied to science in general". Taking his cue from his own report on the subject, now five years old, he goes on to say that "it will have to be recognized increasingly that on the one hand a specialist scientific education will not guarantee employment at a professional level in the subject of a graduate's specialization" and that graduates in science have valuable jobs to do outside the confines of their profession.

The members of the group are as follows: Dr H. O. J. Collier, Mr D. J. B. Copp, Dr F. A. E. Galley, Professor J. M. Mitchison, Professor S. J. Pirt, Professor M. M. Swann and Professor C. P. Whittingham. Apart from statistics which exist already, the working group had access to the results of employment surveys carried out within the research councils and a questionnaire survey within industrial organizations.

By 1968, the 10,918 biologists employed in Britain accounted for more than ten per cent of all scientists, but their numbers were growing more quickly, at an annual rate of 5.5 per cent, compared with 4.4 per cent for scientists as a whole. Understandably, most biologists appear to be teachers at some level, 8,100 of them in schools, universities and further education. These calculations, of course, omit those who work in medicine, dentistry and health, more than 95,000 in 1966.

The essence of the employment problem identified by the working group is that the annual growth of the production of first degrees in biology is accelerating and amounted to 19.9 per cent per year in the late sixties, while the annual percentage growth of biologists with higher degrees amounted to 21.7 per cent per year. These rates of growth are greater than the corresponding rates in other branches of science, but not markedly so. On the other hand, the number of extra jobs likely to arise each year by natural causes is estimated to be something between rather more than 1,000 and rather less than 1,200 qualified people, or roughly ten per cent of the working population of qualified biologists. Either the remaining ten per cent have to be unemployed or have to find jobs elsewhere.

On the broadening of the curriculum, the working group says that this is the best way of minimizing "the undesirable effects of an imbalance between the supply of biological graduates and the demand for their services in specifically biological fields". It recognizes that one consequence must be more mathematics and physics in the training of biologists at all levels. The working group is a little heartened to see that only 33 out of 44 universities now offer separate courses in botany and zoology. At the postgraduate level, the working group is a little taken aback to find that employers seem to prefer what it calls "conventional" postgraduate courses but unabashed, and suspecting that the predilections of government research establishments have had an undue influence in previous inquiries, the working group goes on to say that the PhD course should be improved. It fears that too many specialist PhDs might mean "individual frustration and unhappiness" and asks for bold experiments, for more stringent selection for PhD courses and for graduate courses aimed both at providing professional people with up to date information and with matching the education of biologists to the non-professional jobs which they will increasingly be required to take.

MATHEMATICS

Pressure of the Purse

MATHEMATICIANS in Britain are concerned that academic freedom may be infringed by an apparent change of policy by the Science Research Council Mathematics Committee. A protest on the subject from Professor W. B. Bonnor of Queen Elizabeth College, University of London, appeared in *The Times* last week. He complained that the SRC is instituting standards other than those of academic excellence in allocating research studentships.

The issue has been brewing since March this year, when heads of mathematics departments at British universities were told in a letter from the secretary of the SRC Mathematics Committee of anxiety about career prospects for MSc and PhD graduates in pure mathematics, many of them pensioners of the SRC. The committee said that in the next few years, research in pure mathematics is likely to offer fewer opportunities for jobs than the number of students being trained and that in the circumstances it would be prudent for mathematics departments to broaden the training given to graduate students by means of courses in applied mathematics, theoretical physics, engineering subjects, computer science or business economics. In March, mathematics departments were asked to let the Science Research Council's committee know how they were responding.

Fuel was added to the flames of protest at the end of June by a second letter asking that within twelve months the committee should be told what had been done and saying that it would then "hope to feel well-enough informed to be able to reflect departments' efforts in next year's quotas of studentships".

Professor Bonnor sees this as an attempt to dictate how mathematics should be taught at postgraduate level. He said last week that "although a case can be made for what the SRC is trying to do, there is no justification for making mathematics departments carry it out by threatening their financial support." He also said that the SRC's suggestions were ill-conceived. First, a course of twenty or so lectures on any of the suggested topics would not help students to find jobs. Second, such courses of lectures would lower the standard of the PhD degree. Third, courses would not make students more valuable to employers. Professor Bonnor is only a little more cheerful about intensive courses after completion of the PhD course. He emphasizes that the only criterion that should determine the support for a university department is the excellence of its research.

A written explanation from Sir Brian Flowers, chairman of the Science Research Council, to Professor Bonnor says that "the SRC would not dream of dictating to mathematics departments how they should do their research or teach their postgraduate students and I cannot see that anything that has been written implies this; however, we do hope to encourage mathematics departments to think about the design of their postgraduate activities in the light of the fact that many of the students almost certainly will eventually be seeking employment outside the purely academic field".

Heads of other mathematics departments share Professor Bonnor's views but less strongly. Professor G. Higman, University of Oxford, said last week that his department had answered the letters but that unemployment of Oxford PhD mathematics students is not a problem—general courses for mathematicians are, however, already offered at Oxford. Professor D. J. Bartholomew, University of Kent, is concerned about the implications of the letters and feels that as a matter of principle the SRC should not dictate to departments on matters of curriculum. Professor H. B. Griffiths, University of Southampton, said that the SRC request does not necessarily infringe academic freedom but that the mathematical postgraduate teaching at Southampton had already been "broadened".

The Association of University Teachers is particularly interested in Professor Bonnor's claim and it is on the agenda for discussion at the AUT's meeting in Bath today. Dr Sheila Brenner, senior vice-president of the AUT and chairman of the AUT's education committee, said earlier this week that "although the AUT expects graduates at both first and higher degree level to tackle a variety of problems in industry and other occupations, it is not the university's function to give them job training." She went on to say "Our general opinion is that external direction to educate students in particular ways may well prove counter productive in the short run and in the long term will be damaging to the national interest".

Dr Brenner also said that "many university departments are under considerable financial pressure at the moment and while we would welcome additional funds for those departments which have plans for experiments to improve the education they offer their students, we shall watch carefully to see that this is not done at the expense of departments which do not consider a particular pattern of education appropriate."

RESEARCH AND DEVELOPMENT

No Wolf at the Door?

DR BASIL BARD, managing director of the National Research Development Corporation since July, seems unperturbed at the Docksey Inquiry for the Department of Trade and Industry into the NRDC's arrangements for the exploitation of inventions. The inquiry could mean that the NRDC's days are numbered, but Dr Bard, speaking after the publication of the corporation's Twenty-second Annual Report (HMSO, £0.45), said that until the results of the inquiry became known towards the end of the year, the NRDC was carrying on as usual and that he had "no reason to believe that we won't carry on substantially as usual" after the results become known, with possibly some changes of direction and emphasis. In the report Dr Bard welcomes the inquiry, and says "it seems to us timely that the corporation and its work be reviewed in the light of the present-day and future requirements of the country", adding that "the salient figures for the past four years offer in our view a reasonably encouraging picture" of the corporation's work.

The report shows that the corporation's income exceeded £6 million for the first time and that its revenue account showed a small surplus (£68,960) for the third successive year.

The activities of the corporation expanded during the year with 96 new development projects being undertaken and with 404 projects receiving support compared with 377 in the previous year. Of these projects 186 are joint ventures with industry. The corporation's investment in development projects rose from £5.8 million in 1969–70 to £5.9 million last year, and recoveries from the projects amounted to £2.4 million last year compared with £1.3 million the year before.

The corporation has a borrowing limit from the Department for Trade and Industry of £50 million with which to finance projects, and £24.8 million of this was in use to September 1971, £1.3 million more than at the same time last year. The actual annual borrowing for the year fell from £4.88 million in

1969–70 to £2.85 million. Licence income from patents, the corporation's biggest source of income amounted to £3.7 million, of which £2.7 million were foreign currency earnings. The drug cephalosporin C was again the largest revenue earner.

Submissions of new projects for support rose from 2,194 to 2,535, but the numbers presented by the universities and industry both fell, the increase coming from submissions by private inventors. The corporation felt that the fall in applications from industry was "a possible reflexion of the cutting back of research and development by firms encountering cash flow difficulties". Commenting on this Dr Bard said that he was convinced this was "only a hiccup" in the growth of research and that it would be "the greatest mistake at the present time to cut down on research and development".

RESEARCH AND DEVELOPMENT

Small Firms Feel Pinch

A REPORT on *Scientific and Engineering Manpower and Research in Small Firms* (HMSO, 40p), published last week, concludes that the use of scientific and technical personnel in small companies may be linked to the capital intensiveness of the industry concerned.

The report, one of the research studies commissioned by the Bolton Committee of Inquiry on Small Firms, sets out to examine the degree to which small companies—those with between eleven and 200 employees—are in a position to benefit from, and contribute to, the technological advance of British industry.

The report shows that small companies employ about a third (2.5 million) of all employees in manufacturing industries, but only 15.5 per cent of the equivalent of graduate qualified engineers, technologists and scientists (QSEs). (Figures are for 1968.) This is a proportion of QSEs to other employees of 0.7 per cent, only half that of larger companies. The distribution within small companies is not even, but small electronics companies alone have a higher proportion of QSEs than their larger competitors. The proportion of QSEs in small electronics companies is higher than in other small companies because research in electronics is a rapidly advancing technology at a highly theoretical as well as a purely practical level, and because "materials are relatively inexpensive and large capital facilities are unnecessary". Innovation in fields such as mechanical engineering requires a bigger "technological step" and large expenditure on the trial and testing of new products.

This led to the conclusion that capital-intensiveness may be the key to QSE employment in small companies, and the observation that many small companies rely on contracts with outside laboratories for their research work as this limits the extent of their expenditure and removes the necessity of maintaining their own full-time research facilities.

The expected growth rate for small companies from 1968–71 was 27.1 per cent compared with 20.9 per cent for all companies. If the report's suspicions about a "technological step" are right, then this "implies a barrier to greater employment of QSEs and further technological advance".

MUSEUMS

Timbers to Greenwich

from a Correspondent

THE National Maritime Museum (NMM) at Greenwich is advertising for an archaeologist to be appointed at the relatively elevated rank of Assistant Keeper. This is certainly novel, and may be thought bizarre, but it is the direct result of the archaeological "rescue" of the Graveney boat unearthed in Kent salt marshes last October (*Nature*, **228**, 402; 1970) and since then carbon-dated by the British Museum as late ninth century.

The new director of the museum, Mr Basil Greenhill, has a number of sweeping plans for a new look for the NMM and one of them is to extend the exhibition of boats on display. Apart from the *Cutty Sark* nearby, the museum has relied on its superb collection of contemporary models and numerous fine marine paintings to demonstrate the art of shipbuilding. At present its largest gallery, the Victorian Neptune Hall, is being converted to accommodate boats of different periods, not all of them small, such as the 1900 paddle-wheel tug *Reliant* whose fore-end including the bridge and engine room will form the centrepiece of the display when the hall is reopened next year. The opportunity of adding a pre-Conquest boat to the group was too good to miss although, by any estimate, the Graveney boat is no beauty.

Very considerable expertise is required to derive the full information retained in the lines and timbers of an antique vessel especially when it is sodden with salt water. The expectation is that the successful candidate, whether his or her training is in archaeology, anthropology or naval architecture, will have to acquire a number of other special skills. There is nowhere to train in the field of nautical archaeology, so the unit's archaeologist will have to resort to self-improvement. Besides looking to the eventual display of the original Graveney boat in Neptune Hall, there is a plan to build a replica and row it across the North Sea as the Anglo-Saxons did when they journeyed between Kent and the Continent. Altogether some £50,000 has been committed to this unit.

Once the unit is in existence it will obviously do more than simply process the Graveney boat; a committee of experts will screen other candidate timbers or craft for treatment and preservation. This will provide a unique facility for Britain. There are few other places in the world where waterlogged wood up to 50 foot long can be handled. Will there be a rush of old timbers to Greenwich? One thing is clear—the line is being drawn at boats, and specifically boats less than 50 foot long. There is no possibility that the eighteenth century East Indiaman, *Amsterdam*, buried at Hastings, or Henry V's *Grace Dieu*, still in the mud of the Hamble river, will be imported to the Greenwich tanks.

EDUCATION

Computing in Schools

THE view that teacher training is the most urgent need in the expansion of computer science teaching in secondary schools is put forward in a report of an international seminar held in Sèvres during March, 1970 (*Computer Sciences in Secondary Education*, OECD, Paris; 1971 ; £1.90).

The report, like the papers presented at the six-day meeting, recognizes the need for several types of school computing course, which could be taught by teachers with quite different educational backgrounds. These include appreciation courses which require almost no computer time and could, in principle, be taught by any numerate teacher, and other courses which contain more instruction in programming and in the working of computers; these would have to be taught by mathematicians or scientists. Ultimately, says the report, the aim should be to include at least a computer appreciation course in all secondary school teacher training.

Much of the seminar was taken up with discussions of the significance and objectives of the teaching of computer science in schools. There was agreement that one of the important functions of computer education is the encouragement of skills in organizing and handling information, which are useful in the study of most subjects and which help to convince pupils that information is a means to an end but not an end in itself.

Even the simplest appreciation course requires a certain amount of access to a computer, if the subject is not to appear to be too abstract, and the report suggests that agreements should be encouraged which allow pupils' programs to be run on computers belonging to local authorities, universities and companies. Twenty of the 160 local authorities in England and Wales, for example, encourage the use of their management service computers for educational purposes and about 30 per cent of schools which run computing courses make use of these facilities.

AIRPORTS

Up, Up and Away

For the first time, each of the four airports of the British Airports Authority has shown a net profit over a financial year—that ending March 31, 1971. Taken together, Heathrow, Gatwick, Stansted and Prestwick have been profitable since 1962, but only because the large profits at Heathrow have more than compensated for losses elsewhere. Although the total profit in the past financial year is seven per cent less than the record of £9.5 million in 1969–70, there is obviously merit in the even spread of profit. Edinburgh airport, handed over to the authority on April 1, 1971, is also budgeted to show a small profit in the current year.

Apart from economic considerations, recent months have been marked by the controversy over the siting of the third airport for London, and the final decision, made on environmental grounds, in favour of Foulness. This decision is discussed in the recently published annual report and accounts of the British Airports Authority (HMSO). The authority's view is that none of the four sites on the Roskill Commission's short list is really suitable for a major new airport and that of the four, Foulness is, on economic grounds alone, the least suitable.

Other environmental issues also appear less disheartening than when the 1969–70 report of the authority was published. The noise problem remains, but it has been shown that jet engines are much cleaner than those of surface traffic, so that in the past year—the first in which jets accounted for more than half of the world's airline fleet—airports had less concentrations of pollution than ordinary urban districts. Concentrations of smoke and sulphur dioxide recorded at Heathrow in the summer of 1970 demonstrate this dramatically (see Table).

Table 1 Comparative Average Concentrations of Smoke and Sulphur Dioxide in the Atmosphere at Heathrow, Summer, 1970

In Westerly Winds	From the West (outside the airport)	From the Airport
Smoke	16	15
SO$_2$	152	59
In Easterly Winds	From the East (outside the airport)	From the Airport
Smoke	29	26
SO$_2$	208	91

What of the further growth of air traffic, and the difficulties of coping with this without damaging the environment? Between 1960 and 1970, the number of flights to and from British airports grew from 402,000 to 607,000, while the average number of passengers per air transport movement increased from 25 to 52 as the size of average loads increased. The authority expects that the average load per flight will continue to increase by six per cent a year throughout the 1970s, and that by 1985 the airports of the UK will be handling, on a "middle" forecast, 130 million passengers, 5 million tons of cargo and 1.1 million flights a year. In 1970, the equivalent figures were 32 million passengers, 0.5 million tons of cargo and 600,000 flights. It will, indeed, be a "substantial task" to meet these demands, even if the Foulness development lives up to its proponents' greatest expectations.

Miscellaneous Intelligence

Britain's problems of what to do with some of its graduates and school-leavers do not seem to be shared by the Soviet Union. Mr Boris Kostin, head of the Moscow Employment Board claimed in a recent interview in the Soviet press that no school-leaver in the Soviet Union has any difficulty in getting a job. Those without any professional skills are trained on leaving school for several months at half pay, and a wide choice of jobs awaits them upon completion of training. Moscow in particular has an "insatiable" demand for workers in the service spheres, and for clerical and municipal workers. Moscow's largest construction company alone is building more than 100,000 flats a year.

Between 1960 and 1970 the number of visitors to those of Britain's principal monuments in the care of the Department of the Environment almost doubled from 6,800,000 to 12,500,000 and total fees received quadrupled to almost £1.1 million, a sizable part of the department's 1970 budget for ancient monuments of £2 million.

These figures were quoted by Dr A. J. Taylor, Chief Inspector of Ancient Monuments and Historic Buildings, in Hamburg, where one of the department's two touring exhibitions of "Historic Monuments in Britain" is showing this week. The two exhibitions have toured Britain and the mainland of Europe (the second exhibition is now at the Banqueting House, Whitehall) and the exhibition now at Hamburg will go next to Tokyo.

Scientists from the Soviet Arctic and Antarctic Institute have been studying the movement of glaciers in the Antarctic by means of laser beams. The experiments were carried out in the Molodezhnaya station area on the coast of the Sea of Cosmonauts and were implemented by installing a 20 cm diameter mirror on a glacier. The glacier was then tracked by a reflected laser beam and it was concluded that its movement was random—movement occurred sometimes within seconds and sometime within hours.

The fossils of fifteen dinosaur eggs found at Ologoi Ulan Tsab by the 1968–69 Soviet-Mongolian Geological Expedition bring the number of types of dinosaur eggs found in the Ghobi desert to eight. All are ornithoid in structure, the Ologoi Ulan Tsab eggs having a diameter of 14–15 cm with an estimated fluid content of 1.5 l. The eighteen amino-acids identified by chromatographic analysis suggest that the shell membrane was basically keratin, as in modern reptiles. A comparison of these eggs with the testudoid dinosaur eggs found at Aix in France should provide data on the evolution of the different orders of dinosaurs and their relationship to other fossilised and modern vertebrates.

Research in the USSR has shown that the migratory isabelline wheater (*oenanthe isabellina*) is a carrier of bubonic plague. The bird nests in rat holes and it has been found that its fleas feed as readily on the blood of rats, notorious plague carriers, as on their original hosts which they inflict upon returning to them. It was found during studies that birds so infected lived on for more than ten days, which presents a serious problem in controlling the spread of plague as the migratory birds would travel some distance in that time. The discovery helps account for the resurgence of the plague in areas of Russia where anti-rodent programmes in the early fifties had successfully banished the disease for some years.

NEW WORLD

Yet Another Prescription for Cancer

by our Washington Correspondent

THE National Institutes of Health may yet be rescued from dismemberment by the setting up of an independent cancer research authority. The proposals, which have so far achieved the dubious distinction of almost uniting the Senate in support and the biomedical community in opposition, last week entered a critical stage in their passage through Congress when they became the subject of hearings before the House Subcommittee on Public Health and Environment. But just as it seemed that members of the House of Representatives, like their colleagues in the Senate, would be placed in the unfortunate position of either voting for a measure likely to break up the National Institutes of Health or of recording their dissent and being accused of refusing to support cancer research, Mr Paul G. Rogers, chairman of the Health Subcommittee, offered a solution that may preserve both the structure of NIH and the integrity of Congressmen.

With the support of five members of his subcommittee, Mr Rogers last week introduced a bill designed to give the National Cancer Institute authority for coordinating all the activities of the NIH related to cancer research, and a budget of $400 million for 1972, rising to $600 million in 1974. The bill, which was written with the help of cancer researchers, also keeps the National Cancer Institute firmly within the NIH.

Before Rogers had introduced his bill, it seemed likely that the House would follow in the footsteps of the Senate by voting through a bill which in effect would take the National Cancer Institute outside the NIH umbrella and place it in an agency operating under the unfortunate and misleading name of the Cancer Cure Program. The Senate gave its blessing to the creation of the agency by a vote of seventy-nine to one, and since the bill also bore the sponsorship of the Administration, it looked set fair to sail through the House and into law with the opposing voices of the biomedical community drowned in the political rhetoric.

As passed by the Senate, the bill would set up the Cancer Cure Agency as an "independent agency within the National Institutes of Health" and would endow it with "such sums as may be necessary". The agency would have its own budget, a director at the same executive level as the director of the National Institutes of Health and its own bureaucracy To call it an integral part of the NIH on the basis of its geographical location in Bethesda would therefore clearly be a misnomer, and any doubts about the subsequent bad health of the national institutes if the bill were to become law should have been swiftly cast aside when the National Heart and Lung Institute asked for similar treatment. There is little doubt in Bethesda that the Senate version of the bill would signal the break-up of NIH if it were passed unchanged by the House.

In contrast, the bill introduced last week by Congressman Rogers and his colleagues is designed to represent as closely as possible the views of the biomedical community, but at the same time it makes a few obvious concessions to the thinking that lay behind the Senate's adoption of the Cancer Cure Program. If adopted, the bill would give the National Cancer Institute more independence and considerably more dollars than at present, and make it better known, but its standing in the National Institutes of Health's bureaucracy would not be greatly different from that of other institutes.

The key strategem in Rogers's defence of the NIH is to seek to buy off other proposals with the promise of $400 million to the National Cancer Institute for the present year—more than $60 million above the amount appropriated by Congress last month, which itself included an extra $100 million requested by President Nixon in May. The Rogers bill would therefore distribute Congressional largesse to the National Cancer Institute at almost double the rate for 1971, and by 1974, the NCI would have nearly three times as much money as it is now accustomed to spend each year. Even this bid may, however, be too low to succeed in tempting the supporters of a separate agency to abandon their ideas, for the original proponents of a cancer cure agency were asking for funding to reach $1,000 million by 1976.

As for the bureaucratic arrangements for cancer research within the National Institutes of Health, the Rogers bill would promote the director of the NCI to the level of Associate Director of NIH. And before other agencies have a chance to complain that they would be relegated to the status of poor relations, the bill similarly promotes the directors of the National Heart and Lung Institute and of the National Institute of Neurological Diseases and Stroke and makes all three positions political appointments directly from the White House. The grouping together of these three institutes is suggested on the basis that, between them, cardiovascular diseases, stroke and cancer account for about 75 per cent of deaths in the United States, and it firmly underlines Rogers's belief that the political dust kicked up during the debate about cancer research should not be allowed to obscure the legitimate claims of other areas of biomedical research. Ironically, however, previous suggestions that the director of the NCI should be a political appointment have come under fire for placing unnecessary political ties on biomedical research, and the move to extend this provision to other institutes will do little to head off those criticisms.

Perhaps the most important provision in the Rogers bill is that the budget of the National Cancer Institute should be submitted directly to the President for review and referral to Congress. Although the Director of NIH, the Secretary for Health, Education and Welfare, and the National Cancer Advisory Council would have a chance to look at and make comments on the NCI budget, they would be constitutionally powerless to alter it. This proposal in effect may help to turn the cancer budget into a political football, to be debated separately in Congress each year, but it will also keep public attention focused on the efforts of Congressmen to help find a cure for cancer—a sure way of ensuring that funding for cancer research is maintained at a high level.

This proposed budget mechanism, although generally regarded as a lesser evil in comparison with setting up an entirely separate agency, will present a few difficulties for the National Institutes of Health. For one thing, the flexibility built into the present system, whereby budgets for the separate institutes are channelled through the director of the NIH, would be lost if the Rogers bill were put into effect. At present, revisions are made in each institute's budget right up to the time that the Administration's budget goes to press. But if the NCI's budget is to be reviewed by the Director of NIH, the Secretary of HEW and the National Cancer Advisory Council, not only must it be drawn up a good deal earlier but it would also not be open to last minute change One official of the

NIH described this arrangement last week as a "formula for chaos", but Rogers's supporters defend it on the basis that it will assist the NCI in its planning if it can be sure that its budget request is transmitted to the President without arbitrary alterations designed to make the NIH's budget request fit the global sum allowed by the Office of Management and Budget.

Another provision in the Rogers proposals that has been billed as a means of speeding up grant applications, and therefore, by implication, the development of a cure for cancer, is the suggestion that all the directors of the research institutes should be able to distribute grants of less than $20,000 without first seeking approval from the National Cancer Advisory Council. In the past, the advisory council has met only three times a year, and this has led to accusations of unnecessary delays in the processing of grant applications. But the force of the new proposal is probably more rhetorical than actual, for it will only speed up grant applications by at the most one or two months in a process that now takes between six and eight months, and there are no suggestions that researchers and equipment are standing idle during the application process.

The proposed arrangements are, nevertheless, being welcomed for two reasons. First, they will take some of the burden of reviewing straightforward and minor grant applications from the shoulders of the National Cancer Advisory Council, and make it less of a rubber stamping body. For another, if the proposal is accepted, it would do little damage to the established review processes of the NIH. NIH officials are naturally suspicious of any change in the grant review process, and they are particularly concerned to preserve the scientific peer review, but they accept that the force for change has probably gained irresistible momentum. The Rogers bill is regarded as doing the least damage since it applies to about 26 per cent of the NCI's grants, and in any case to the grants which usually generate the least controversy.

What chance has the new bill of succeeding where previous attempts to inject some rationality into the debate about cancer research have failed? One of the chief obstacles in the path of the bill is clearly the fact that an independent NASA-style agency dedicated to finding a cure for cancer makes an ideal subject for political hyperbole—the Senate debate on the proposal provides a good example—while a proposal in effect to give more money to existing institutions lacks the same lustre. Another difficulty facing Rogers and his supporters is the fact that the Senate has already passed the Administration's bill designed to give the National Cancer Institute independent status, and whatever the House passes must be amalgamated with the Senate bill in a conference committee. Although members of the biomedical community can find many acceptable elements in the new bill, it is already undoubtedly a compromise with the Senate position, and may become badly emasculated in the conference committee.

Whatever compromise is finally worked out by the committee and by the House, the new bill has placed the Administration in an embarrassing position, for when the Administration's bill was first introduced, it advocated elevating the National Cancer Institute to a bureau, but keeping it firmly within the bureaucracy of the NIH. The Administration's original proposal was designed to head off attempts to create a separate cancer agency that were embodied in a bill introduced into the Senate by Edward M. Kennedy. The Administration found it politically expedient, however, to compromise with Kennedy's supporters by agreeing to a compromise bill that retained the essence of Kennedy's proposals, but which bore the Administration's name. The introduction of Rogers's bill has therefore put the Administration in the situation of defending a position which it had previously attacked, against proposals which it once supported.

Guide to the Bill

THE bill introduced into the House last week by Congressman Paul G. Rogers and five members of his Subcommittee on Public Health included the following major provisions:

- The National Cancer Institute would be preserved as an integral part of the National Institutes of Health, and it would be charged with the task of coordinating all the cancer research in NIH.
- The National Cancer Institute's budget would be transmitted separately to the President, but the Director of NIH, the Secretary of Health, Education and Welfare and the National Cancer Advisory Council would have the chance to comment on, but not alter it. The NCI would be authorized to spend $400 million in 1972, rising to $600 million in 1974.
- Directors of the Heart and Lung Institute, the Institute of Neurological Diseases and Stroke and the National Cancer Institute would all be promoted to the level of Associate Director of the NIH, and all would be direct appointments by the White House.
- All the institutes would be able to approve grants of less than $20,000 without having to seek approval from the advisory councils, although scientific peer review for all grants must be maintained. It is hoped that this would help prevent the National Cancer Advisory Council from being bogged down with minor decisions.
- Finally, so that Congress can keep a check on the way the provisions are working, the director of the National Cancer Institute is required to present an annual report to the President for transmittal to Congress.

DETERGENTS

Algae Better than Burns

by our Washington Correspondent

THOSE who take a delight in watching bureaucratic somersaults will have been particularly amused last week to witness three government agencies vigorously backtracking on their policies for controlling phosphates in detergents. Not so amused, however, are detergent manufacturers, who have spent millions of dollars seeking alternatives to phosphates only to be told that the cure is worse than the disease; housewives, who have switched in droves to the low phosphate detergents in their desire to do something for the environment; and congressmen who have submitted bills designed to force detergent manufacturers to remove phosphates entirely from their products. Placed in an even more invidious position are those counties and states that have banned the use of detergents containing phosphates, only to be told last week to reconsider their policies.

What caused the Environmental Protection Agency, the President's Council on Environmental Quality, the Food and Drug Administration and the Surgeon-General to declare last week that although phosphate detergents are the largest single cause of eutrophication of waterways, they should be used in preference to other detergent types? The answer is simply that substitutes for phosphates are undesirably toxic. The problem is that legitimate concern over deterioration of the environment has reached such a pitch that environmental groups are blessed with the political force to influence legislators and with enough consumer backing to pack a painful punch against industries that can be shown to abuse the environment, and this irresistible force is apt to produce overhasty reactions. As far as detergents are concerned, the environmentalists' punch forced manufacturers into producing a product that provides less of a hazard to the environment, but more of a hazard to people.

The scenario leading up to the abrupt policy reversal of federal agencies last week is an object lesson in how the lobby system can overreact to produce a result that is acceptable neither to the harassed manufacturer nor to the concerned consumer. As evidence began to accumulate about the contribution of phosphate detergents to the eutrophication of lakes and rivers (the stimulation of plant life at the expense of the oxygen supply to other aquatic organisms), they became an ideal object on which environmentalists could vent their anger. A congressional committee in April last year recommended that detergent manufacturers should be made to remove phosphates from their products by 1972, the Canadian government banned phosphate detergents from that date, several states and counties, including Indiana and New York, outlawed the sale of phosphate detergents, and housewives began to switch to detergents labelled as phosphate-free. In addition, countless other state legislatures have bills pending before them, enjoining manufacturers either to remove or severely restrict the amount of phosphate in their detergents.

Flailed by the public and Congress, detergent manufacturers set to work developing alternatives to phosphates in detergents—the chief role of phosphates is to soften the water. The most promising substitute seemed to be nitrilotriacetic acid (NTA), and chemical manufacturers were hard pushed to meet orders from the detergent manufacturers. But doubts about the carcinogenicity and teratogenicity of NTA, first voiced by Dr Samuel Epstein, then a pathologist at Harvard, led eventually to a voluntary ban on the substance by detergent manufacturers in December last year. That ban was upheld last week by the federal agencies charged with protecting public health, chiefly on the basis of a study carried out at the National Cancer Institute, which produced no direct evidence of carcinogenicity at low dose levels, but which nevertheless failed to remove the doubts.

After that setback, manufacturers began to substitute caustic materials—such as sodium hydroxide—in place of phosphates. This led to action by the FDA, forcing some products to be labelled as toxic. Detergent manufacturers protest that they cannot produce a non-toxic substitute for phosphates, and legislators were continuing to force them to produce phosphate-free detergents. Finally, the Environmental Protection Agency, the Council on Environmental Quality, and the Surgeon-General decided last week to advise the housewife to choose detergents containing phosphates.

AEC

How To Sell Cannikin

by our Washington Correspondent

It has been esimated that Washington boasts more public relations personnel per square mile than any other city in the world. While most of these are hired to impress their clients' views on the Federal Government, the government itself has a small army of information officers whose role is to keep the public informed of departmental and agency projects and policies. The difference between the two groups is that the lobbyists are expected to deal in propaganda, while the government public relations officers are expected to deal in facts.

That at least is the theory, but few people accept it as the fact. A particularly fine example of how one particular government agency, the Atomic Energy Commission, set about selling a potentially distasteful project, the explosion of a nuclear weapon under Amchitka Island in 1969, and how it intends to use the public relations experience gained in that exercise to sell the Cannikin project, was uncovered last week by Senator Mike Gravel of Alaska. Gravel, a vociferous opponent of the Cannikin nuclear test scheduled to take place under Amchitka Island in October, published in the *Congressional Record* an internal AEC report describing how the AEC "is running a well-oiled, well-financed, well-coordinated machine to tell Alaskans and other Americans about the need for Cannikin".

Gravel's chief complaint is that the AEC report provides ample evidence that the commission dismissed out of hand the views of its opponents by suggesting that their opposition to the test was motivated by a desire for headlines, disillusionment with the political system or by opposition to the ABM. The AEC, he complains, "discounts all legitimate criticism of its programs" and uses tax dollars to support an illegitimate propaganda campaign. "I call this situation to the attention of the Senate, not to beat the ghosts of past errors out because the issue is very much alive today", Gravel declared. "Cannikin is upon us and the selling job is all too familiar."

The report itself describes how the AEC's public relations effort for the Milrow test in 1969—the nuclear explosion that was designed as a proving shot for the five megaton Cannikin test—was planned in three stages. The first, preliminary stage started in December 1966, and gradually picked up momentum during the two and a half years to July 1969. The chief object of this phase of operations was to inform the public that the AEC was conducting a feasibility study of Amchitka to explore the possibility of using the island for nuclear testing. "Throughout this period", the report points out, "policy did not permit confirming that a nuclear test would be detonated on Amchitka. Public statements were framed in such language as 'determining the feasibility of Amchitka for possible use in underground nuclear testing' ". The policy, however, became less than credible when it had become widely known that the AEC had let a $12 million drilling contract, but the public relations team nevertheless stuck to its original story.

From July 18, 1969, when the AEC finally let it be known that an explosion was planned to take place under Amchitka, to October 2, when the Milrow test took place, the report describes an intensive build up in its public relations effort. Until September 20, the chief effort of the AEC's propaganda was directed towards building up public support and good will. An office was set up in a hotel in Anchorage, films documenting the AEC's efforts to save sea otters were made and distributed, and thousands of publications outlining why the AEC tests weapons, how it ensures the safety of its testing, and other background information were distributed. The report also explains how it enlisted the support of a newspaper editor by associating him with the sea otter film and keeping in touch with him by letter and telephone, so that in the end he would accept and print AEC statements that the Alaskan public would not be endangered. The AEC also took space in two of the state's largest fairs and showed exhibits of archaeology on Amchitka and a pictorial history of the development of the site on Amchitka Island.

The report finally gives the details of a campaign conducted during the two weeks before the test took place and designed to offset public opposition in the press and on the radio and television. The most disturbing aspect of this phase in the activities, Gravel maintains, is the AEC's unwillingness to accept that its opponents were motivated by anything other than desire for publicity. For one thing, the report consistently terms the demonstrators in Canada as "hysterical", and castigates the press for giving extensive coverage to opponents of the AEC. Seemingly, anyone who wanted to get his name in the newspapers or on radio—regardless of expertise or qualifications—could do so by making a statement against the test, the AEC complains. The commission also resented its opponents bringing in seemingly irrelevant material, but nevertheless carried on distributing all kinds of information on other activities of the AEC to the state schools.

NEWS AND VIEWS

Does Molecular Shape Determine Odour Quality?

TRAINED odour judges are said to be able to distinguish as many as 15,000 different odours. One of the puzzling aspects of the sense of smell, however, is that there is little relation between chemical constitution and odour. Theories of olfaction are thus legion; all attempt to answer the central question as to what properties of the odourant molecules are responsible for the wide variety of odour quality.

M. M. Mozell holds the theory that the olfactory epithelium behaves towards odourants in a manner analogous to a gas chromatograph and that it is the temporal as well as the spatial aspects of the resulting neuronal response which gives rise to differences in odour quality (*J. Gen. Physiol.*, **56**, 46; 1970). J. T. Davies has the theory that the initial event in the olfactory stimulus is the puncture of a lipid membrane by the adsorption of an odourant molecule onto it (*J. Theoret. Biol.*, **8**, 1; 1965). He finds that when the molecular cross-sectional area of odourant molecules is plotted against their free energy of desorption from a lipid water interface, compounds of similar odour quality are found together in certain areas of the plot. These areas merge into each other indicating that there is a continuous spectrum of odour quality. Neither of these two theories requires the existence of specific receptor sites which respond to only certain types of odourant molecules.

Of the theories which start from the assumption that there are several different types of receptor sites, those of J. E. Amoore and of R. H. Wright at present excite the most interest. Wright starts with the idea, gleaned from Hainer's "information theory of olfaction", that there are about twenty-five different types of receptor. He considers that only the wide range of low energy molecular vibrations possible for different molecules could give sufficient variety to satisfy so many different receptors. The evidence for most of these vibrational modes is to be found in the far infrared spectra of the molecules and hence Wright has attempted to correlate odour quality with the frequencies of the peaks found in this spectral region. This correlation is not at all apparent on looking at the spectra and, even after Wright has picked out what he calls "osmically active bands", statistical tests are required to bring out a correlation.

From a study of the comparison between molecular shape and odour quality, Amoore came to the conclusion that there are seven primary odours, five of which are characterized by a particular molecular shape and each fits a corresponding receptor site with an appropriately shaped cavity. Other odours, supposedly more complex, are associated with molecules that fit into more than one of these hypothetical sites. This theory has met with some success in the prediction of the odour quality of new compounds. Amoore has since modified his ideas as to the number and types of primary odours and their corresponding sites, but still maintains that molecular shape is of major importance in determining odour quality.

On page 270 of this issue of *Nature*, Amoore makes an attempt to get a direct comparison between his theory and that of Wright. To do this he uses twenty-five compounds, the spectra of which have been measured by Wright and which have odours similar to bitter almonds or cumin. In order to get a measure of odour quality he uses a panel of observers, selected for their olfactory acuity, to compare the odours with that of benzaldehyde. The numbers which he gives for odour similarity are essentially a rank order scaling. The procedure of comparison is analogous to asking persons of good aural discrimination to place a series of notes in their correct relationship to each other by comparing them with a standard note by ear only. This would probably result in the notes being placed in the correct sequence but the numbers assigned to the notes would show no more than a crude correspondence to their frequencies.

In the absence of any known odour property analogous to sound frequency, the odour similarity values are the only available parameters which can be used in testing theories of odour quality. Amoore finds a good correlation between his values and a computer generated index of similarity of molecular shape to that of benzaldehyde. He challenges Wright to show as good a correlation between these same odour similarity values and some measure of spectral similarity. This places Wright in the unenviable position that whereas failure to show a correlation will tend to discredit his theory, a correlation as good or better than Amoore's is unlikely to convert anybody not already committed to it.

Limits on Seyfert Galaxies

DECIDING whether the infrared flux from extragalactic objects such as galaxies and quasars varies significantly over short time scales has recently occupied much of the time of infrared astronomers. Significant flux variations on time scales of months or days would place quite severe constraints on the size of the infrared source in these objects But infrared astronomy is a young science, and published evidence for time variations has so far been habitually followed—after a decent interval—by expressions of doubt that the evidence is convincing enough to be regarded as real.

Whether the same sequence of events will overtake the work reported by F. J. Low and G. H. Rieke of the University of Arizona on page 256 of this issue of *Nature* remains to be seen, but Low and Rieke find their evidence for a short-term variation in the infrared flux from NGC 1068 "compelling". Yet the fact that the change in the flux occurred at a time when there was a change in the instrumentation that was being used to monitor NGC 1068 is bound to raise a few eyebrows. But to be fair, Low and Rieke have done a convincing job in demonstrating that the low fluxes that have been recorded from NGC 1068 this year are likely to reflect an intrinsic change in the source, and are not an artefact introduced by the alterations to the equipment.

NGC 1068 is one of the Seyfert galaxies, which are characterized by small, bright nuclei and highly broadened emission lines setting them apart from other spiral galaxies. On average the Seyfert galaxies are no mean emitters of infrared radiation, but NGC 1068

Pure Cl [illegible]
[illegible] COLLEGE

surpasses any of them at these wavelengths—at the infrared wavelength of 22 μm its flux density is thirty times that of the otherwise comparable Seyferts NGC 4151 and NGC 1275. But the placing of constraints on the model for the emission is of more general interest than its applicability to Seyfert; for the infrared emission from Seyfert galaxies is likely to arise by a similar mechanism to the unexplained infrared emission from quasars.

The infrared emission from extragalactic objects such as quasars and galaxies has previously been interpreted either in terms of synchrotron emissions from electrons, or by thermal emission from a shell of dust grains surrounding a compact source of energy. Neither view is entirely satisfactory, the synchrotron mechanism because an unusual spectrum of emission would be required which, although not totally impossible to obtain, would place difficult constraints on the behaviour of electrons in extragalactic objects which would be hard to fulfil. On the other hand, the dust model is usually regarded suspiciously because of the fear that time variations of the infrared emission would one day show it to be untenable, even though the observational evidence has not been convincing.

In the dust model, a central source in the nucleus of the Seyfert galaxies is taken to emit energy in the form of ultraviolet radiation, or possibly as particle radiation, which is thermalized by the shell of dust grains around the central source. The grains reemit the energy, chiefly in the infrared. But as Low and Rieke point out in their article, and as others have, of course, done before them, short-term variability of the emission will place constraints on the size of the dust shell, the constraints becoming more severe as the time scales are reduced from months to days.

According to Low and Rieke, the observations reported this week are consistent with an optically thick shell of dust having a diameter of the order of 3 parsec (about ten light years) containing dust at 400 K, or an optically thin shell having a diameter less than about 0.3 parsec at a temperature greater than 1,200 K. So, in addition to verifying the variability by continuing the observations on NGC 1068 and other Seyferts, astronomers will want to discuss whether these size and temperature constraints can be met.

DEVELOPMENTAL BIOLOGY

Embryologists Meet in Glasgow

from a Correspondent

THE tenth international conference on embryology, which took place in Glasgow on August 30 to September 3, was well run, with only three principal speakers in each session. Each speaker therefore had enough time to develop an argument and could speak to a relatively fresh and attentive audience. The sessions included oogenesis, genetic interactions in development, the control of protein synthesis, the development of pattern and neuroembryology. There was also a film session, several meetings of discussion groups and about ninety demonstrations.

Dr. F. H. Ruddle (Yale University) showed that the assignment of linkage groups to particular human chromosomes was proceeding rapidly. In his work he uses the technique of intraspecific somatic cell hybridization and half-selection to produce hybrids in which the expression of particular differentiated traits can be examined. For example, in a hybrid derived from a mouse renal adenocarcinoma (RAG) and a human fibrocyte (Wi 38), cells were either deficient in esterase-2 activity, which is characteristic of the human parent, or possessed it, which is characteristic of the mouse parent. On prolonged cloning, the $ES\text{–}2^-$ strain occasionally reverted to $ES\text{–}2^+$, but $ES\text{–}2^+$ never reverted. Ruddle concluded that it was possible that the expression of the mouse phenotype could be controlled by the presence or absence of a human chromosome, either C8 or C9.

Dr E. Sidebottom (University of Oxford) uses hybrids between chicken erythrocytes, which do not normally show nuclear activity, and HeLa cells in combination with antisera to human nucleoli, nucleoplasm and cytoplasm. He was able to show a good correlation between the renewal of DNA and RNA synthesis by the reactivated chick nucleus and the appearance of chick antigens on the cell surface shortly after the reappearance of chick nucleoli. He found that although human nuclear material occasionally appeared in chick nuclei, human cytoplasmic material never did. Similarly, in mouse–human hybrids he demonstrated the synthesis of a human enzyme under the control of mouse nuclear material.

Dr P. J. Bryant (University of California, Irvine) discussed the properties of *Drosophila* imaginal disks—the segmented larval tissues from which adult structure develops. Each disk is a more or less tubular structure which is folded and attached by a stalk to the epidermis. After the last moult the disks evert, unfold and differentiate to produce a segmental structure such as an eye or a limb. He used genetic mosaics, made by irradiating flies heterozygous for "yellow" and "singe" (pale cuticle and bent bristles). This leads to somatic crossing-over in cells of the imaginal disks, some of them becoming homozygous by recombination so that the characters are expressed. Adults therefore have patches of pale cuticle and

Selection in Quasar Redshift Measurements

IN the flurry of publications concerning the observed clumping of quasar emission line redshifts at certain values, very little attention has been given to the problem of selection effects. Nobody would argue against the suggestion that the observations favour some values of redshift (z). But it is a different matter when the question of periodicities in the favoured values of z are considered, and this is an opportune time for R. C. Roeder's analysis in next Monday's *Nature Physical Science*.

The most well known and least questionable region of favoured redshifts lies around $z=1.95$. Various authors have claimed that other peaks in the histogram of quasar redshifts can be related to this peak and one another, with a "periodicity" in z of 0.06. Other workers have argued with equal conviction that the statistics are inadequate to support such a claim, and the possibility of selection effects has also been raised, although not usually in any explicit form. Roeder's work now suggests that in some objects there are simply more spectral lines to measure—in a few cases at the other extreme redshifts have been claimed on the basis of the "identification" of only one line in the spectrum of a quasar.

The correlations observed by Roeder are statistically significant, and of course if there are more lines to measure at some redshifts then it is easy to understand why more quasars have had their redshifts measured at these values. It seems that the "ease of measurement effect" may be related to the movement of spectral features across the optical window as z increases. Most notably, the deficiency of redshifts measured at $z=1.25$ could be attributed to the shift of Mg II out of the window, and the rise at $z=1.8$, peaking around $z=1.95$, could be attributed to the shifting of Lyman α into the window.

epidermis bearing "singe" bristles on a normal background. Each pattern presumably derives from a single clone, because its outline is entire and cells are never individually determined.

From experiments in which the legs were transected, Dr Bryant showed that there was good evidence for an axial developmental gradient which could partially regulate. The upper part of the limb tends to develop normally, the lower half to duplicate with mirror symmetry. This is as if a single gradient is halved: the low end of the top half relaxes towards zero, presumably because of diffusion of the substance in the gradient, the high end of the bottom half doing the same. Some positional values for specifying the limb structure thus only occur in the original top portion of the gradient, whereas those in the relaxed lower portion are duplicated. (Schubiger has reported similar results and it is interesting that there is a lethal mutant with giant disks in which structures tend to duplicate, possibly because the disk becomes too large to be covered by a single gradient.)

The most significant result of the conference was the rejection, by Dr R. M. Gaze (National Institute for Medical Research, Mill Hill) and others, of the ideas of neuronal specificity and modulation. By neuronal specificity is meant the possession of specific chemical labels by neurones and their processes. Correct recognition of such labels is supposed to be instrumental in the formation of ordered connexions between, for example, the optic nerve and the rectum in amphibians. Remodulation is the relabelling of central neurones as a function of their peripheral connexions. Neuronal specification came to be discussed because in those situations for which it has been theoretically required it now seems that there is relatively little specificity involved.

Furthermore, connexion patterns can regulate after damage in such a way that axons become inputs to neurones that they would not originally have contacted. For example, if half the optic tectum is removed and the optic nerve regenerates, the system regulates to preserve a retinotopic projection. As Gaze has shown, normal retinal growth is by division of cells in a ring at the ciliary margin. It is likely that each cell divides to leave a central daughter which will differentiate and a peripheral stem cell which will divide again. The axes whereby the position of retinal ganglion cells are specified are determined when the retina is only twenty cells in diameter, so that the specificity involved might not be very great—connexions subsequent to those of the first disk of cells could be made in the order in which ganglion cells mature and send out their axons. The tectum grows from a single line of dividing cells, however, so that the actual geometry of connexion formation is still difficult to envisage.

Most experiments in which remodulation is supposed to occur can apparently be reinterpreted as if random neuromuscular connexions are made after a motor nerve is cut. The patterns of movement of a reinnervated limb are in fact so limited that they cannot afford evidence for either specific reconnexion in detail, or for remodulation. Indeed, Dr L. Marotti (Monash University) showed that in the goldfish the inferior and superior oblique eye muscles can both be reinnervated by the nerve supplying the inferior oblique. Apparently, however, even though "incorrect" synapses are formed they are not functional under physiological conditions, though she has not yet checked to see whether they are electrically excitable.

RNA SYNTHESIS

Messenger Mathematics

from our Cell Biology Correspondent

THERE are obviously two potential ways in which a bacterial cell might increase or cut back its synthesis of RNA and protein in response to changes in its environment which either increase or decrease the growth rate. The rate of elongation of RNA and polypeptide chains could be altered, or the number of new chains initiated could be regulated while the rate of elongation of chains once initiated remained constant. During the past several years at least half a dozen groups have grappled with this question and the majority opinion is that the rates of elongation remain more or less constant in cells which are growing at rates differing by up to sixfold. The implication of these results is, of course, that regulation occurs at the initiation step. But one or two dissenters have reported evidence which suggests that rates of elongation may vary and this evidence, together with the fact that in most previous experiments the range of growth rates of the cells was restricted, prompted Coffman, Norris and Koch (*J. Mol. Biol.*, **60**, 1; 1971) to measure the kinetics of appearance of β-galactosidase after the addition of inducer to cultures of *Escherichia coli* with doubling times ranging from 50 minutes to 24 hours.

Exploiting the sophisticated techniques now available for measuring the early kinetics of enzyme induction and a sensitive fluorometric assay for β-galactosidase, Coffman *et al.* found that the delay time—the interval between the addition of inducer and first appearance of detectable β-galactosidase activity—was 95 ± 5 seconds in cells with doubling times ranging from 50 minutes to 12.5 hours. And even in cultures doubling extremely slowly (doubling time 24 hours), the delay time was a mere 150 seconds and in this extreme case the binding and penetration of inducer may be retarded.

In short these experiments confirm that over a thirteen-fold range of growth rate the elongation of RNA and polypeptide chains in *E. coli* is invariant. Furthermore, the average lag between adding inducer and the achievement of a steady-state of β-galactosidase activity does not vary significantly with changes in the growth rate; this finding presumably means that messengers survive for about as long in cells doubling every 50 minutes as in cells doubling every 12.5 hours.

In an appendix Koch presents an algebraic analysis of the induction curves for β-galactosidase, obtained when cells are either pulsed with inducer or allowed to grow in the continued presence of inducer, in an attempt to decide between the various models proposed to explain the decay of a messenger RNA. He claims that the results of experiments in which inducer is added and not removed from the medium exclude models which envisage that each messenger is read for a fixed number of times before it is degraded. The data are, however, compatible with a model which envisages that messenger decay is random with respect to time and place, or a model which envisages that there is a constant probability that a "killer" ribosome will initiate translation and inactivate the messenger as a result.

While Coffman and his colleagues have been measuring the kinetics of expression of the *lac* operon—and the objection that their data are relevant only to inducible operons cannot as yet be ruled out—Eron, Morse, Reznikoff and Beckwith (*ibid.*, **60**, 203; 1971) have been looking at the transcription of the *lac* genes in a strain of *E. coli* which because of a deletion has the structural genes of the *lac* operon fused to the *tryp* operon. In this strain the expression of the *lac* genes is regulated by the controlling elements of the *tryp* operon, and Eron *et al.* have tested to see if a *tryp*/*lac* fused messenger RNA is ever made. They find that some 4–10 per cent of the messengers made from these two fused operons are indeed covalently linked. They conclude that an RNA polymerase can initiate at the *tryp* promoter and read through the *tryp* and into the *lac* operon. But why is the amount of fused messenger so small? Either read through is rare, or it is the rule, but for one reason or another the fused messenger is broken during isolation or its 5′ end is rapidly degraded *in vivo*.

REEFS

Old and Modern

from a Correspondent

UNDER the auspices of the Palaeontological Society, a well attended meeting on the palaeoecology of reefs was held at the University of Edinburgh on September 9, being one of the events held to celebrate the centenary of the Department of Geology.

Drs D. J. Bellamy (University of Durham) and E. Drew (University of St Andrews) described their work on the zonation of hermatypic corals off the reef front at Aldabra including reference to a major system of channels which are explicable only on the basis that they represent the effect of erosion during aerial exposure of a preglacial formation. Dr P. Garrett (University of Leeds) transferred attention to the reefs of Bermuda and emphasized the complexity of a reef mass formed primarily by coral skeletons, the overlapping growth of which produces internal cavities encrusted with algal and animal growths.

Dr J. Taylor (British Museum (Natural History)) drew attention to the high diversity of shallow water macro-invertebrates in coral reef areas. Reefs present a unique diversity of habitats—a consequence of the resistance their formation presents to the forces of the sea—ranging from exposed reef faces to sheltered sandy and mangrove areas. Computers are now used to obtain objective comparisons of habitats of molluscan species.

Dr C. J. R. Braithwaite (University of Dundee) was concerned with the need for criteria for the recognition of fossil reefs and drew attention to those features of modern reefs which are particularly significant, notably the platform with its superimposed organisms. The fact that recent reefs have grown upon Pleistocene formations presents a major difficulty when comparing these with fossil reefs. Dr B. R. Rosen (University of Newcastle upon Tyne) considered ecological stratification in coralline environments in terms of hard and soft non-living substrates for life on which corals are very differently adapted.

Dr T. P. Scoffin (University of Edinburgh) described conditions of growth in the Wenlock reefs where the most vigorous growth occurs on what was the seaward fringe; colonies are preserved in the condition of growth indicating calm conditions. Dr C. T. Scrutton (University of Newcastle upon Tyne) spoke about the effect of the environment on fossil colonies and indicated that rugose corals were generally less well adapted for life in rough. "high energy", environments than were the probably poriferan stromatoporoids. Drs F. M. Broadhurst and I. M. Simpson followed by Dr J. Miller (all University of Manchester) were concerned with descriptions of limestones of coral reef origin. In the Castleton area of Derbyshire the limestones show marked faunal changes marginally, and the limestones present in knolls around the Clitheroe area, described by Dr Muller, are associated with dense crinoid thickets. Dr D. B. Smith (Institute of Geological Sciences, Leeds) dealt with the well known Upper Permian barrier reefs of the Guadalupe Mounts and compared these with smaller but similar reefs in Durham.

The meeting concluded with a lively discussion on many of the matters raised by the various speakers; a satisfactory definition of the term "reef" proved hard to find. Finally, Sir Maurice Yonge drew attention to some recent work on living corals which is providing some interpretation of the factors controlling the distribution and ecology of reef-building (hermatypic) corals.

FLUID MECHANICS

Pneumatic Conveying

from a Correspondent

THE behaviour of gas-suspended solid particles flowing in pipes is of much interest in modern powder processing industries. For many years this topic of research has also been a satisfying bone for many academic fluid dynamicists to chew on. For the first time a conference has been devoted entirely to pneumatic conveying. The meeting was held at Churchill College, Cambridge, from September 6 to 8, and was sponsored by the British Hydromechanics Research Association in conjunction with the City University of London.

On the applications side, systems for conveying some rather troublesome materials were described; asbestos slurry was the theme of a contribution by Dr D. C.-H. Cheng *et al.* (Warren Spring Laboratory, Stevenage); on-site con-

Messenger Transport *in vitro*

MESSENGER RNAs transcribed in the nuclei of eukaryotic cells have to be transported to the cytoplasm to be translated and there is increasing circumstantial evidence that this transport process is an important regulatory step in the expression of genes. The process is, however, extremely difficult to analyse not least because of the heterogeneity of nuclear RNAs and the biochemical complexity of cell cytoplasm and these factors prompted Raskas, as he describes in next Wednesday's *Nature New Biology*, to attempt to set up an *in vitro* system for the analysis of RNA transport across the nuclear envelope. He elected to use cultivated human KB cells infected with adenovirus type 2 as a starting material because some 18 hours after infection most RNA being made in the cell nucleus is adenovirus specific, and he now claims that, in the presence of an ATP generating system, nuclei isolated from such cells release RNA by a mechanism similar to that occurring *in vivo*.

The release of RNA by isolated nuclei is strictly dependent upon a continuous supply of ATP, without which less than 10 per cent of the RNA leaves the nuclei, and once released the RNA remains precipitable by TCA and presumably, therefore, undegraded. Analysis of the released RNA by centrifugation in sucrose gradients reveals two broad peaks, one sedimenting at about 35S and the other at about 10S. When the salt concentration is increased, the 10S RNA behaves as before but the 35S peak disappears because, Raskas suggests, it consists of ribonucleoprotein complexes which are dissociated at high salt concentrations. The buoyant density of this material is consistent with this suggestion.

Both 10S and 35S components contain viral RNA which will hybridize with adenovirus DNA, and an analysis of the total RNA released by the isolated nuclei in 20 min on polyacrylamide gels reveals RNA molecules long enough to be adenovirus messengers, in addition to low molecular weight RNAs, and the 6S RNA synthesized at late times during adenovirus 2 infections. Raskas suggests that the release of these RNAs *in vitro* is relevant to transport *in vivo* for several reasons. First, the release is specific; significant amounts of nuclear protein and DNA are not released. Second, the size of the released RNAs suggests that a maturation by cleavage goes on inside the isolated nuclei as it does *in vivo*. Third, the release *in vitro* cannot, of course, depend on the synthesis of new ribosomes and studies of intact infected cells indicate that movement of adenovirus RNA into the cytoplasm does not depend on ribosome synthesis. Finally, much of the adenovirus RNA released *in vitro* is in the form of a ribonucleoprotein and the same seems to be true of transport *in vivo*.

There is therefore every reason to believe that further analysis of this *in vitro* system will throw light on the process of RNA transport and, as Raskas comments, one of the first things to do is to analyse the protein components of the 35S ribonucleoprotein material to see if only a few, specific "transport" proteins are present.

crete distribution was described by Dr R. H. Jones (University of Nottingham); even proposals for a domestic refuse-disposal system were outlined by Dr J. A. Hayden (Hayden, Harding and Buchanan Inc., USA) and Dr A. W. Breidenbach (Environmental Protection Agency, USA).

On more fundamental issues the meeting was rather disappointing in that few contributions added much to present understanding of basic flow mechanics. The influence of dense, locally-concentrated particle clouds on basic fluid mechanics was scarcely mentioned. Furthermore, agglomeration and other multi-particle collision effects received rather scant attention, as was pointed out by Dr C. J. Stairmand (ICI Ltd, Teeside) in the discussion.

More definite advances were reported in the contributions describing experimental work. In particular, a more interesting statistical approach to particle continuum mechanics was evident in the work of Dr M. S. Beck *et al.* (University of Bradford) and Drs R. G. Boothroyd and P. R. Arundel (University of Birmingham). Drs J. Jokati and Y. Tomita (Kyushu Institute of Technology, Japan) described another example of more useful presentation of experimental data: they gave probability distributions of particle velocities at different points in a pipe. This break from earlier research, in which the interest has tended to remain in time-averaged fluid-dynamic parameters, is a most welcome and necessary development. Professor S. L. Soo (University of Illinois) twice expressed the opinion that the facility with which experimenters can examine the motion of individual particles should not be an excuse for ignoring the continuum viewpoint of the solid phase. To illustrate his point he reminded his audience that the motion of molecules is rather unimportant in one-phase fluid dynamics.

HISTORY OF SCIENCE

Kepler Honoured

from a Correspondent

THE thirteenth international congress of the history of science, held at Moscow State University from August 18 to 24, and followed by an international symposium at the Leningrad Planetarium from August 26–28, held to celebrate the four hundredth century of Kepler's birth, provided delegates from many countries with some chance of meeting Soviet scholars and seeing the fine collections in the host country.

Academician B. M. Kedrov opened the congress with an address on the history of science and principles of its research, in which he emphasized the importance of linking together past, present and future in the development of science. Colloquia topics (for which full simultaneous translation facilities were available) included the Rutherford centenary and seventy-five years of radioactivity studies (see *Nature*, **233**, 167; 1971); the evolution of classical mechanics; Mediaeval science: East and West relationships; ways of Development of Functional Analysis; and new technology in the developing countries from the eighteenth to twentieth centuries.

The general standard of contributions was high, but discussion time was, as so often is the case, somewhat restricted. The colloquium on the teaching of history of science was rather disappointing and uncoordinated; the Royal Society *Report on the Teaching of the History of Science, Medicine and Technology in Universities and Technical Colleges in the United Kingdom 1971* was presented, but was felt by many participants to be an uneven document.

The sections were less formally organized and did not entirely avoid language problems. It was felt by some participants that some of the "questions" asked were more of the nature

More about Interstellar Grains

IN spite of increasing efforts to identify the composition of interstellar grains, conclusive results remain elusive. Observations in the past were restricted to visible wavelengths where the shape of the interstellar extinction curve is fairly uniform throughout the galaxy and almost featureless, apart from a slope discontinuity at 4300 Å and several diffuse bands. Now that ultraviolet and infrared astronomy have widened the scope of investigation, the accumulating evidence points to large differences in the general trends of extinction from region to region. There are also several observed spectral features to be explained and the discovery of more can be anticipated. The conspicuous 2200 Å peak has been frequently attributed to graphite, although theoretical calculations tend to predict too broad a feature. Silicates and hydrocarbons have recently been proposed as alternatives and no doubt others exist.

In the infrared, much of the activity is concerned with emission from circumstellar shells (for example, Gillett *et al.*, *Astrophys. J.*, **164**, 83; 1971). The characteristic 10 μm excess in luminous M stars is suggestive of silicates and a limited amount of 20 μm photometry has supported this. Spectral features observed in absorption may, however, be more representative of intrastellar dust, because circumstellar grains are supposed to have been produced locally in the stellar atmosphere. Several unsuccessful searches for the 3 μm ice band indicate that most interstellar grains contain little ice, at least in the proposed form of H_2O ice (Knacke *et al.*, *Astrophys. J.*, **158**, 151; 1969); the 3 μm absorption in NML Cygnus, however, remains unexplained. Medium bandwidth observations of the bright infrared continuum of the galactic centre (20 to 30 magnitudes of visual extinction) combined with other observations have been interpreted by Hackwell *et al.* (*Nature*, **227**, 822; 1970) as showing absorption near 10 μm and 20 μm due to metallic silicates. These results must be regarded as tentative because of the considerable difficulty in establishing the true continuum against which absorption or emission is to be distinguished. Observations of three B supergiants were inconclusive because of the much lower amount of extinction, and an earlier measurement of 10 μm absorption in the M2 Ib star 119 Tau was not confirmed.

Following up these observations W. A. Stein and F. C. Gillett report in next Monday's *Nature Physical Science* a search for 11 μm absorption in the highly reddened B8 Ia star IV Cyg No. 12. Although most of the ten magnitudes of visual extinction probably arise from dust localized in the OB association, possibly even in the immediate vicinity of the star (Reddish *et al.*, *Pub. Roy. Obs. Edinburgh*, **5**, 111; 1967), evidence such as the shape of the extinction curve, the amount of polarization and the strength of the diffuse 4430 Å band suggest a similarity to interstellar grains. The continuum beyond 5 μm seems well established as the Rayleigh-Jeans portion of the stellar spectrum; there is no circumstellar emission out to 11 μm although there could be at longer wavelengths. More important, no evidence for absorption was found, the upper limit to the 11 μm optical depth being τ=0.1. This limit is at least a factor of 2 to 3 lower than predicted by scaling the observations of Hackwell *et al.* ($\tau \simeq 0.7$) but abundance variations of this size might be expected.

Stein and Gillett also estimate that less than a third of the mass of the grains can be metallic silicates. With the improved infrared optical constants reported by Nandy and Kelly (XVII Liège Symposium, June 1971) this estimate could be refined and extended to several other minerals. Clearly, many more observations with as high resolution as possible and at as many wavelengths as possible will be required before a definitive identification of the interstellar grain materials is finally achieved.

of doctrinal filibusters than requests for clarification or information. Questions such as methodology, the organization of research and the development of technologies, are obviously more open to controversial social and political interpretations than is, say, mediaeval mathematics; the time range of sectional topics from ancient science, medicine and technology to the development of transport, electronics, constructional engineering and aircraft, rockets and space science, provided most speakers with a forum.

The Kepler symposium at Leningrad was a much smaller and more homogeneous affair. The location was very appropriate because most of Kepler's surviving manuscripts and related papers are in Leningrad, and many of these were included in a small and interesting exhibition of works on and by Kepler. There was also an opportunity to visit the nearby Pulkova observatory, rebuilt following its wartime destruction, and see and discuss many aspects of modern astronomy. Academician Mikhailov opened the proceedings, and was followed by Dr W. Gerlach (Munich) who spoke on Kepler's life and work. Subsequent contributions (not all presented in person) dealt with Kepler's contributions to celestial mechanics, optics, the development of mathematics, gravitation theory, comets, the supernova of 1604, structural crystallography, the origin and derivation of the laws of planetary motion and his neopythagoreanism. There were also contributions on Kepler's connexions with Galileo, his time in Prague, his astronomical instruments, his theory of hypotheses, the Kepler manuscripts in the Soviet Union, as well as his relationship to the interest of modern physicists. Although no particularly outstanding new information or insight into Kepler's work was presented, it was clear that his scientific and methodological achievements continue to be of interest and even inspiration to many historians of science, quite apart, of course, from the historical problems involved.

VIRAL INFECTIONS

Green Monkey Disease

from our Medical Virology Correspondent

In August and September 1967, an outbreak of a severe haemorrhagic fever occurred among monkey handlers and laboratory workers in Marburg, Frankfurt and Belgrade. Thirty-one cases of severe illness with seven deaths were traced to direct contact with the tissues or tissue culture of a batch of African green monkeys (*Cercopithicus aethiops*), which had been trapped in Uganda. Several secondary cases occurred in hospital personnel by contact with the blood of patients and one further case was apparently transmitted by sexual intercourse. Many of the features of the illness, including liver and renal damage, a haemorrhagic diathesis and the association with monkeys originating from Uganda, suggested initially that the infection was caused by yellow fever virus or some other arbovirus. It soon became apparent, however, that this was a previously unrecognized disease caused by an infectious agent probably new to medical science. Today, four years after the infection, the origin of the disease remains obscure.

Studies in several laboratories established that guinea pigs, Rhesus (*Macca mulatta*) and vervet monkeys could be infected and the agent was subsequently isolated in tissue culture. The structure of the agent, which was named the Marburg virus, is that of an elongated sinuous organism 800–1,000 nm in length but generally curled in the form of a figure 6 or a horseshoe. Single organisms longer than 2 μ were occasionally found in the blood. A periodic cross-striation of 5 nm along the surface and an inner structure of about 65 nm in diameter with a central axis was also described. It was suggested that this agent was related morphologically to the Rhabdovirus family.

The possible origin of the infection has been investigated intensively since the outbreak. The monkeys were sent from Uganda at the time when there was considerable disruption of air traffic during the Six Days war. The monkeys were held overnight in London in a room containing many other animal species including birds and reptiles. A disturbing report from the United States based on serological study of complement-fixing antibodies to the Marburg agent revealed a high prevalence of antibody in many African monkeys. Strickland-Cholmley and Malherbe (*Lancet*, i, 476; 1970) pointed out, however, that the antigen used in the United States was not fully specific and that it probably contained a second non-specific component for the Marburg agent. W. Slencza and his associates (*Amer. J. Epidemiol.*, **93**, 496; 1971) were also unable, after extensive studies, to find evidence of infection with the Marburg agent (based on antibody results) in free-living monkeys.

The origin of the infection is thus still unknown and it must therefore be assumed that infection of man may recur. Furthermore, infection may come next time from other species of animals because it is now clear that vervet monkeys are not the maintenance hosts of this bizarre agent and it cannot be predicted where it may next occur.

Protein Kinase in Tumour Viruses

In *Nature New Biology* next week, Strand and August add a protein kinase to the list of enzymes, which includes reverse transcriptase, ligase and nucleases, that have been detected in RNA tumour viruses. The kinase, which is present in mouse leukaemia virus, avian myeloblastosis virus and the non-oncogenic vesicular stomatitis virus, catalyses the phosphorylation of several virion proteins. Its presence in these particles suggests that modification of proteins by phosphorylation may play a part in the interaction between an infecting enveloped virus and its host cell.

The kinase was detected by simply incubating mouse leukaemia virus particles with $(\gamma\text{-}^{32}\text{P})$ ATP and assaying for the incorporation of ^{32}P into virion proteins. Further experiments established that the kinase seems to be an integral part of the virion and is not adventitious; the phosphorylation reaction is stimulated by added protamine, depends on the presence of metal ions, is inhibited by caffeine and is enhanced by first disrupting the virions with detergent. Cyclic AMP, which stimulates by some two to three-fold the activity of other cellular kinase, and by this route exerts at least some of its regulatory effects, stimulates the phosphorylation of leukaemia virus proteins by only 25 to 50 per cent in the absence of protamine and in its presence stimulation is even less marked. As Strand and August remark, this lack of response of the virion kinase to cyclic AMP may mean either that the enzyme already has bound to it this nucleotide or it may lack the regulatory subunit of kinases which binds cyclic AMP.

The virion kinase will phosphorylate exogenous substrates including lysine and arginine rich histones, and a protein of *Escherichia coli* which is one of the two host factors required for the replication *in vitro* of QB RNA and which closely resembles histones. In the absence of added substrates the kinase phosphorylates at least ten different proteins or polypeptides in leukaemia virus particles including the internally located interspecies specific antigen (gs 3) and the two group or species specific antigenic determinants. Chemical tests indicate that serine and threonine residues are phosphorylated. Strand and August have not, however, been able to determine whether or not the glycoproteins in the envelopes of the virions, including the sub-group antigens, are phosphorylated.

NUCLEIC ACIDS

Collapsible DNA

from our Molecular Biology Correspondent

WITH a metre or so length of DNA in each of one's cell, it is fitting that one should from time to time ponder the question of how this relates to the well-known hydrodynamic rigidity of the thread of life, once this is out of the living cell and in the ultracentrifuge cell, where in the view of many people it properly belongs. Its properties, one might hazard, are modified by the basic proteins in which, in higher organisms, it is packaged. In other surroundings, such as phage heads, such a facile evasion will not do, and this is the starting point of Lerman's efforts (*Proc. US Nat. Acad. Sci.*, **68**, 1886; 1971) to find conditions in which native DNA will pack into a compact form, as it does in the phage.

In dilute salt solutions DNA is a rather stiff "worm-like coil". In the presence of high concentrations of neutral, unreactive polymers, Lerman reasoned, an effective phase separation, such as occurs macroscopically in mixtures of mutually repelling polymer species in solution, could be achieved by a collapse of this extended structure into a compact domain. Moreover, if the intermolecular forces in such a system are indeed predominantly repulsive, one would not expect that this would have to be accompanied by denaturation of the double helix.

The argument was evidently sound, for in the presence of the neutral polymer, polyethylene oxide ('Carbowax'), and at a sufficient salt concentration, presumably to minimize internal repulsions, a dramatic collapse of the DNA structure occurs. T4 phage DNA, which normally sediments at about 80S, now forms a broad band in a sucrose-D_2O gradient, centred at about 300S, and extending to 500–600S. With T7 DNA the results are qualitatively similar: from a normal sedimentation rate of 62S, it changes to give a peak at 200–250S, trailing out to 400S. The transition to the compact state occurs within a critical range of neutral polymer concentration and of sodium chloride (between 0.2 and 0.3 M). The polyethylene oxide itself undergoes no detectable change, as judged by its viscosity, in this ionic strength range, and moreover another neutral polymer, polyvinylpyrrolidone, will serve just as well. A striking demonstration of the existence of a threshold polymer concentration was achieved by sedimenting the DNA through a sucrodensity gradient containing an inverse concentration gradient of polyethylene oxide. On encountering a low polymer concentration the DNA reverts to the slowly sedimenting form, so that the back of the sedimenting zone catches up the front, and practically stops.

Examination of the buoyant density of the compact DNA after sedimentation excludes any question of denaturation. The sedimentation patterns are independent of DNA concentration, so that one may take it that the rapidly sedimenting form is not aggregated material. The high partial specific volume of the neutral polymer means that the formation of a complex with DNA, even with a large excess of polymer, would make little impression on the sedimentation coefficient of the DNA. Moreover, a similar effect is exerted by polyacrylic acid, which it would be hard to envisage forming a complex with DNA. It thus seems justified to infer that a true compact form is indeed generated. One may calculate sedimentation coefficients of the DNA molecule in various forms, and one may with reasonable certainty exclude supercoiling, which would change the sedimentation rate far too little, and a range of other possibilities. A compact sphere would sediment too rapidly, but an ellipsoid of axial ratio about 7:1 would give a result of the right order, and so would a platelet made up of double-helical stretches of DNA some 160 Å long folded concertinawise on each other.

So far as theory for phase relations can be applied, it is by no means inconsistent with a microscopic phase separation in the DNA-polymer system. Lerman suggests that the intracellular environment, pullulating as it is with other macromolecules, may be not unlike his model system. The implications of the ready transition from a stiff to a highly folded form in relation to the structure of the double helix will have to be carefully considered.

Reverse Transcriptase Initiates on RNA Primer

IN next Wednesday's *Nature New Biology*, Baltimore and four of his colleagues report that reverse transcriptase requires an RNA primer to initiate the synthesis of a DNA chain, which is covalently bound to the primer RNA. They describe a series of experiments which prove beyond doubt that the enzyme initiates DNA synthesis by adding a deoxynucleotide to the 3′ hydroxyl group of the primer. In short, the mechanism of DNA synthesis by reverse transcriptase seems to be essentially identical to that of the Kornberg DNA polymerase I of *Escherichia coli*, except the reverse transcriptase can use an RNA primer and an RNA template. The similarities between the two enzymes are indeed so great that Verma *et al.* even suggest that an RNA molecule might serve as the initiator or primer for DNA synthesis in *E. coli* by enzymes such as DNA polymerase I.

The first real clue that reverse transcriptase might require a primer RNA came from experiments with exogenous templates. Baltimore and Smoler found that although the enzyme often uses exogenous templates more efficiently than the endogenous tumour virus genome, it does so only when a primer, which can be as short as a tetranucleotide, is present; the product made comprises the new DNA chain physically attached to the primer. Having made these observations Baltimore's group asked the obvious and important question—does the enzyme when it transcribes the endogenous tumour virus genome require a primer and if so what is the primer?

They first noticed that the 20 minute product of the endogenous polymerase reaction with murine leukaemia virus particles was a single stranded DNA with a density slightly greater than expected. By treating this DNA with ribonuclease or alkali its density was reduced to that of single stranded DNA. Turning to avian myeloblastosis virus particles, which can be had in large amounts, they analysed the product DNA made after 2 to 30 minutes by the endogenous reaction. As the reaction proceeds the density of the DNA product shifts from that of a 1:1 RNA.DNA duplex to close to that of single stranded DNA.

After a series of treatments which hydrolyse RNA all the reaction products assumed the density of single stranded DNA. Using purified avian myeloblastosis virus enzyme and isolated avian myeloblastosis virus RNA instead of the virus particles, they obtained essentially identical results. And experiments with the inhibitor of reverse transcriptase, dideoxythymidine triphosphate, which have yet to be published by Baltimore's group apparently confirm that DNA synthesis is initiated by the attachment of the first deoxynucleotide to the 3′ hydroxyl group of the primer.

But what acts as primer in the endogenous reaction? It could of course be that the 3′ end of the 60–70S viral RNA genome forms a hair pin bend; alternatively small RNA molecules might associate with the 60–70S RNA. Small RNAs, including transfer RNAs, are present in tumour virus particles and Baltimore's group favour the idea that these act as primers, not least because many DNA molecules are made per viral genome.

ACOUSTICS

Hungarian Meeting

from a Correspondent

THE seventh international congress on acoustics, held at Budapest from August 18 to 26 under the presidency of Professor Tarnóczy of Hungary, was the first occasion on which the meeting had been held in a country of the Eastern block and it is noteworthy that just over 40 per cent of the 1,200 delegates came from these countries. There were also 300 guest members and the size of the gathering emphasizes the growing importance of the subject.

The revived interest in models was evident in the appearance of a few contributions on the subject such as those on the use of a model to evaluate various possible changes to a studio by Dr A. N. Burd (BBC Research Laboratory), and on diffusion and absorption of sound in a model reverberation room by the fathers of modern acoustics, Drs V. O. Knudsen and L. P. Delsasso (University of California, Los Angeles). It is sad to report that Delsasso died suddenly when travelling to the congress.

A balanced selection of topics over the wide field of acoustics had been chosen for the invited fourteen plenary one-hour lecturers. Unfortunately for many listeners nearly half of these were in French or German. Dr J. L. Flanagan (Bell Laboratories, Murray Hill) gave an excellent lecture with demonstrations of advances in selected areas of speech communication. The advances in research in this field are largely due to the expanding and the in-depth understanding of the theory of sampled-data systems and also to the wide adaptability of the moderately sized, fast digital computers. The transmission of speech in digital form, by contrast with analogue transmission, can be made effectively independent of distance as regards quality of reception, and a variety of signals—for example, voice, telegraph and the like—may be interleaved without special consideration. Digital encoding methods for speech are very varied and source coding leading to lower bit rates has resulted in an increased study of speech synthesis. Synthetic speech provides storage economies and vocabulary flexibility which promotes different possibilities in new automatic information services, and every push-button telephone becomes a potential computed terminal. For use in computer answer-back the synthesis of formant data or of printed text both seem attractive. With printed text, the machine stores a pronouncing dictionary which includes a phonemic transcription of each word, word stress and rudimentary syntax information. It generates connected speech solely from a knowledge of the linguistic rules of the language and the dynamic acoustic properties of the human vocal apparatus.

The frequency range of acoustical investigations has been extended considerably upwards in recent years and, as was mentioned by Dr E. G. S. Paige (Royal Radar Establishment, Malvern), mechanical surface waves can now be generated up to 10 GHz. Mechanical waves of these frequencies (up to 100 GHz) are often termed hypersonic and are being used in physical investigations of the condensed state of matter involving their interaction with electromagnetic, spin and acoustic waves (Dr J. P. Joffrin, University of Paris). At the other extremity of the frequency range (Dr R. W. B. Stephens, Imperial and Chelsea Colleges, London), the wavelength of the sound radiation becomes comparable with the natural frequency of various parts of the human body, and unpleasant, if not dangerous, effects can arise in consequence. There is a real need for more planned investigations in this frequency region.

The growing field of ultrasonic applications to medicine was made evident by the appearance of several contributions from workers in various countries. Dr J. C. Somer (TNO, Utrecht) described his development of an array of electroacoustic transducers which comprises twenty-one elements, spaced a half wavelength apart and suitably phased. This technique has been adopted for electronic sector scanning, and provides two-dimensional scanning with a substantially stationary probe. It has particular application to diagnosis of the brain where mechanical scanning has not proved very successful chiefly because of the high absorption of the skull.

Bacterial Purple

NEXT Wednesday's *Nature New Biology* contains a study of the purple membrane found in a species of halophilic bacterium, *Halobacterium halobium*, which shows it to have remarkable resemblance to retinal rods. The cells flourish only at extremely high concentrations of sodium chloride, and towards the end of the logarithmic growth phase there is a rapid accumulation of the purple membrane. Oesterhelt and Stoeckenius have found that when the cells are caused to disintegrate by removal of salt, the fragments of the purple membrane are easily separated by centrifugation and washing from other parts of the membrane.

The absorption spectrum of the purple membrane is essentially that of a visual pigment, the maximum in the visible being nearer to that of the cone pigment, iodopsin, than rhodopsin. Denaturation with acid causes bleaching, the purple colour giving way to yellow. The bleached chromophore can be extracted with solvents, and is identifiable as retinal.

In SDS-gel electrophoresis, the dissociated membrane displays only one protein band, with an estimated molecular weight of 26,000. This is also the equivalent of protein found by nitrogen analysis to be present in the membrane for each equivalent of the chromophore. Thus the protein may be supposed to have a molecular weight of 26,000 (supported also by minimum numbers of the sparsely represented amino-acids, for example, one histidine residue corresponding 26,000 molecular weight), which is at the low end of the range of molecular weights at various times offered for rhodopsin. The analogy extends also to the attachment of the retinal to the protein: when reduced after bleaching with borohydride it can no longer be extracted with solvents, and is evidently therefore attached in the native state by way of a Schiff base linkage to a lysine side chain. Oesterhelt and Stoeckenius make the reasonable inference that the purple membrane may be a photoreceptor.

An X-ray diffraction study of the isolated purple membrane fragments by Blaurock and Stoeckenius accompanies this characterization. The characteristic spacings for a membrane bilayer, corresponding to two dense layers 40 Å apart, are observed. Furthermore, there are reflexions that show the presence of a large hexagonal lattice, which must therefore be the form of surface packing of the protein molecules. Freeze-fractured specimens of whole cells show in the electron microscope evidence of a regular lattice on patches of the membrane (it being assumed that the cleavage plane is in the bilayer). Because these increase in number towards the end of logarithmic growth, it seems that they correspond to the purple areas. Light-diffraction patterns are also consistent with a hexagonal array.

From measurements of partial specific volume, Blaurock and Stoeckenius have calculated that the unit cell in the purple membrane preparations contains some forty molecules of lipid and three or four molecules of protein. Because hexagonal packing in a plane demands that the unit cell contain three units, Blaurock and Stoeckenius suggest that the protein is disposed in two layers rather than one. The visible absorption band of the chromophore shows strong dichroism, the long axis of the retinene lying in the plane of the membrane, exactly as found in retinal rods. This seems to be the first example of the existence of specialized functional areas in cell membranes.

Combustion Temperatures: The Future?

F. J. WEINBERG
Imperial College, London SW7

An examination of the relative merits of burning at high and low temperatures leads to new proposals for designing future combustion systems for particular purposes so as to minimize pollution and optimize intensity and efficiency.

A 100 h.p. horse would be inconveniently large. In every other way, biological converters oxidize their fuel most efficiently, give rise to very little pollution and, indeed, dispose of those effluents which are caused by the low quality of their fuel in a convenient and elegant way. To go to the other extreme, a stabilized hydrogen–oxygen detonation could achieve the throughput equivalent to 100 h.p. in a disk of less than 1/4 cm diameter and of very small thickness. The main reason for this vast difference in volume, and hence in combustion intensity, lies in the steep dependence of the rate on temperature (see Fig. 1), the horse being some 3,000° C cooler than the detonation.

Even if we omit biological systems and confine ourselves to combustion reactions, the history of mankind has been intimately associated with this steep temperature dependence of the rate law. The observation that fuels and oxidants will not react at any appreciable speed when left alone at normal temperatures, but will do so at an alarming rate once they are raised to a high temperature, must have been one of mankind's first scientific discoveries. Since then the trend, very broadly, has been to ever higher temperatures and combustion intensities—that is conversion rates averaged over the volume of the combustion chamber—and under more controllable conditions. In view of the diminishing resources of fossil fuels (and their potential usefulness for producing more interesting chemicals than carbon dioxide and water), of the falling costs of nuclear power generation and of the public awakening to the effects of pollution, it seems opportune to reassess the principles available for controlling the temperature in combustion reactions and to give serious consideration to any suggestion which may emerge for modifying practical systems.

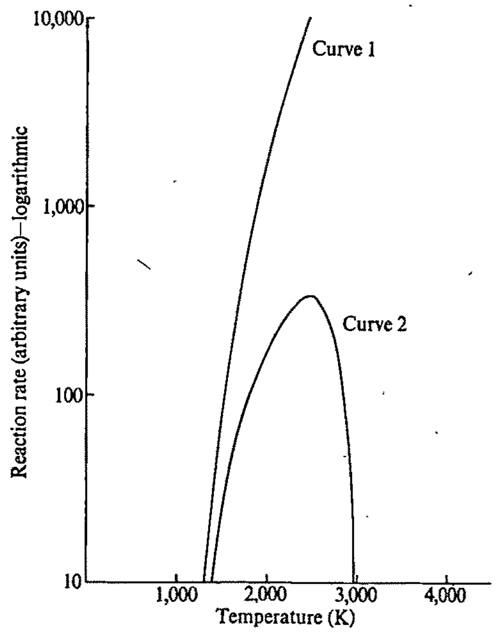

Fig. 1 Curve 1 shows the variation of reaction rate with temperature at constant pressure taken as $T^{3/2}\exp(-44\times10^3/RT)$. Curve 2 as curve 1 but with depletion and dilution of reactants, that is the temperature rise is due to reaction and/or mixing with hot products. It is curve 1 multiplied by $[1-(T-300)/(3{,}000-300)]^2$.

The potential advantages of high combustion temperatures are: high reaction rates, high thermodynamic efficiency in the case of conversion to power, high heat transfer rates to surfaces on which dissociated species can recombine, higher ionization (which may be useful in particular applications such as magnetohydrodynamic control or power generation) and the opportunity of producing endothermic products by sudden quenching. These advantages are obviously over-riding for some purposes. For others, however, they are vitiated by the production of certain pollutants at high temperatures—particularly NO—and, chiefly, by the difficulty of handling such hot gases. These are so much above the melting points of the devices used to contain (for example, combustion chambers) and exploit (for example, turbine blades) them that one cannot realize the potential advantages in practice. In the case of heat transfer rates to surfaces there are applications—such as cutting, melting, welding, spheroidizing, and so on—in which the heat sink is not intended to remain intact. In most others, however, the melting of the confining walls would be disastrous. In this way, the chief advantages such as high combustion intensity or thermodynamic efficiency may be wasted if the high temperature cannot be maintained over the entire volume of the combustion chamber or converter. Yet the high temperature may nevertheless be necessary, in conventional combustors, in order to keep the combustion zone stable at the desired throughput. Thus we may be forced to accept the disadvantages of high temperatures—for example, excessive heat losses and formation of NO—yet at the same time have to cool the gases before they become acceptable, for example, to turbine blades.

The combustion temperature range is limited, at its lower end, by the least temperature at which a stable flame can be maintained—not much below 1,000° C under optimum conditions. This is determined by the interplay between the above mentioned temperature dependence of heat release rate with that of heat loss from the reaction zone. The upper limit is set, in practice, by the difficulty of containment within a solid container—or at best a liquid melt held against the cylindrical walls of its parent solid by rotation-induced centrifugal force. Ionization does not become adequate for magnetohydrodynamic confinement until enthalpies attain values which dwarf the contribution from the heat of combustion. There is also some much higher temperature limit beyond which the heat of reaction is not retrievable from the dissociated species until they are allowed to cool down. Both these limits depend on the application envisaged and do not apply in cases where maximum heat transfer—for example, for cutting or welding—is the desired objective.

In thinking about pre-mixed flames we tend to associate flame temperature absolutely with the initial reactant composition—that is, the fuel to air ratio. The adiabatic final flame temperature is given, for a given mass of mixture, by

$$Q_c = \int_{T_{\text{unburnt}}}^{T_{\text{burnt}}} C_p \mathrm{d}T = [H_b - H_0]$$

where Q_c is the heat of combustion and C_p the heat capacity of the products at constant pressure. It is convenient to work in terms of enthalpy, H, so as not to have to take into account the effect of dissociation. For a simple flame (Fig. 2*a*), the reaction occurs over a range of temperatures close to T_b. If a converter is operated at this temperature its efficiency generally falls far short of the Carnot cycle value.

To maintain flexibility, however, it is better if we allow ourselves the variable of adding, subtracting, or recirculating some of the energy. Addition of energy to the reactants is perhaps the most obvious further degree of freedom and method of control. In its simplest form, we can preheat the reactants, though doing this by means of a solid preheater is limited to relatively low temperatures, both by the onset of preignition and by melting of the containing walls. Beyond this, we can use radiation, adiabatic compression, or electrical heating. As regards radiation, the difficulty is that in a gas (unlike in a dust cloud, for example) there is virtually nothing to absorb it. To succeed, the radiation flux has to be high enough to create a sufficient concentration of free electrons to absorb the energy. This can be achieved transiently at the focus of a Q-switched laser[1] but cannot, as yet, be done continuously. Adiabatic compression in continuous flow systems has been applied in the form of a stabilized detonation or, at least, shock initiated combustion[2,3]. The burner here looks more like a supersonic wind tunnel, the gases emerging under-expanded from a nozzle and being rapidly heated across the standing shock wave. Experimentally, it is easier and cheaper to add the energy electrically by means of some kind of discharge and various devices based on a.c., d.c., magnetically rotated, arcs and radio frequency discharges have been discussed in the literature[4].

In all these cases, if Q_a is the energy added, the final temperature, T_f, is obtained from

$$\int_{T_0}^{T_f} C_p \mathrm{d}T = Q_c + Q_a = H_f - H_0$$

and the idealized thermodynamic efficiency corresponds to the higher temperature level. Again, this cannot be approached in practice, the additional problems here being associated with the containment and utilization of the much higher temperatures involved. Now there are some special purposes[4] for which such augmented flames promise to be valuable, because of the large heat transfer from their dissociated products, their ability to stabilize very large reactant throughputs by generating specific radicals when they are used as pilot burners in high intensity combustion systems[7], or for producing endothermic compounds by quenching their products. As the chemical energy from fuels tends as yet to be much cheaper than that from other supplies mentioned above, it is economically unacceptable for general purposes to heat these systems from an external source. The above mentioned increase in efficiency is small compensation for having to supply Q_a as electrical power, particularly when losses in a compressor, or to arc electrodes, have to be taken into account.

Of greater economic viability is the concept of recirculating some of the combustion energy. Perhaps the most frequently used method of flame holding which operates on this principle is the recirculation of some of the hot combustion products. Widely used, particularly in propulsion devices, in its simplest form this requires only some baffle or change in contour of combustion chamber which will induce a vortex in the appropriate region. This kind of recirculation is, however, always accompanied by dilution of reactants with products and is useful only because of the particular form of the rate law which implies that the effect of increasing temperature is very considerably greater (see Fig. 1, curve 2) than the corresponding consumption of reactants and dilution with products, over a large part (at least the first 75%) of the conversion scale. The normal flame temperature (and hence the maximum efficiency of any converter) remains unaltered. Only the maximum throughput of the combustion chamber is increased because the volume giving a high combustion intensity is greatly enlarged by increased mixing over that in a laminar flame in which it is confined to a very narrow zone by the small scale of molecular transfer processes. Further improvements in mixing eventually lead to homogeneity and the idealization of the perfectly mixed reactor[5] in which conditions are deemed to be uniform. The dilution effect, however, places an absolute maximum on the reaction rate attainable in this way. This is reached when the conditions of the apex of the reaction rate curve (2, Fig. 1) apply to the entire volume of a perfectly stirred chamber.

I shall now consider a simple alternative to which the above limitation does not apply—recirculating heat alone. In its simplest form, consider a burner whose premixed reactants are being preheated by a single encounter with the flame products (Fig. 2*b*). The enthalpy chart is included as a corrective to the impression that this device is suitable for producing infinite temperatures in the steady state. Indeed, once the steady state has set in, the exit temperature is the normal T_{burnt} value, calculated as above, since the outgoing enthalpy must be equal to the energy input. At this point it does not differ from the scheme based on recirculating hot products. In between the initial and the ultimate final stages, however, we have achieved a higher temperature on borrowed heat and this will produce a higher reaction rate (following a curve such as 1 in Fig. 1) or any of the other desirable features mentioned above. On taking the inlet tube round once more and postulating two perfect single stage heat exchangers (Fig. 2*c*) the maximum would correspond to double the borrowed enthalpy and so forth. To extend the concept, let us introduce a counter flow heat

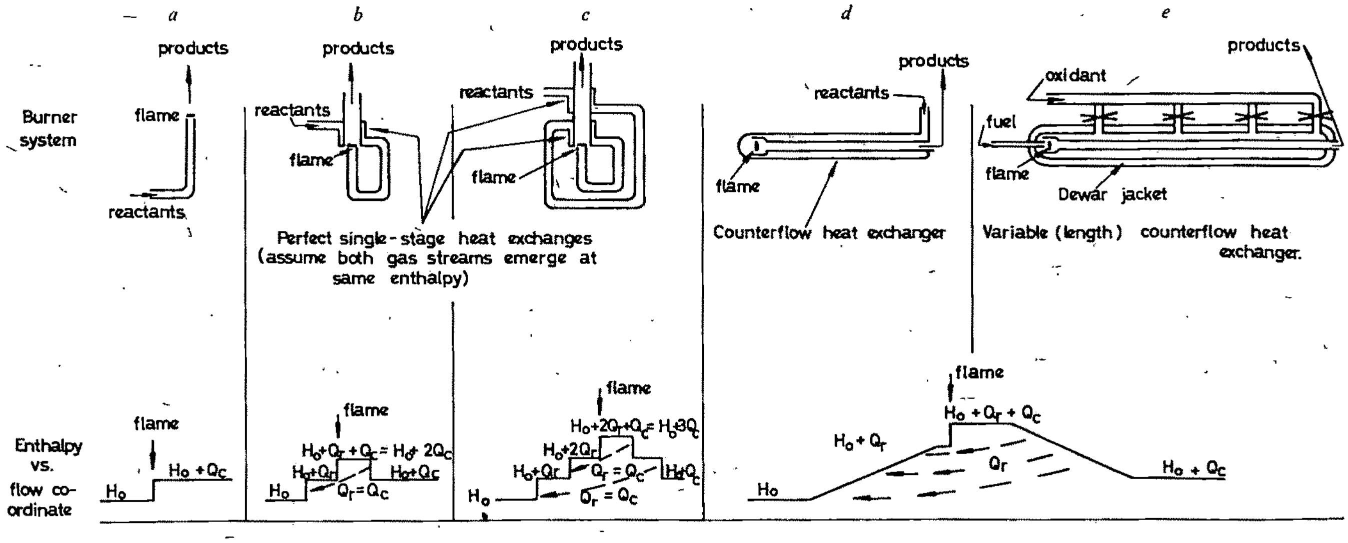

Fig. 2 Relation between enthalpy and flow coordinate for various burner systems.

exchanger (Fig. 2*d*) which we can make as long as we wish. In Fig. 2*e* some further refinements have been added: a vacuum flask surround to minimize heat losses from the device; a separate fuel and oxidant inlet, to prevent premature ignition; and a means of varying the heat transfer between outlet and inlet during operating conditions—all of which are perfectly feasible in practice. As regards the latter, there are, of course, more elegant methods of varying heat transfer than by the variation of effective length by selecting the appropriate inlet—the drawing is purely schematic. These devices dissociate the flame temperature from the initial composition. The enthalpy immediately beyond the reaction zone, H_c, is now given by

$$H_c - H_0 = Q_c + Q_r$$

being determined as much by the heat recirculated—Q_r—as by the input energy, Q_c. Moreover, the efficiency of a converter now operates on $(H_0 + Q_c + Q_r)$ instead of $(H_0 + Q_c)$. The output is therefore correspondingly higher and the overall efficiency can be increased by increasing Q_c, providing only that a small temperature differential is left to drive the heat transfer. In the case of a suitable converter it is possible to reject the thermodynamically unusable heat to the incoming gas—making the power cycle part of the heat exchanger. (For example, a thermoelectric generator could be operated between the combustion chamber and the inlet tube.) At first sight it seems surprising that such increases in overall efficiency should be possible without violating the laws of thermodynamics. In fact, we are merely "building a dam in the heat flow" and using the additional potential of releasing the chemical energy at its highest point.

Of course, in the case of mixtures of the now usual heats of reaction the heat exchangers in Fig. 2 would melt before more than 75% of the enthalpy could be recirculated. If, however, we can increase temperature arbitrarily by recirculating heat, we are no longer confined to such flames. At this point it will therefore be convenient to divide the entire combustion field into a high and a low temperature branch, the dividing line being drawn at the highest available melting point of any material of which a heat exchanger could be constructed. For the high temperature branch, if it is desired to raise the reaction temperature further, the principle of Fig. 2 must be interpreted schematically. Instead of the heat exchanger we might use a generator of electric power downstream which would supply an arc heater ahead of the flame, or we could make use of a detonation, in fact. In a steady state detonation, the degradation of momentum of the exit gases feeds the shock wave in front, which preheats the gas and is thus responsible for the high rate of conversion. Burners in which detonation is constrained to rotate in a torroid while the reactants are fed in, and products removed through slots in its side, have been proposed[6].

For many applications, however, it may well be that the low temperature branch will appear more promising. Since the melting point of the container may not be exceeded even immediately downstream of the combustion chamber, this makes possible the use of extremely lean mixtures, or of very low grade fuels. In this way it would be possible, for example, to burn the ventilation air of gassy mines; it has been shown that a 1% mixture of methane and air will produce a selfsustaining flame, when it is preheated to less than 1,000° C, even though its own heat release contributes only another 250° C or so. This is, of course, an extreme case and, by varying the fraction of heat recirculated, the burner could be adapted to any mixture, so long as the normal adiabatic final flame temperature itself does not exceed the melting point. At the same time the scheme retains all its advantages of producing no high temperature pollutants, providing gases at temperatures acceptable to other mechanical components without an intermediate cooling stage and allowing some of the energy to be drawn at a higher temperature, and therefore efficiency, level, using a suitable thermoelectric converter or a Stirling motor, perhaps. An experimental quartz burner of this type (Fig. 3) instrumented with thermocouples to monitor gas temperatures in various parts of the stream is now being operated in very lean mixtures of methane and air.

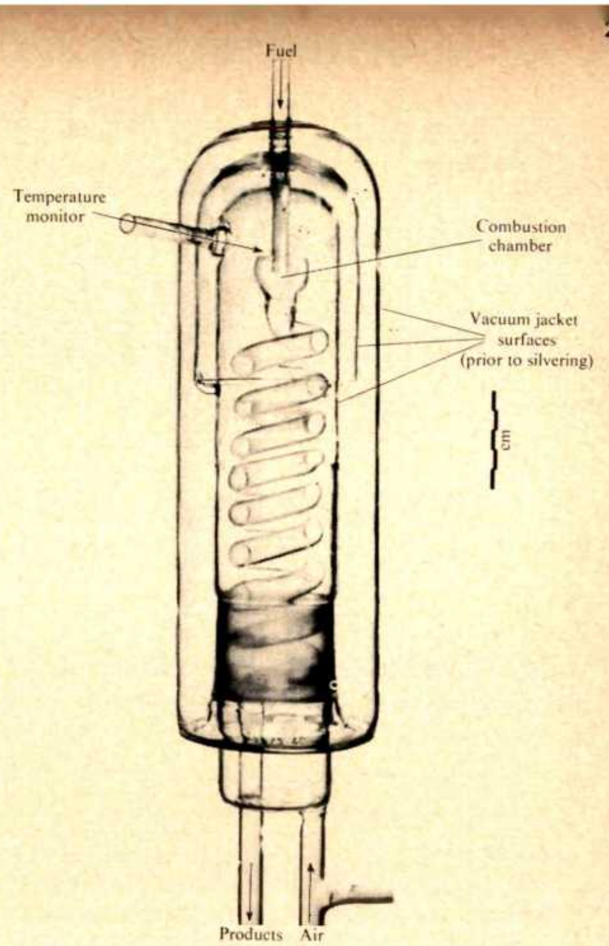

Fig. 3 Heat recirculating burner for lean fuel to air ratios.

With the advent of coal dust and other fluidized bed reactors, the subject has been drifting in this direction during the past few years. A fluidized bed does, of course, act as a very efficient heat exchanger. In the more remote future it may well be, when further improvements in the combustion intensity of low grade fuel mixtures are required, that they will be achieved by hybridizing the high and low temperature branches. It has become apparent already that an augmented flame pilot producing radicals at high temperatures would greatly help to stabilize a large throughput of mixtures of low heats of combustion[7], particularly if these have already been preheated by the recirculation scheme.

Thus, once we can control the reaction temperature independently of the heat of combustion of the mixture by one of the methods mentioned, it becomes feasible and desirable to design combustion chambers for specific purposes. In this way we can increase combustion intensity and converter efficiency, minimize pollution, burn low grade fuels efficiently and generate product gases at a temperature acceptable to machinery downstream without either subsequent cooling or having to reduce reaction temperature and hence throughput.

I thank Drs A. R. Jones, D. R. Hardesty and J. B. Cox for helpful discussions.

Obsidian Source Identification by Fission Track Analysis

S. A. DURRANI, H. A. KHAN & M. TAJ*

Department of Physics, University of Birmingham, Birmingham B15 2TT

COLIN RENFREW

Department of Ancient History, University of Sheffield, Sheffield S10 2TN

Fission track analysis has been used to determine the age and uranium content of obsidians from sources in south-east Europe and Anatolia, and from archaeological deposits in mesolithic levels at the Franchthi Cave in southern Greece. It is confirmed that the Franchthi obsidian came from the Aegean island of Melos. This is the earliest positive indication available for maritime travel, and carries the history of seafaring back a thousand years.

OBSIDIAN, or volcanic glass, was widely traded in prehistoric times, and the investigation of the trading pattern has long been a preoccupation of archaeologists and prehistorians. To characterize the obsidian, of which an artefact is made, physical or chemical properties of the material must be recognized which distinguish it as deriving from a specific natural source. Optical spectroscopy, X-ray fluorescence, and neutron activation are among the analytical techniques which have been used[1] for this purpose.

Trace element analysis usually works well: when concentrations of appropriate elements (for example, barium against zirconium) are plotted, obsidians from single sources form distinct clusters, well separated from one another. Difficulties, however, arise when obsidians from several different sources show convergent compositions. This has been observed[2] in Greece, where obsidians from the sources on the Cycladic island of Melos in the central Aegean Sea resemble in composition those from the Dodecanesian island of Giali in the eastern Aegean, lying 240 km east of Melos. As a further complication, both resemble, in their trace element composition, obsidian from the Tokaj region of Hungary, 1,300 km to the north-west, and from the central Anatolian source at Acigöl near Kayseri, 1,000 km to the east of Melos. These are the sources nearest to the Aegean, and it has been suggested that Hungarian or Anatolian obsidian reached Greece by trade in prehistoric times.

When obsidian artefacts are found in very early archaeological contexts in mainland Greece, an Aegean source for the material (in Melos or Giali) seems the most likely. But clearly the possibility of trade with Anatolia or with Hungary cannot be ruled out, especially because recent work[3] has confirmed that there was already an extensive early trade in seashells between the Aegean and the Balkans, in neolithic times. The possibility also remains, although it is remote, that obsidian was also obtained from some Aegean source at present unknown.

To overcome these problems it seemed useful to consider other variables which might discriminate between sources. The date of eruption in which the obsidian was formed is one such parameter, and the fission-track analysis method of age determination was a possible approach. The method, of course, has its limitations: two geographically remote eruptions may have occurred at roughly the same time; or, conversely, successive eruptions may have taken place in a given area over a long time. This is known to be the case in the Lipari islands off the coast of Sicily in the Tyrrhenian Sea, where dated archaeological deposits lie intercalated between obsidian-bearing strata. The same may hold for the Acigöl source, where several obsidian flows are known in the source region. In such cases the determination of a further parameter, the uranium content of obsidian samples, which is an integral part of the fission track analysis technique, may be useful in supplementing other criteria available for source identification. It may be added here that our purpose has not been to date the use of the artefacts (which are made by chipping or flaking, and not melting, of the obsidian). That only becomes possible if the artefact has been heated to high temperatures during its use[4], thus annealing out the then-existing fission tracks and, effectively, re-setting the clock.

Our attention has been focused on obsidians designated as Group 1 on the basis of the existing trace-element classification of Cann and C. R.[5], the aim being to distinguish between the various members of this group (which comprises obsidians from Melos and Giali in the Aegean Sea, as well as those from central Anatolia and the Carpathian Range in Hungary). Samples from these sources, the trace-element composition of which had previously been determined by optical spectrography[2,6], were selected for analysis (Table 1). Furthermore, three samples were chosen from the "mesolithic" (that is, pre-farming) levels at the Franchthi Cave in South-East Greece, excavated by Professor T. W. Jacobsen[7]. Radiocarbon dates for this period at Franchthi, lying in the eighth and seventh millennia BC, establish this as the earliest prehistoric context in the Aegean where obsidian has been found. For instance, stratum H-1, A117, from which obsidian was examined, yielded dates of 7527 BC and 6792 BC on the 5568 year ^{14}C half-life.

---

*Present address: University of Surrey, Guildford.

Table 1 Ages and Uranium Contents of the Obsidians Investigated

Obsidian sample *	Age (m.y.) †	U-content (p.p.m. by weight) ‡	
		Primary detection method	Auxiliary detection method
Hungarian			
Borsod (60)	3.86±0.24	8.6	7.7
Borsod (22)	3.37±0.27	8.9	
Central Anatolian			
Bor (100)	2.29±0.32	2.5	
Acigől (269)	1.95±0.33	3.5	
Acigől (156)	8.14±0.59	9.0	
Aegean			
Giali (390)	2.01±0.26	11.1	
Giali (218)	8.04±0.65	4.1	
Melos, Adhamas (120)	8.95±0.94	4.7	
Melos, Adhamas (25)	8.54±0.73	4.8	
Melos, Dhemenegaki (119)	8.35±0.72	4.9	
Melos, Dhemenegaki (116)	2.36±0.53§	—	9.1
Franchthi cave (S. Greece)			
Sample 6936 (H-1, A117)	8.48±0.55	4.6	
Sample 7077 (H-1, A123)	8.82±0.57	4.1	
Sample 7066 (H-1, A99)	9.33±0.60	4.4	

* The code numbers are in accordance with those in refs. 2 and 6.

† All ages are determined by using equation (1) (see text), based on the primary detection method, except for sample 116. No corrections are necessary for thermal lowering of ages (see Table 2). The quoted uncertainties in ages are made up of statistical (Poisson) errors, background subtraction errors, and fluence uncertainties (±5%).

‡ The U-content is determined in all cases by the primary detection method (that is by counting natural and induced tracks in the sample itself), except in the case of sample 116 where the auxiliary detection method was used (placing an external detector to receive induced fission fragments emanating from the sample). In the case of sample 60, both methods were used for comparison purposes. The uncertainty in uranium content values is estimated to be ~10%.

§ The age is based on natural track counting in conjunction with uranium-content determination by the auxiliary detection method in view of the poor optics of the sample. These two factors result in the unusually high error quoted (±22.5%). It is hoped to make a more precise determination of this age later.

Fission Track Analysis

The fission track analysis method has been used by several authors, both to determine the ages of obsidians (see, for example, refs. 8–11) and to obtain their uranium (and thorium) content[9,11–12]. It can be readily shown (refs. 13 and 14, and unpublished work of H. A. K. and S. A. D.), that the age A (in years), and the uranium content C_u (in p.p.m. by weight) in a material, are given by

$$A=(\rho_n/\rho_i).5.01\times 10^{-8}.F \qquad (1)$$

and C_u (p.p.m.)$=9.445\times 10^{7}\times \rho_i/(D.R_{ap}.\cos^2\theta_c.g.f(t).F)$ (2)

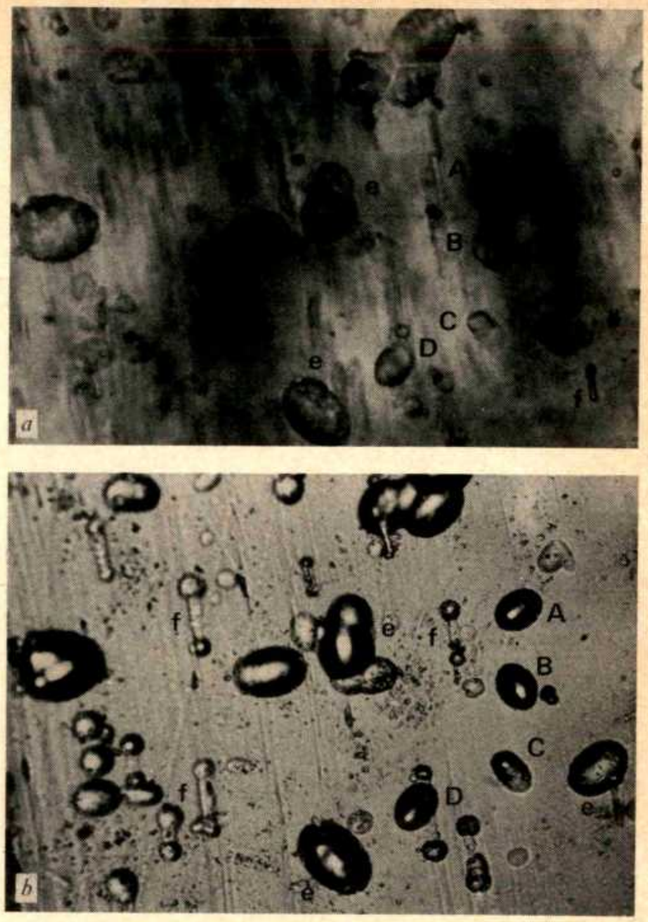

Fig. 1 Contrast between the two modes of microscopic viewing. The same field of view in the Dhemenegaki sample 119 is shown in the two photomicrographs under (*a*) transmitted light mode and (*b*) "epi-illumination" (reflected-light) mode. In *a*, the poor optics of the sample (notice streaks of varying colour and refractive index) results in ill-defined fission etch pits, which are difficult to distinguish from spurious pits and defects. In *b*, epi-illumination brings out the genuine fission etch pits (A, B, C, D) quite clearly. Pits marked e are spurious etch pits on the adopted criteria; configurations marked f are believed to be feldspar crystals the extremities of which appear to offer preferential etching channels to the acid as seen in *b*; (in *a* the feldspar crystals are in deeper layers which have not been etched).

Here ρ_n and ρ_i are the densities of etch pits per cm^2 produced by spontaneous and induced fission, respectively, the latter being induced by a fluence F of thermal neutrons per cm^2, D is the density (g cm^{-3}); R_{ap} the "apparent range" of an average fission fragment; θ_c the "critical angle" of etching; g a geometrical factor; and $f(t)$ the "prolonged etching factor" for the material. We take the value of $D\times R_{ap}$ to be the same as found[14] for a "reference glass" (U-2) containing a known amount of uranium (namely, 2.41 g $cm^{-3}\times 15.2$ μm), and $g=1$ (that is "4π geometry": the contribution of fission fragments from both sides of each etched surface being taken into account). The numerical factors in equations (1) and (2) result from various natural constants; in particular the fission decay constant of ^{238}U has been taken to be 8.42×10^{-17} yr^{-1}.

The critical angle, θ_c, is defined as the minimum inclination, with the surface, of a track that can be successfully etched. We have determined the value of θ_c for (Hungarian) obsidian (unpublished work of H. A. K. and S. A. D.), using an external collimated fission source of ^{252}Cf, to be 26° 00′±30′.

The prolonged etching factor $f(t)$, first introduced by H. A. K. and S. A. D. (unpublished work; see also ref. 14) is defined as the ratio ρ/ρ_0, where ρ is the track density observed on etching the sample for time t, and ρ_0 is the extrapolated value corresponding to zero etching time. The factor cancels out in equation (1) if identical etching conditions are used to determine both ρ and ρ_i, but not in equation (2). The value of $f(t)$ for obsidian is found to be 1.17 at $t=60$ s (on etching in ≈ 40 vol. %HF at 13° C).

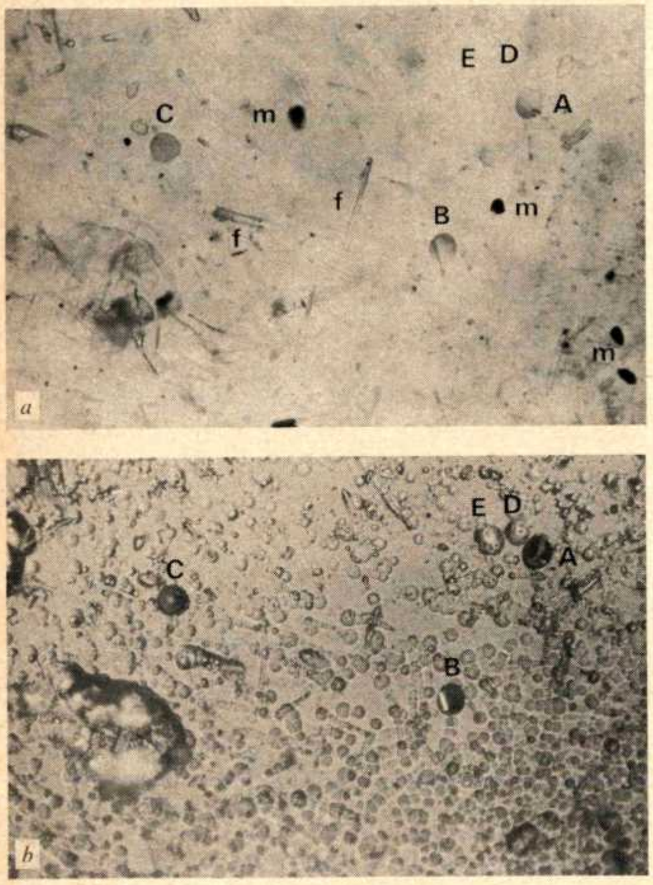

Fig. 2 Acigöl sample 269 observed under (*a*) transmission mode and (*b*) epi-illumination mode of microscopic viewing. In *b* the genuine fission etch pits (A, B, C, D, E) on the top surface are easy to pick out, whereas they remain indistinct in *a* which covers the same field of view. The needle-like objects marked f are feldspar crystals; the black inclusions marked m are believed to be magnetite or other iron ore crystals in the body of the sample (seen in *a*). Such crystals and inclusions, when they cross the top surface, get etched and result in the spurious pits seen in *b*. That most of these pits and other defects are unconnected with fission damage is confirmed by their survival on high temperature annealing (see text). The bright line in etch pit B seen in *b* is the reflexion from a feldspar crystal lying in a different plane.

Although the fission track analysis technique is simple in principle, considerable difficulties were encountered in applying it to obsidians. Several samples were optically very "dirty", containing dark streaks of varying colours and inclusions of crystals of magnetite, feldspar and the like. The latter were found to lie along "flow bands", indicating that feldspar crystals had formed while the obsidian was still partially fluid and in the process of cooling down. On etching in hydrofluoric acid, when a feldspar crystal (or less frequently, a limb of a skeletal magnetite crystal) crossed the etched surface, it seemed to offer a preferential etching channel to the acid, thus yielding an etch pit which was often difficult to distinguish from a genuine fission-fragment etch pit. That most of the pits and other defects were unconnected with fission damage was confirmed by the observation that, in spite of heating the obsidian samples for 1 h at 700° C, the number of etch pits subsequently produced remained largely unchanged. Fleischer and Price have shown[10] that even pure fused silica loses all fission tracks under these annealing conditions (tektite glass requires[10,15] only ~500° C for 1 h for this to happen).

These problems of extraneous, but optically similar, etch pits and enclosed "blisters" and other defects were largely overcome by adopting the "epi-illumination" mode of viewing, instead of the transmitted-light mode used hitherto. The microscope used was a Zeiss 'Photomicroscope'. Figs. 1 and 2 show two pairs of typical photomicrographs under these two viewing conditions.

Ages and Uranium Contents

Table 1 records the ages and uranium contents of obsidian samples from Hungary (Borsod region), central Anatolia, and the Aegean Sea (three different locations). It is interesting to note that although the two samples from Hungary have, within experimental errors, identical ages of formation, the Aegean and the central Anatolian samples show a certain sequential eruption. Thus the two samples (120 and 25) from Adhamas as well as one each from Acigöl (156), Giali (218) and Dhemenegaki (119) all show eruption ages between 8 and 9 m.y., thus suggesting a general volcanic activity in the region at that time. A further simultaneous activity in the whole area (indicated by the central Anatolian samples 100 from Bor and 269 from Acigöl; sample 390 from the island of Giali; and sample 116 from Dhemenegaki on the island of Melos) seems to have taken place about 2 m.y. ago. These conclusions are of considerable potential interest to geologists and petrologists. From our point of view, however, the coincidence of eruption dates (~2 m.y. and ~8 m.y.) in the various locations of interest is a little unfortunate, because it makes clear-cut identification of obsidian sources more difficult. This coincidence is, nevertheless, fortuitous and the principle of the method remains unaffected.

A further variable at our disposal is the uranium content. Here, the two Hungarian samples are found (within experimental errors) to have identical uranium contents as well as eruption ages; the same applies to three of the samples from the island of Melos (120 and 25 from Adhamas, and 119 from Dhemenegaki). The two obsidian samples each from Acigöl, Giali and Dhemenegaki can, however, be clearly differentiated on the basis of both age and uranium content. The uranium content of sample 116 from Dhemenegaki (which was optically very dirty) has been determined by H. A. K. and S. A. D. (unpublished work) using the auxiliary detection method (by irradiating the sample, while in contact with an external plastic detector, in a nuclear reactor). The U-content (9.1 p.p.m.) is quite distinct from the other Dhemenegaki sample (119), as is the age.

In comparing ages, it is necessary to ensure that some of them have not been thermally lowered. It is known (see, for example, refs. 15 and 16) that the application of heat results in track fading, leading to an apparent reduction of age. This can be corrected[14-16] by examining the etch pit diameters (in identical etching conditions) of freshly induced fission and spontaneous (or natural) fission: for fading of tracks is accompanied by a general diminution of the resulting etch-pit diameters. Table 2 shows the results for induced and spontaneous fission in the obsidians studied by us. Application of t test to each of the distributions listed shows that no significant diminution of etch-pit diameters has taken place. The ages recorded in Table 1 can thus be taken to be the true ages.

Franchthi Cave Obsidian

It is clear from the foregoing that, in favourable circumstances, the eruption age and uranium content of obsidian samples can serve as source identification criteria. As a test case, a heuristic assay was made on three obsidian samples from mesolithic levels of the Franchthi Cave in the Argolid, southern Greece. Nearly all the obsidian artefacts and waste flakes at Franchthi show the pearly lustre common in obsidian from both the Melian sources at Adhamas and Dhemenegaki. Melos, lying 120 km south-east of Franchthi, is the nearest known source of workable obsidian. Preliminary spectrographic analyses by Dr J. E. Dixon of the University of Edinburgh place the Franchthi specimens in Group 1 of the existing classification, which is consistent with a Melian origin. The very early date of the Franchthi material, and the lack of other evidence for maritime travel in the eighth or seventh millenium BC made a fresh approach, by fission track analysis, desirable.

Table 2 Comparison of Etch-pit Diameters of Spontaneous and Induced Fission Tracks in Obsidian Samples in Order to Judge whether Thermal Lowering of Ages has Taken Place

Obsidian sample*	Etching time (s)	Mean etch pit diameter (μm) (and the number of pits measured)‡ Spontaneous fission	Induced fission
Hungarian			
Borsod (60)	90	14.16±2.30 (80)	14.39±2.22 (67)
Borsod (22)	60	9.74±1.32 (80)	10.01±1.55 (70)
Central Anatolian			
Acigöl (269)	60	8.81±1.49 (100)	9.06±1.57 (100)
Acigöl (156)	60	8.93±1.46 (120)	9.06±1.37 (120)
Aegean			
Giali (390)	60	8.96±1.23 (103)	8.90±1.34 (112)
Giali (218)	60	8.76±1.16 (89)	8.71±1.05 (81)
Melos, Adhamas (120)	90	11.51±1.28 (103)	11.29±1.29 (98)
Melos, Adhamas (25)	60	8.63±1.10 (90)	8.61±1.12 (88)
Franchthi cave (S. Greece)			
Sample 6936 (H-1, A117)	60	8.56±1.22 (95)	8.70±1.19 (98)
Sample 7077 (H-1, A123)	60	8.86±1.32 (105)	8.85±1.25 (105)
Sample 7066 (H-1, A99)	60	9.00±1.14 (91)	8.98±1.23 (91)

No significant difference in diameters is found in any sample, as verified by the application of *t* test to the means and the standard deviations of the distributions.

* The code numbers are in accordance with those in refs. 2 and 6.

† Etching is always carried out in ≈40 vol. % HF at 13° C.

‡ The numbers of etch pits measured are shown in parentheses immediately after the values of diameters. For elliptical pits, major axis has been measured instead of diameter. The errors shown are standard deviations of "single observations".

Table 1 records the results for age and uranium content from these samples. It will be seen that not only do the ages and U-contents agree between the three samples, but they are also very similar to those for Melian obsidian from Adhamas (samples 120 and 25), and for one of the Dhemenegaki samples (119). They are also compatible with one of Giali samples (218) but not with any of the central Anatolian or Hungarian samples.

The results are thus entirely consistent with an origin in the Melian sources at Adhamas or Dhemenegaki. They exclude a Hungarian or central Anatolian origin, and are particularly useful in reducing the likelihood of an origin in some source in mainland Greece so far unknown, a possibility suggested by some scholars[17]. Although the possibility of unrecorded obsidian sources in mainland Greece could not be excluded, it already seemed unlikely that such a source would fortuitously produce material resembling that of Melos both in appearance and trace element composition. That it should further match the Melian material both in age and uranium content (which the prehistoric finds from Franchthi now do) would be an altogether remarkable coincidence. We therefore suggest that the possibility of such an origin for the Franchthi material, from an unknown source, may now be excluded.

The conclusion that the Franchthi obsidian came from Melos is of great interest. Hitherto, the earliest evidence for a traffic in Melian obsidian was from early neolithic sites at Knossos in Crete, at Sesklo in Thessaly and at Nea Nikomedeia in Macedonia, all a full millenium later. It seemed that in the Aegean, as in the Near East, the obsidian trade began in earnest at the time of the development of farming. Now it seems that the hunters and fishers of southern Greece were already, by the beginning of the seventh millenium BC, and perhaps earlier, reaching Melos by boat. The occurrence of obsidian in successive layers at Franchthi suggests, moreover, that Melos was reached on several occasions. As Jacobsen points out[7], it may be relevant that obsidian first occurs at Franchthi at about the same time that its inhabitants were beginning the intensive exploitation of marine fish. Seafaring and trade may have been the consequence of the intensive use of the sea as a food source.

The Franchthi Cave obsidian is the earliest positive evidence available, from anywhere in the world, of the transport of goods by sea. The very rare obsidian from early neolithic Cyprus, brought by sea from the central Anatolian sources[18], is not found there until 1,500 yr later. The corroboration by fission track analysis of a Melian origin for the Franchthi Cave obsidian thus carries back the history of seafaring by more than a thousand years.

We thank Professor T. W. Jacobsen for allowing C. R. to study the Franchthi Cave obsidian, and for arranging (with the cooperation of the Greek Archaeological Service) that selected samples be made available for analysis; Mr E. D. Lacy for advice on the chemistry of obsidians; and the SRC and the staff of HERALD reactor at AWRE, Aldermaston, for irradiation facilities. H. A. K. and M. T. thank the Pakistan AEC and Colombo Plan authorities, and the Government of Pakistan, for financial support.

Evolution of the Scotia Arc

IAN W. D. DALZIEL & DAVID H. ELLIOT

Department of Geology and Lamont-Doherty Geological Observatory of Columbia University in the City of New York, and Department of Geology and Institute of Polar Studies, Ohio State University

---

In this article the evolution of the Andean–West Antarctic Cordillera, and its subsequent bending, disruption, and fragmentation in the Cenozoic to form the Scotia Arc, is documented by geological evidence.

THE suggestion that the Andean mountain chain reappears in the Antarctic Peninsula[1] (Fig. 1) has in the past been supported by geological similarities[2,3] and the discovery of the discontinuous arcuate submarine Scotia Ridge (Figs. 1 and 2) that joins the two continents[4]. Significant detail has been added in the past thirty years to strengthen this hypothesis.

In earlier models for the evolution of the Scotia Arc, as the whole feature is generally known, the islands of the North and South Scotia Ridges (Fig. 2) were assumed to be parts of an originally straight north–south Cordillera displaced eastward relative to South America and Antarctica during the drift of these continents westward relative to Africa[5–9]. Recently, however, it has been suggested that the present east–west trend of the North and South Scotia Ridges is primary[10–12]. Our review[13] of the published data, and of unpublished data resulting from recent field work[14–17] (also personal communications from G. Grikurov, 1970; M. K. Rickard and K. T. Burns, 1970; J. Stewart, 1971; and E. González P., 1971), leads us to support the concept of an essentially rectilinear Andean–West Antarctic Cordillera. In what follows, we shall reconstruct this Cordillera in some detail. The bending, disruption and fragmentation which formed the Scotia Arc imply less shortening of the Pacific margin than has been assumed[18].

Geological Considerations

The Scotia Ridge system is discontinuous, and locally emergent, forming small, high and extremely rugged islands (Fig. 2). The islands on the east–west trending North and South Scotia Ridges consist mainly of pre-Cenozoic rocks of continental character that can be correlated with those in both southern South America and the Antarctic Peninsula[2,3,5,6,9,13,16,22–24]. The islands of the South Sandwich Ridge, which closes the arc in the east, are wholly volcanic (most are active volcanoes)[25], and lie in a seismically active belt to the west of the South Sandwich Trench (Fig. 1).

The basin of the western Scotia Sea and Drake Passage (47° W to 70° W) are underlain by "normal" oceanic crust[26,27], but in some eastern parts of the basin there is a layer with P-wave velocity 7.5 km s^{-1} at the base of the crust[26–28]. Refraction profiles across the Burdwood Bank and the platform south of the South Orkney Islands (Fig. 2) reveal layers that are interpreted to be continental[26–30]. South Georgia and the South Shetland Islands (Fig. 2) are underlain by approximately 4 km of low velocity rocks (possibly consolidated sediments) over high velocity crustal material that may be either continental or oceanic[26,31].

The structural framework of the Scotia Arc in terms of plate tectonics is not entirely clear. It is generally assumed that the northern boundary of the Antarctic crustal plate lies along the Chile Rise and the South Sandwich Fracture Zone, both apparently consisting of fracture zones connecting short spreading-ridge segments[32,33]. But neither the North and South Scotia Ridges, nor the continental margin of southernmost South America have marked seismicity now (Fig. 1). Consequently the intense seismicity associated with the South Sandwich Trench seems to be anomalous. The problem remains of why there is relative motion between the American and Antarctic plates only along the South Sandwich Fracture Zone and the South Sandwich Arc (Fig. 1). Recently magnetic evidence has been presented for a late Cenozoic–Recent spreading-ridge, trending north-east–south-west in the Drake Passage, and for another situated immediately west of the South Sandwich Islands (Fig. 1) that trends north–south. The presence of the latter, if still active as proposed, helps to account for the seismicity of the South Sandwich Trench[10,12,21]. Reconstructions based on the former have led to an hypothesis that the Andean–West Antarctic Cordillera formed an easterly directed cusp in the area of the Drake Passage prior to 20–25 m.y. ago[10,12].

The geology of the Scotia Arc region can be simplified by emphasizing what seem to us to be the fundamental tectonostratigraphic units. This admittedly involves certain assumptions in correlation[13]. The units are

- Cenozoic sedimentary and volcanic deposits
- Late Mesozoic–Cenozoic plutons (the "Andean" igneous complex)
- Jurassic and Cretaceous sedimentary and volcanic deposits
- Late Palaeozoic sedimentary rocks
- Metamorphic basement complexes (? Palaeozoic; possibly Pre-Cambrian)

The metamorphic basement complexes (mostly low to medium grade paraschists) and the late Palaeozoic sedimentary rocks (mostly graywackes and shales) were both deformed prior to the deposition of the unconformably overlying mid to late Jurassic rocks; the sediments were deformed during the early Mesozoic Gondwanian Orogeny (known elsewhere in Antarctica as the Ellsworth[34] or Weddell[35] Orogeny), and the metamorphics probably earlier[13,22,36,37]. The age relations of the metamorphic basement and the Palaeozoic sediments are not certain, but recent Rb–Sr analysis of cores from the metamorphic basement east of the Andes[38,39] support a pre-late Palaeozoic age for the metamorphism. The Jurassic and Cretaceous rocks, including a thick sequence of mid to late Jurassic calc–alkaline volcanics, were deformed and metamorphosed with variable intensity[13–16] in the late Mesozoic–

earliest Cenozoic Andean Orogeny. They were intruded by pre-, syn-, and post-tectonic plutons of the batholithic "Andean" igneous complex[13,15,16].

Cenozoic sedimentation was scattered and locally interrupted by volcanism. No ages older than 4 m.y. (ref. 25) have been recorded from the South Sandwich Islands. But correlation of the magnetic anomalies immediately west of the islands[10,21] implies that volcanism began at least 8 m.y. ago.

The tectono-stratigraphic units can be traced in South America in continuous belts trending parallel to the Andean Cordillera. They are irregularly distributed in the islands of the Scotia Ridge and the Antarctic Peninsula (Fig. 2). The two main physiographic and tectonic provinces of southern South America are the Andean Cordillera and the extra-Andean lowlands to the east. The lowlands are underlain by the virtually undeformed Mesozoic and Cenozoic sediments and volcanics of the Magallanes Basin (Fig. 2) resting on a Palaeozoic or older metamorphic basement[38,39]. The Cordillera consists of deformed late Jurassic and Cretaceous volcanics and sediments that unconformably overlie the metamorphic basement complex, and are cut by plutons of the batholithic complex. In Tierra del Fuego the Jurassic volcanic deposits are disposed in an anticline with the metamorphic rocks in the core (M. K. Rickard and K. T. Burns, personal communication, 1970). This anticline probably continues northward along the Cordillera (unpublished data of Empresa Nacional del Petroleo, Instituto de Investigaciones Geologicas, and I. W. D. D.), although the structure is complicated by thrusting from the Pacific side[40] (also unpublished data of Empresa Nacional del Petroleo, M. K. Richard and K. T. Burns, and I. W. D. D.). Cretaceous flysch-type sediments flank the High Cordillera, those on the Pacific side being interbedded with mafic volcanics. The "Andean" igneous complex forms much of the Pacific side of the Cordillera. Late Palaeozoic sediments of the Madre de Dios Basin occur on the west coast at 50°–52° S (Fig. 2).

Our detailed reconstruction of the Andean–West Antarctic Cordillera prior to the inception of the Scotia Arc is based largely on the recognition of the tectonic provinces of southern

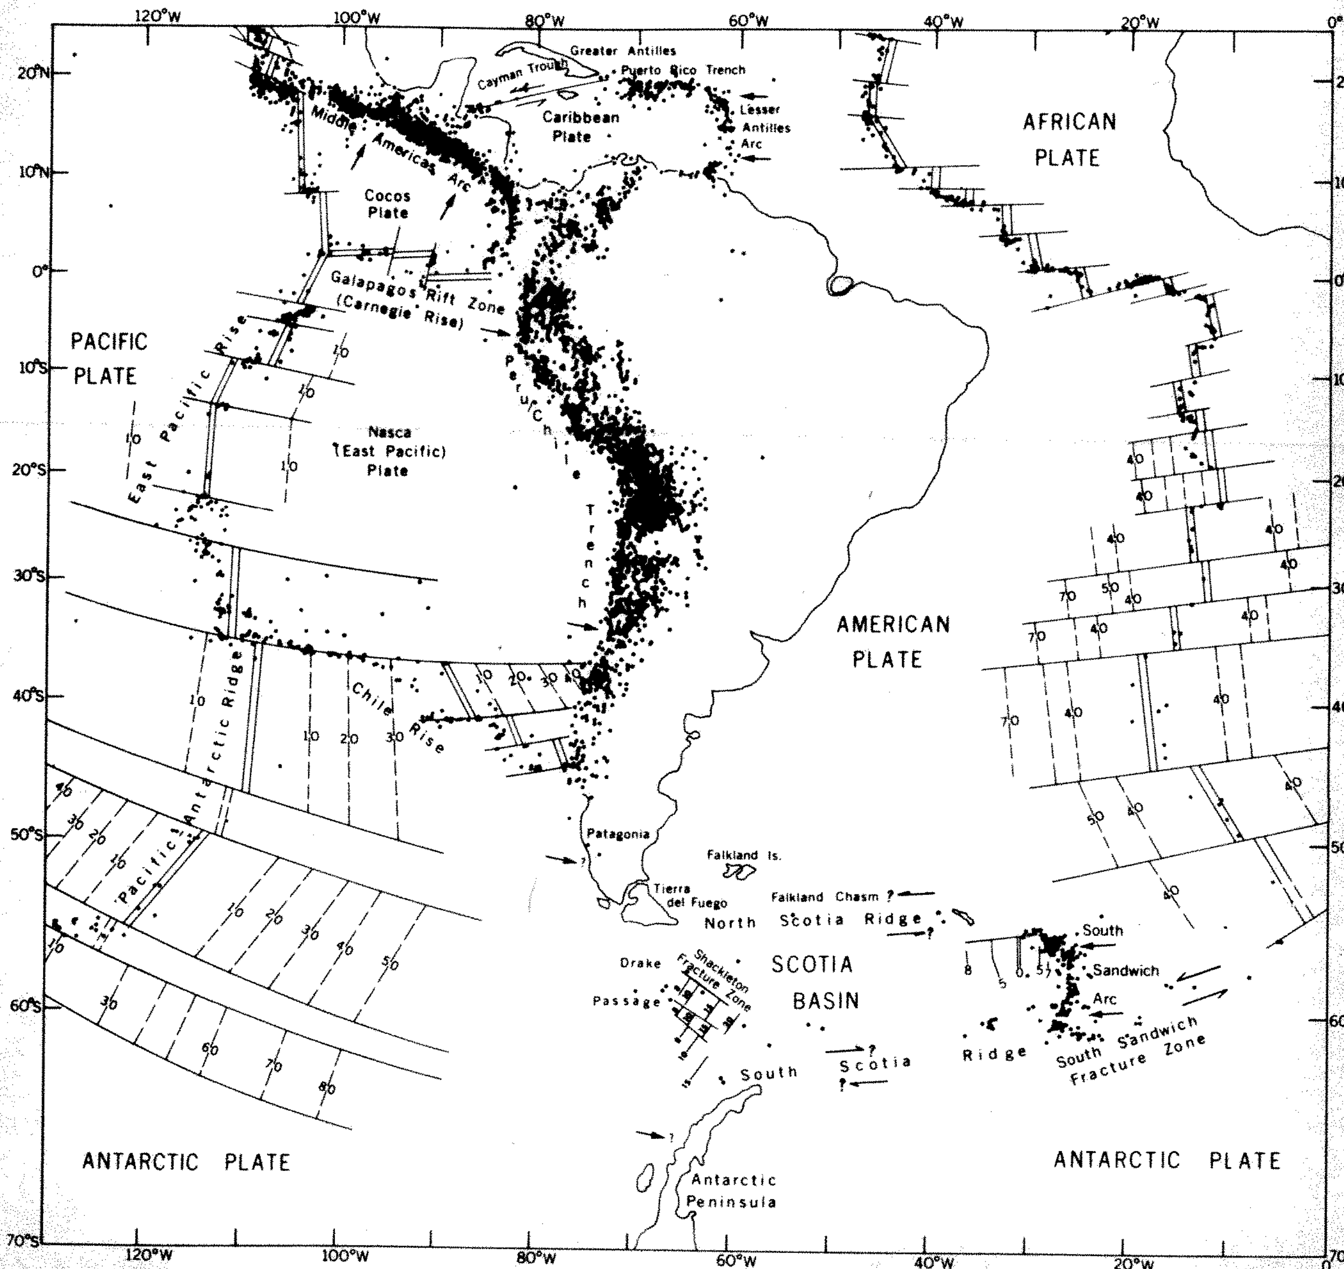

Fig. 1 The geotectonic setting of the Scotia Arc. Epicentres of earthquakes at depths of 0–700 km for the period 1961–1967 (ref. 19) are shown by black dots. The approximate age in millions of years of the floor of the Atlantic and Pacific Oceans, and of the Scotia Sea, as inferred from marine magnetic anomalies[10,20,21] is also shown. Arrows indicate inferred relative motion of the lithospheric plates on which they are drawn.

South America along the North and South Scotia Ridges, and in the Antarctic Peninsula. Extrapolation of the onshore geology (Fig. 2), our interpretation of the seismic refraction profiles[26,29], and dredging[41], indicate that the shallow Burdwood Bank immediately east of Tierra del Fuego is a structural continuation of the extra-Cordilleran Mesozoic–Cenozoic sedimentary basin. Refraction data[26,29] also show higher velocities in the basement of the basin that underlies the bank and forms its southern margin. This (seismic) basement is likely to be the Jurassic volcanics that underlie the sedimentary succession of the extra-Cordilleran basin in Tierra del Fuego[29,42], and which are known along strike as far east as Isla de los Estados (Fig. 2). Lack of appreciable magnetic expression along the southern margin of the bank[12,27] is not surprising, for the volcanics are largely felsic[13,15,16,40,42].

The metamorphic rocks of islets called the Black and Shag Rocks, the flysch-type rocks of early Cretaceous age intruded by an "Andean"-type igneous complex on South Georgia and the "Andean"-type igneous rocks of the Clerke Rocks[43–45] (Fig. 2), all indicate that the platforms supporting these islands also form part of the Cordillera. Moreover, the mafic volcanic rocks interbedded with the flysch-type sediments on South Georgia demonstrate that the island is a fragment of the Pacific side of the Andean Cordillera rather than a complete cross-section of it, as implied by earlier reconstructions[5–7], or part of the Atlantic side, as recently proposed[12]. We believe, therefore, that South Georgia originally adjoined Burdwood Bank, close to Isla Navarino with which it has often been compared geologically[23,24]. Thus the original length of the North Scotia Ridge is unlikely to have been as great as is suggested by earlier reconstructions[5,6,18].

The rocks of the South Orkney Islands, principally schists, amphibolites, and other metamorphic rocks, and intensely deformed, possibly late Palaeozoic sediments, are Cordilleran types[13,16,22], and the platform along whose northern margin they lie apparently constitutes an extra-Cordilleran Mesozoic–Cenozoic basin like the Magallanes Basin[30]. A similar basin is located east of the Antarctic Peninsula[13,16] (Fig. 2), and probably forms much of the submerged platform adjoining the Weddell Sea. The Antarctic Peninsula itself is Cordilleran.

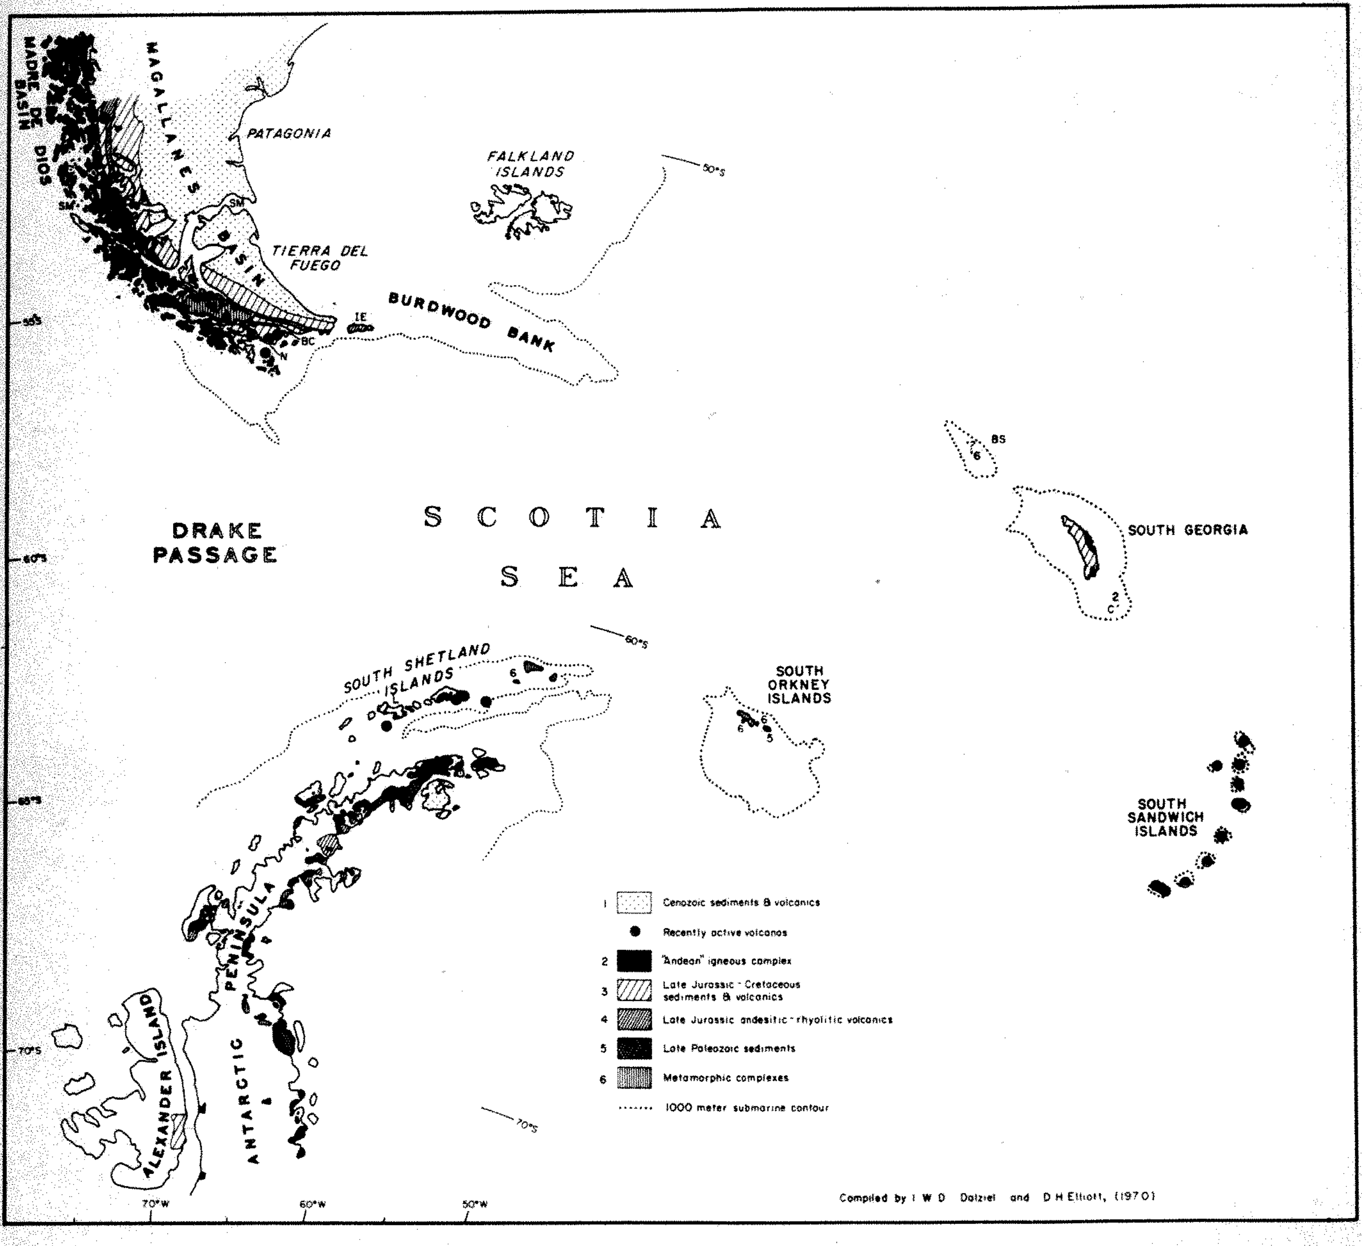

Fig. 2 Geological map of the Scotia Arc region modified after maps by the British Antarctic Survey, the Instituto de Investigaciones Geologicas (Chile), and Direccion Nacional de Geologia y Mineria (Argentina). BC, Beagle Canal; BS, Black and Shag Rocks; C, Clerke Rocks; IE, Isla de los Estados; L, Livingston Island; N, Isla Navarino.

North of 68° S it consists of "Andean" plutons intruding possibly late Palaeozoic sediments and late Jurassic volcanic rocks[22]. Irregular distribution of tectono-stratigraphic units results from the mild deformational effects of the Andean Orogeny in this area. The late Mesozoic rocks are therefore essentially flat-lying, and the outcrop pattern is a function of exposure level[13]. Farther south, however, on the Lassiter Coast (75° S, 67° W), deformed Jurassic clastic sediments are intruded by granitic plutons[47,48] and are analogous to the Andean Cordillera. This may be the case elsewhere south of 68° S in the Antarctic Peninsula, but there is insufficient published data.

Undoubted late Mesozoic sedimentary rocks with interbedded volcanics, comparable with the Pacific side of the Andean High Cordillera, are confined to Livingston Island in the South Shetland group[49,50] and to Alexander Island[51-53] (Fig. 2).

Evolution of the Andean–West Antarctic Cordillera

Southern South America, the North and South Scotia Ridges, and the Antarctic Peninsula are underlain at least in part by continental rocks certainly as old as Palaeozoic[38,39], and possibly Pre-Cambrian[37]. The structure of the basement metamorphic rocks is, however, too complex, and at present too poorly known[13,15-17,54] for any conclusion to be drawn concerning their relationship to the present Cordillera.

Marine magnetic data (W. C. Pitman, III, personal communication, 1971) and the results of the Deep Sea Drilling Programme[55] indicate that southern South America and the Antarctic Peninsula formed a marginal strip of Gondwanaland until the late Jurassic. The sedimentary contact between the late Jurassic lavas and the late Palaeozoic sedimentary sequences[13,17,22,46,54], together with the parallelism of the major fold axes in the Antarctic Peninsula and Miers Bluff Formation in the South Shetlands with the trend of the peninsula and the South Shetland chain[54], suggest that the late Palaeozoic sequences were deformed adjacent to Gondwanaland during the early Mesozoic Gondwanian Orogeny. Therefore it is unlikely that the late Palaeozoic sequences were deposited elsewhere and tectonically emplaced adjacent to Gondwanaland.

Deformation of the late Paleozoic sediments is the first recognizable sign of tectonic instability on the margin of Gondwanaland in the Mesozoic. It occurred not only in what is now the Scotia Arc region, but also in the Ellsworth and Pensacola Mountains of interior West Antarctica, the Cape Fold Belt of southernmost South Africa, and the Sierra de la Ventana of Argentina. In all of these areas (Du Toit's "Samfrau" geosyncline, see Fig. 4*a*) thick sedimentary deposits were highly deformed in the early Mesozoic (late Triassic–early Jurassic). The deformation was characteristically accompanied by at most low grade metamorphism, which may indicate little underthrusting. On the other hand, the extensive mid to late Jurassic calc-alkaline volcanism following uplift and erosion probably represents the surface evidence of a subduction zone that developed along the margin of South America and West Antarctica, as they began to move westward relative to Africa by spreading of the ocean floor. The most recent estimates of the time of opening of the South Atlantic, based on marine magnetic data (W. C. Pitman, III, personal communication, 1971) and the Deep Sea Drilling Programme[55], are consistent with this interpretation.

Deformation and uplift along the axis of the present Cordillera began in the early Late Cretaceous in western South America and was pre-mid Cretaceous at the southern end of the Antarctic Peninsula[47,48], but did not occur until the latest Cretaceous or earliest Cenozoic in the sub-Andean belt on the Atlantic side of the Cordillera in South America[56]. Pre- and syn-tectonic granitic plutons do occur[13,15,16,39,40], and post-tectonic intrusions of latest Cretaceous age[13,15,16,38-40] are common in the Cordillera. One intrusion as young as 12 m.y. (refs. 38 and 57) occurs in the sub-Andean belt between the High Cordillera and the extra-Cordilleran basin. The widespread structural effects of the Andean Orogeny on the rocks of the South Scotia Ridge and the northern Antarctic Peninsula were limited to relatively open folding, faulting and intrusion[13,16,22].

Evolution of the Scotia Arc

The geology and geological history of the region place the following constraints on the evolution of the Scotia Arc:

(1) The similarity of the geology and geological history in southern South America, the continental fragments bordering the Scotia Sea, and the Antarctic Peninsula make it virtually certain that there was once a continuous Andean–West Antarctic Cordillera.

(2) The right-angle bend in the southernmost Andes, the direction of overfolding and overthrusting there (always at right angles to the Cordillera and from the Pacific side), the fact that South Georgia represents a part of the Pacific side of the Cordillera, and limited palaeomagnetic data from the Antarctic Peninsula[7,58] all indicate bending, disruption, and eventual fragmentation of the Cordillera.

(3) Dating of the deformational and intrusive events of the Andean Orogeny indicates that the fragmentation cannot have occurred before the end of the Mesozoic. The striking similarity of Mesozoic tectonostratigraphic provinces around the Scotia Basin seems to demand continuity at least until the end of the Andean Orogeny.

(4) The disruption must have occurred prior to the inception of volcanicity in the South Sandwich Ridge, where the oldest dated rocks are 4 m.y. old (ref. 25). But the magnetic data are interpreted[10,21] to indicate an age of at least 8 m.y. for the South Sandwich Ridge, and that sea floor spreading has occurred from at least mid-Cenozoic (20–25 m.y. ago) until Recent in the Drake Passage. Hence the disruption and fragmentation of the Andean–West Antarctic Cordillera occurred in the early Cenozoic prior to 20–25 m.y. ago, or else accompanied spreading in the Drake Passage. Dott has[9,59] postulated that the fragmentation was entirely late Cenozoic, accompanying a global late Cenozoic tectonic episode.

Fig. 3 shows our concept of the evolution of the Scotia Arc based on these constraints. The Falkland (Malvinas) Platform is regarded as being a stable part of the South American continent at this time, so that bending of the Andean Cordillera resulted in the creation of the Falkland Trough between the North Scotia Ridge and the Falkland Platform.

Note that elimination of the South American and Antarctic Peninsula "oroclines" with the continents held in their present positions (inset) results in considerable and unacceptable overlap. This suggests that despite the spreading in the Drake Passage indicated by Barker's identification of the magnetic anomalies there[12,21], South America and West Antarctica are closer together now than they were when they separated from Gondwanaland (Fig. 3*a*). Some of the late Cenozoic–Recent spreading in the Drake Passage could have been taken up in subduction zones along the North and South Scotia Ridges. This is likely along the South Scotia Ridge that is bordered on its northern side by deep troughs[60], and was the site of andesitic volcanism in the early Cenozoic, prior to the onset of mildly alkaline activity at the beginning of the Pliocene[22,61]. Troughs also occur along the southern margin of the North Scotia Ridge[59], but the only sign of Cenozoic volcanism there is the presence of a few small vents north and west of Cape Horn.

Even if much of the spreading was not taken up in subduction zones, but rather by movement of the continents, the geology does not allow a cusp-shaped original connexion between the continents as suggested by Barker and Griffiths with the Pacific margin of the Cordillera extending no farther east than Cape Horn and Elephant Island[12] (Fig. 2), and with South Georgia on the Atlantic side. South Georgia is clearly part of the Pacific side of the Cordillera[13,23,24]. The geological evidence, however, dictates only a latest Cretaceous maximum age limit for the disruption and fragmentation of an originally near rectilinear Cordillera. It is possible, therefore, that the two continents approached one another more closely than at present during the early Cenozoic. The spreading in the Drake Passage over the past 20 m.y. may document subsequent separation from a cusp-shaped contact if little subduction occurred. Hence the two lines of evidence do not necessarily lead to mutually exclusive models.

The reason for the disruption of the original Cordillera in the Drake Passage is not entirely clear. The predominant factor appears to have been the narrowness of the continental connexion between the two parts of Gondwanaland that are now South America and West Antarctica when the South Atlantic Ocean Basin began to open. In all probability the lithospheric plate underlying the Pacific Ocean tended to bend and disrupt this continental strip rather than continue to be consumed beneath it. The initial bending of the Cordillera may, therefore, have accompanied rather than post-dated the Andean Orogeny. Katz[62] has pointed out that pronounced virgation of folds in the sub-Andean belt of South America occurs at the hinge of the orocline.

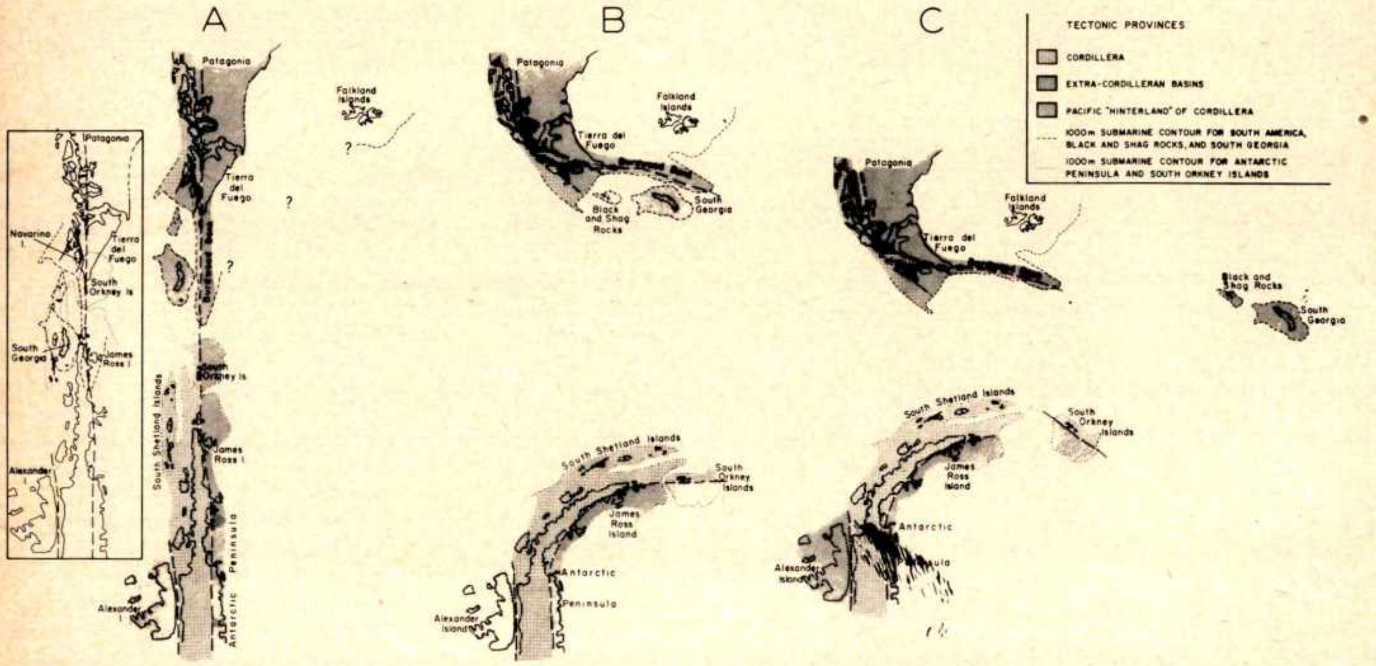

Fig. 3 Evolution of the Scotia Arc. *a*, Andean–West Antarctic Cordillera in the latest Mesozoic following the Andean Orogeny and preceding bending and disruption (insert: restoration of Cordillera assuming no north–south separation of South America and the Antarctic Peninsula). *b*, Scotia Arc in the (?) early Cenozoic following bending and disruption of the Cordillera, but preceding dispersal of continental fragments. *c*, Present distribution of continents and continental fragments around the Scotia Sea.

Reconstruction of Gondwanaland

Attempts to reconstruct the initial configuration of Gondwanaland[63–70] have all encountered difficulty in the area of the Scotia Arc and West Antarctica (Fig. 4). This is probably in part due to the distortion of parts of the continental fragments since their separation from the supercontinent. The main problems in reconstruction have arisen because of unacceptable overlap of the Antarctic Peninsula and Africa[65] (Fig. 4*c*), distortion of the Scotia Arc[64,68], and overlap of South America and Antarctica[70].

Our model demands that an essentially rectilinear Cordillera connected South America and West Antarctica until the end of the Mesozoic. This could be reconciled with the generally accepted "fit" of South America and Africa[71] in several ways—or in a combination of them: (1) anticlockwise rotation of the Antarctic Peninsula relative to East Antarctica following continental separation, (2) right-lateral strike-slip faulting along the margin between East and West Antarctica subsequent to continental separation, (3) a "fit" of East Antarctica and Africa other than those recently proposed[64,65].

There is stratigraphic evidence to support the existence of a sedimentary basin with deep water facies in the South Atlantic area in the late Palaeozoic[65]. This basin need not necessarily have been oceanic in character, nor as large as has been proposed (Fig. 4*d*). Strike-slip displacement and/or rotation of West Antarctica relative to East Antarctica have been proposed elsewhere[65–67] and might well explain the anomalous swing in strike and termination of the early Mesozoic fold structures in the Ellsworth Mountains[68]. Finally, the East Antarctica–Africa "fit" seems to have considerable geological and bathymetric uncertainty.

Final solution of the problem must await further work on the magnetic anomalies from the southern oceans, and a better understanding of the different parts of Du Toit's "Samfrau" geosyncline[63] (Fig. 4*a*). Our model, however, demands a solution close to that of Fig. 4*e* (ref. 67).

To summarize, there seems little doubt that the southernmost Andes once continued into West Antarctica as an essentially rectilinear Cordillera. A proto-Cordillera developed at latest in the early Mesozoic, and the main Cordillera resulted from the Andean Orogeny in late Mesozoic to early Cenozoic time. Oroclinal bending probably began during the Andean Orogeny, but complete disruption and fragmentation of the Cordillera did not ensue until the Cenozoic. The Pacific margin has been shortened in the vicinity of the Scotia Arc, but only by about 1,000 km. Our model places constraints on the reconstruction of Gondwanaland.

We thank R. H. Dott, jun., R. J. Fleck, M. Halpern, W. J. Ludwig and L. R. Sykes for reading the manuscript. The project was supported by the National Science Foundation,

Andean Orogeny and Ocean Floor Spreading

R. W. R. RUTLAND

Department of Geology and Mineralogy, University of Adelaide, Adelaide, South Australia 5001

The periodicity and eastward migration of the Andean orogeny is explained in terms of periodic loss of marginal continental crust by crustal subduction.

ALTHOUGH there is strong evidence[1-4] that new oceanic crust is being created along the oceanic fracture system at rates of several centimetres per year, the evidence that oceanic crust is being destroyed at similar rates in the continental fracture system is less compelling, and some have rejected this hypothesis in favour of the hypothesis of an expanding Earth[5].

The rate of crustal subduction in the Peru–Chile trench is about 6 cm yr^{-1} (ref. 6), although changes of spreading rate and direction may have occurred in the past 25 million years[7,8]. Even so, calculated rates have always been high (5 cm yr^{-1}), and no pauses in spreading have been detected. The undeformed nature of the sediments in the Peru–Chile trench is a problem[9-13], however, and so is the disappearance of the probable westward extension of the continental crust of Chile[14]. This article gives an account of my view of what has happened, and is based on field studies of the Antofagasta segment in northern Chile (Fig. 1). I suggest that the orogenic history of Chile may be understood in terms of ocean floor spreading if there has been periodic loss of continental crustal material from the continental margin.

The Andes in the Antofagasta segment (Figs. 1 and 2) consist of two main geosynclinal belts, the Cambrian–Devonian East Andean geosyncline and the Jurassic–Cretaceous West Andean geosyncline. On the face of it, this suggests a westward migration of the main trough of sedimentation from the Palaeozoic to the Mesozoic. The West Andean geosyncline, however, was certainly developed on an older continental basement, not on oceanic crust. This basement locally consists of virtually unmetamorphosed Upper Palaeozoic sediments, or more commonly of metamorphic foliated rocks which have usually been regarded as Precambrian but which are probably of Palaeozoic age[15]. Thus the Mesozoic geosyncline probably developed on an outer metamorphosed and deformed Palaeozoic geosynclinal belt parallel to the unmetamorphosed inner belt of the East Andean geosyncline. This interpretation is supported by the fact that a belt of Palaeozoic granites and Triassic volcanics lies along the junction of the East and West Andean geosynclines.

The West Andean geosyncline was divided into a "eugeosynclinal" volcanic (coast range) zone and a "miogeosynclinal" sedimentary (longitudinal valley) zone during the Jurassic (ref. 16, Fig. 5, p. 42), and "infraneritic" and "bathyal" facies have been recognized in the latter zone (ref. 17, Fig. 6, p. 60). The geosyncline was apparently narrower in the Lower Cretaceous and the facies boundary between so-called eugeosynclinal and miogeosynclinal facies was displaced to the east (ref. 16, Parte II, Fig. 4). This was a consequence of the phase of mobility at the end of the Jurassic (chiefly faulting and plutonism) which led to the uplift and erosion of the coast range zone (Fig. 2).

The sea was already excluded from the longitudinal valley zone north of 26° S at the end of the Jurassic and was excluded from the southern part of the West Andean geosyncline before the main phase of mobility at the beginning of the Upper Cretaceous (although marine sedimentation continued still further south in parts of the Magellan geosyncline). Thus it appears that the present difference in elevation between north and south Chile reflects a difference in crustal structure which dates from at least Jurassic time.

Folding in the West Andean geosyncline began with a Cenomanian phase and was continued by later Cretaceous and early Tertiary phases. The Cretaceous folding was not accompanied by regional metamorphism, nor was it characterized by large strains or cleavage development. The folds are generally of large wavelength and amplitude and open in style. In the later phases folding was more localized and generally less intense, giving way to block faulting (with major reverse faults) and acid volcanism. Thick deposits of Upper Cretaceous continental sediments were accumulated in the longitudinal valley zone of the Western Andes in the Upper Cretaceous. The Puna zone also began to develop as a basin and has a thicker Cretaceous sequence than the East Andean zone. Marine incursions in the East Andean zone appear to correspond to the Middle Cretaceous tectonism of the Western Andes.

Following further tectonism in late Cretaceous or early Tertiary time, the Western and Eastern Andes became positive areas subject to repeated uplift and erosion while the Puna and Sub-Andean zones became syn and post-orogenic basins in which the later phases of mobility were concentrated. The western margin of the Puna zone became the site of the main ignimbritic volcanism of the late Miocene and Pliocene and then of the Plio-Pleistocene central volcanoes. The present longitudinal valley and associated topographic features did not develop as basins until Miocene time, when the main uplift of the Puna zone began. Possibly the Peru–Chile trench is of the same age, as discussed later[13].

There is a tendency for the site of the most intense deformation to migrate eastwards with time. Thus the most intense deformation in the coast range zone was at the end of the Jurassic, in the longitudinal valley zone during the Upper Cretaceous and in the Sub-Andean zone during the Pliocene. The Puna zone, however, is similar to the Sub-Andean zone and probably had its main deformation after the East Andean zone. The crustal shortening associated with the orogenic deformations is not easily estimated. If the open folding of concentric style is entirely the consequence of crustal shortening and if some allowance is made for the effect of reversed faulting, the total shortening since mid-Cretaceous time might be as much as 40%. The maximum width of the belt is about 700 km, so that the maximum crustal shortening would seem to be 500 km. The actual amount might be much less, and is therefore at least an order of magnitude less than the amount of crust postulated to have been consumed by crustal subduction in the same period.

Plutonic and volcanic activity also migrated from west to east. Upper Jurassic plutons lie on the eastern margin of the coast range zone, with Upper Cretaceous plutons immediately to the east and scattered smaller Tertiary intrusions further east again. The main volcanism was in the coast range zone in the Jurassic, in the longitudinal valley zone in the Cretaceous and early Tertiary, and in the Puna zone in the later Tertiary.

The present coast of north Chile seems to be a fault scarp modified by marine erosion in Plio–Pleistocene time. The steep coastal cliffs are usually several hundred metres high and display a Jurassic lava sequence dipping gently inland. Clearly the Jurassic volcanic zone originally extended considerably further west. Moreover there is no Mesozoic or Tertiary low temperature, high pressure schist belt in Chile like the Franciscan belt of California or those of island arcs. Only a low pressure, high temperature belt is present, so that if paired metamorphic belts were developed the outer belt either lies offshore or has disappeared. Several mechanisms for the removal of marginal continental crust have been put forward[9,14], and it seems possible that the missing crust has been dragged under the continent where it has been remobilized and has thickened the crust by processes of plutonism and volcanism. The crust in this part of the Andes seems to be thicker than in western North America, for example, where little or no marginal crust has disappeared[17].

The disappearance of marginal crust in this way suggests an explanation for the periodicity and spatial migration of Andean plutonism and volcanism. If the Benioff zone maintains a roughly constant attitude through time, then the site of volcanic and plutonic activity should be a roughly constant distance from the subduction zone. The periodic eastward migration of plutonism and volcanism is then a consequence of periodic loss of marginal continental crust in the subduction zone. The site of Jurassic volcanism was roughly 200 km west of the present site, so it may be supposed that about 200 km of continental crust lay west of the present coast at the beginning of the Jurassic. The three principal phases of granitic plutonism at the end of the Jurassic, in Upper Cretaceous and in Tertiary time may represent three stages in the destruction of the marginal continental crust. The width of the main fault blocks of the present day Chilean Andes (100 km) suggest that each phase of volcanic and plutonic activity is related to the subduction of one fault block.

This hypothesis also suggests that there should be some correlation between tectonism and plutonism. A phase of compressional tectonics causing the subduction of a strip of marginal continental crust should precede each phase of plutonism and a phase of isostatic uplift should accompany the plutonism. This appears to hold for the history of plutonism and tectonism in Chile.

The theory of crustal subduction, including subduction of continental crust, therefore seems to provide a satisfactory model for the development of the Andes of northern Chile, and adjacent Argentina and Bolivia. The chief difficulties, however, are the undeformed nature and the volume of the sediments in the Peru–Chile trench[8–13]. Scholl *et al.*[13] have concluded that: (1) Sediment removal probably occurred at the base of the continental margin and adjacent deep-sea floor in late Cretaceous and perhaps earliest Tertiary time. (2) Uncertainties in denudation–sedimentation budget leave open the question of tectonic removal of sediment in Tertiary time. (3) Reasonable estimates of erosion suggest that late Cenozoic underthrusting at the postulated rate has not taken place or that it has taken place without removing sediment from the trench. They are driven to suggest that sinking of the plate may take place seaward of the trench.

Fig. 1 Major tectonic zones of the Andes of South America in relation to major tectonic and topographic features of the East Pacific. Note that the continuity of the spreading system of the East Pacific Rise is well established but a portion has been omitted from the map for lack of available data.

The hypothesis of subduction of marginal continental crust effectively explains the absence of Mesozoic and early Tertiary sediments. The third point is therefore the most crucial. It is partly based on the inference that most of the fill of the trench south of 36° S consists of turbidites deposited in glacial episodes of lowered sea level during the past three million years and that the volume of these sediments is close to their maximum estimate for this period. Yet, on the basis of the present configuration of the trench, the rate of removal of sediment from the trench by crustal subduction should be greater than the rate of supply. For this reason too, the problem becomes more severe if the trench fill is assumed to be of greater age.

The only alternative explanation that suggests itself to me is that denudation rates on land are not directly relevant to the rate of accumulation in the trench, but that rapid submarine erosion of the onshore flanks of the trench is responsible for the fill.

The present relief of the Andes has developed largely in the past ten or possibly twenty million years, and it seems probable that the present submarine relief is partly of the same age. Prior to the development of this relief large quantities of sediment may have accumulated on the onshore side of the subduction zone. As the relief of the onshore flank developed, much of this sediment, with the help of earthquake activity, would become unstable and be transported rapidly into the trench. In this way the erosional products of some tens of millions of years might be transported into the trench in a fraction of that time.

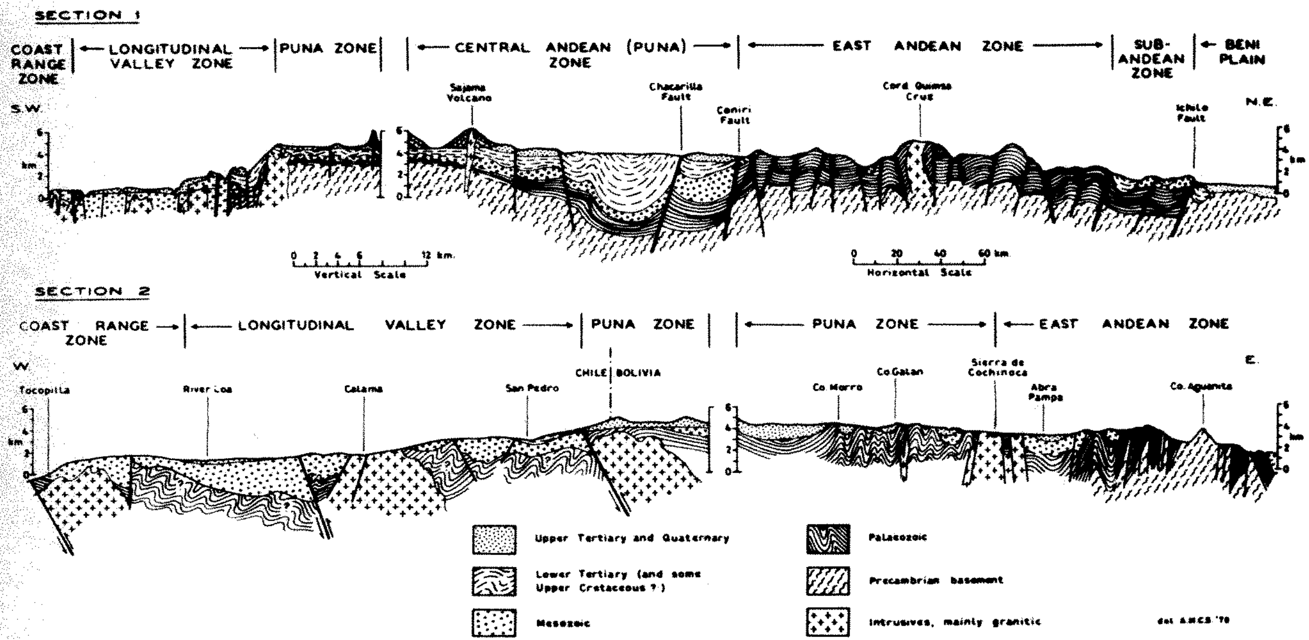

Fig. 2 Sections across the Andean orogenic belt. Section lines are shown on Fig. 1. Section 1 runs north-east from Arica in Chile. The south-western portion is after Salas *et al.* in ref. 16. The north-eastern portion is after Ahlfeld[27]. Section 2 is across the Chilean and Argentinian Andes near 22° S. The eastern portion is interpreted after Turner[28].

The study by Scholl *et al.*[13] did not extend south of 44° S but earlier studies have shown a very different sediment distribution south of the Chile Rise where seismic evidence suggests that crustal subduction has ceased[1] (although more recent studies have tentatively suggested that subduction is continuing at a reduced rate[18]). Sedimentary accumulation is not confined to the southern continuation of the trench but extends westwards for 200 km (ref. 19). The absence of such a wide belt north of the Chile Rise is itself strong evidence for crustal subduction there.

The volume of the sediments in the trench may not therefore mean that crustal subduction is not taking place. Further evidence on the nature of sediments in the trench and their undeformed character comes from an analogy between the trench and onshore fault blocks, which will now be developed.

Contrary to some statements[20] which have been quoted recently[19], the fault-blocks of northern Chile are certainly a consequence of compressive tectonics and are limited by reverse faults[21-23]. These faults are exposed, for example, in gorges on the east side of the Pampa de Tamarugal and on the road from Calama to San Pedro de Atacama on the west side of the Cerros de Purilactis. In both cases the faults dip steeply to the east. A similar fault may lie offshore and may be responsible for the coastal scarp, and yet another may occur in the trench. Movement along such faults may well account for the loss of marginal blocks by crustal subduction although the rate of movement required would be extremely high compared with the observed rates onshore.

The block faulting was initiated in the early Tertiary. In the Antofagasta segment[21-23] filling of the intermontane troughs began in the Oligocene or Miocene with the Tambores, San Pedro and Lower Loa Formations. Intermittent tectonism in the east of the segment then accompanied the deposition of the Pliocene San Bartolo and Upper Loa Formations.

The Loa Formation (probably the Upper part only) representing an ancestral valley of the River Loa is now preserved at a height of about 400 m in the coastal scarp a few kilometres north of the present gorge of the River Loa. Clearly therefore the Loa Formation extended further west and probably continued into the ocean before the uplift of the coast range.

These relations suggest that the Peru–Chile trench is at least as old as the block faulted onshore basins and that the surface of acoustic basement is likely to be the unconformity developed across folded Cretaceous and older rocks. In this case four kinds of fill might be expected in the trench or in sediment traps on its onshore flank in the Antofagasta segment: (1) products of dissection of the block-faulted terrain prior to deposition of the Loa Formation, (2) equivalents of the Loa Formation carried into the ocean by the ancestral River Loa, (3) sediment carried to the ocean during the period when the present River Loa gorge was cut, and (4) material removed from the coastal fault scarp by marine erosion.

The evidence of points (1), (2) and (3) demonstrates that the present climatic zonation has not controlled offshore sedimentation through most of the Tertiary. The large volumes of coarse piedmont deposits of pre-Pliocene age in N. Chile shows that discharge and erosion from the high Andes was sometimes much higher than at present. Periods of piedmont aggradation have alternated with periods of dissection[24,25]. The estimates of denudation rates used by Scholl *et al.*[13] are therefore questionable. If denudation rates were in fact higher than their estimates, their data on sediment volumes suggest that insufficient Tertiary sediment is now to be found offshore in N. Chile. Consumption of sediment in the Benioff zone or its conversion to acoustic basement may therefore have occurred in the Tertiary as required by the hypothesis of ocean floor spreading.

The onshore intermontane basins show that reversed faulting of their eastern margins has proceeded since the Miocene without deformation of their sedimentary fill. If such reversed faults are utilized for the crustal subduction process it seems quite possible that the process could proceed without folding of the trench sediments. The subsidence of the oceanic crust beneath the prow of continental crust can probably be achieved by reversed faults conjugate to the main easterly dipping reversed fault. If normal faults are commonly developed by the downbending of the oceanic crust[24,25] on the offshore flank of the trench, these normal faults would probably be utilized as the conjugate reversed faults as the oceanic crust passes into the Benioff zone beneath the continental flank of the trench. I therefore conclude that although the postulated rate of subduction of oceanic crust is startling in comparison with processes in the adjacent continental crust, the known geology of the trench and adjacent continental margin is not incompatible with the theory of crustal subduction.

The application of the theory of ocean floor spreading, and in particular of crustal subduction therefore offers a possible explanation of the periodicity within the West Andean orogenic cycle and of why sedimentary facies boundaries, deformation, volcanism, and plutonism should have migrated eastwards. Belts in which there has been no loss of the continental margin or in which continental accretion has occurred should show distinctly different relations. It also seems possible that the extremely high percentage of volcanic rocks in the Andean geosyncline and the nonmarine character of the geosyncline during much of its history may be a consequence of isostatic effects resulting from subduction of marginal continental crust.

Studies of the development of the Chile rise in relation to South America and comparative studies of the Andes on either side of the rise clearly provide a fruitful field for further research on the relation of ocean floor spreading and orogenic processes. A superficial study of the geology and of palaeogeographic maps[16] does not reveal the development of startling contrasts in the Tertiary when the Chile Rise, presumably moving north from Antarctica, may have begun to prevent the easterly flow of oceanic crust beneath southern Chile. Young volcanoes, for example, are developed well south of the Chile Ridge in the Andes just as they are further north although petrological differences have been noted. The limitation of the Peru–Chile trench by the Galapagos and Chile ridges is striking, however, and current seismicity appears to be similarly controlled.

In this connexion it may be noted that the concave disposition of the seismic zone towards the Pacific appears to be related to its dip. North and south of the sub-Andean zone (Fig. 1) the epicentres of deep focus earthquakes have colinear distributions at a substantial angle to the orogenic trend. The overall trend of the epicentres is NNW approximately normal to the major ENE lineaments crossing the orogenic belt. Thus it appears that the dip of the seismic zone is at a maximum at the apex of the arc. The symmetry of the pattern also suggests that movements in the subduction zone are in the ENE direction parallel to the major lineaments. It may also be noted that the bathymetric maps of the Pacific reveal a ridge approximately parallel to the orogenic belt, the significance of which is unknown.

The application to the Andean orogenic belt of the hypothesis of ocean floor spreading as developed here does not explain the progressive change in the orogenic belt as a whole. Analogy with older orogenic belts shows that the orogenic cycle is virtually complete but the implications of this for ocean floor spreading are not clear. Perhaps the cycle comes to an end when indigestion in the subduction zone can no longer be relieved by lateral migration of the geosyncline.

But the Mesozoic–Tertiary orogenic cycle shows similar broad features in terms of geosyncline development and subsequent uplift in all areas irrespective of whether the continental margin has been destroyed as in Chile, created as in the Philippines, or is marked by transform faulting as in California. These features are found not only on present continental margins but also in the Alps and Himalayas where two areas of continental crust have been brought together. Rejuvenation of relief in Neogene times also characterizes older Phanerozoic and Late Precambrian orogenic belts. Attempts[26] to explain orogeny in general and vertical movements in particular in terms of constant rate ocean floor spreading therefore appear inadequate at present.

My conclusions are as follows: (1) The Andes of Northern Chile and adjacent Argentina and Bolivia display a periodic eastward migration of volcanism, plutonism and tectonism which can be explained by periodic subduction of blocks of marginal continental crust. Thus the Jurassic coastline was probably 200 km west of the present coast. (2) The hypothesis explains the absence of Mesozoic and Tertiary sediments offshore. (3) The volume and undeformed nature of the young sediments in the Peru–Chile trench provide obstacles to the easy acceptance of the crustal subduction hypothesis. These obstacles may be overcome if rapid submarine denudation of the onshore flank of the trench is accepted along with the analogy between the onshore fault basins and the trench. (4) Further work on the relations north and south of the Chile Rise is needed to relate orogenic processes to the postulated differences in rates of crustal subduction. (5) The late Cenozoic vertical movements in orogenic belts may not be directly dependent on ocean floor spreading.

This discussion is partly based on work in collaboration with the late Professor S. E. Hollingworth, with the support of the United Kingdom Department of Scientific and Industrial Research. Dr M. R. Walter helped with the figures and criticized an early draft.

PHYSICAL SCIENCES

Variations in the 10 μm Flux from NGC 1068

ALTHOUGH there is considerable evidence of rapid variability of the intense infrared sources in the nuclei of galaxies and quasars, conclusive data have been lacking. NGC 1068 is one of the most powerful of the extragalactic infrared sources ($L_{IR} = 6 \times 10^{45}$ erg s^{-1}) and, with the exception of M82 which is extended, has the highest signal-to-noise ratio at 10 μm. We have therefore monitored NGC 1068 for several years to look for variations. The pertinent observations are summarized in Fig. 1, where data obtained during the past 3 yr have been combined into four points. The results of the individual observations are given in Table 1.

Table 1 Observations of NGC 1068 at 10 μm

Julian date	Flux level (10^{-26} W m^{-2} Hz)	Standard deviation (10^{-26} W m^{-2} Hz)	Field of view (arc s)
2440167	20.9	1.7	20
2440171	26.8	3.0	20
2440230	25.1	2.5	20
2440509	28.1	1.2	6
2440568	25.2	1.1	6
2440594	26.2	1.3	6
2440868	21.1	2.5	20
2440873	23.0	1.6	20
2440882	25.5	1.4	20
2440889	22.9	1.6	6
2440910	24.6	1.7	6
2440963	18.6	1.2	6
2440993	18.5	1.9	20
2440996	17.9	0.9	6
2440997	17.2	1.0	6
2441033	20.3	1.1	6

The error bars used in Fig. 1 and throughout this discussion are to be interpreted as one standard deviation. They include statistical errors determined from an analysis of the data for each observation and an overall estimate of non-statistical errors determined from the non-repeatability of observations of bright stars. Thus they include all the known errors of observation except an uncertainty of 15% in the absolute calibration of the photometric system. Our discussion is concerned only with measures relative to certain standard stars and so the absolute calibration is not relevant.

The older data on NGC 1068 (refs. 1, 2) have been reanalysed to insure a uniform reduction procedure and to refer all observations to the same standard star, α Tau. Reference to α Tau could usually be made directly but for cases in which secondary standards were used, the estimated errors were increased accordingly. Our observations show that α Tau has remained constant relative to other standard stars to within 4% during this time. The observations were also carefully re-examined; all data for which there is reasonable doubt about the standardization or observational procedure have been rejected.

The evidence for variability is considerably strengthened by the observations since Julian Date 2440950. Most of these data were obtained with a new photometer; it is important, therefore, to examine whether the observations were affected by the change in instrumentation. We know of only two ways in which this change could affect our results: a shift in the filter passband, and, if the source is polarized, the polarizing effect of a 45° diagonal mirror used to deflect the radiation onto the detector. The filters used in the two photometers have been examined carefully and the only significant difference is that the new filter cuts on at about 7.6 μm whereas the old one cuts on near 7.8 μm. According to unpublished data, the atmospheric transmission from 7.6 to 7.8 μm at our site averages less than 15%. From these measurements, we can place a conservative upper limit of 2% on the effect of the change in filters on our observations. The polarizing effect of a front-aluminized, 45° diagonal mirror at 10 μm is less than 1% (H. M. Dyck, private communication). To make sure that the change in instrumentation does not influence our conclusions, all flux levels from NGC 1068 observed with the new photometer have been increased by 3%, the combined upper limit to the two effects.

The conclusion that variations have occurred does not depend solely on the data obtained with the new instrument. There is evidence for variability in the data obtained before JD 2440950. In addition, the measurement on JD 2440993 was made with the old instrument and is in excellent agreement with other measurements made at about the same time. This observation alone differs from the mean of the observations before JD 2440950 by 3.3 standard deviations. The work on JD 2440910 was done with the same filter used in the new photometer; it differs from the mean of the measurements made since JD 2440950 by 3.5 standard deviations.

Most kinds of systematic error would appear equally in observations of all objects with similar spectra. For this reason, it is customary to present observations of a comparison star together with evidence for variations of an astronomical object. Such a procedure is, however, meaningless in this case, because the spectra of stars and galactic nuclei are quite different at 10 μm. The only reasonable comparison object is another galactic nucleus. Sufficient data to permit such a comparison are available for NGC 1275 and NGC 4151 (refs. 1, 3) although the ratio of signal to noise is much lower for these objects than for NGC 1068; the data are shown in Fig. 1. A detailed analysis of these data shows that the fluxes measured with our new photometer average 0.98 ± 0.08 times those measured with the old one, a result which tends to confirm our conclusion that the observed variation in NGC 1068 is not an instrumental effect.

NGC 1068 and NGC 1275 have frequently been observed on the same nights. It is therefore possible to compare these galaxies directly, without any reference to standard stars. Such a comparison should be independent of most kinds of systematic error. Data are available for four nights near JD 2440550 and for three nights near JD 2441000. They show that the flux from NGC 1068 decreased by 30 ± 8% relative to that from NGC 1275 during this period of time.

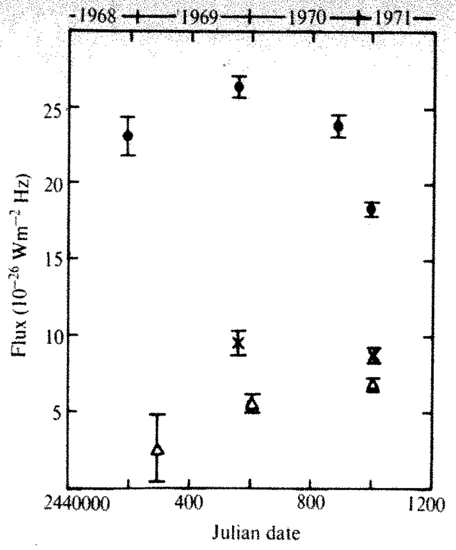

Fig. 1 Variation in the 10 μm flux from the nucleus of NGC 1068. The error bars include all known sources of error except for an uncertainty in the absolute calibration; they are to be interpreted as one standard deviation. The observations of NGC 1275 and NGC 4151, which are included as comparison objects, have been arbitrarily renormalized. ●, NGC 1068; ×, NGC 1275; △, NGC 4151.

Similar but larger variations during an earlier period of time have been described for 3C273 and NGC 4151 (ref. 1). The evidence for these variations was not conclusive because the observations had a low signal-to-noise ratio and were made in conditions which made a detailed study of the errors impossible. Neither of these problems affects the data on NGC 1068; the evidence of variation is compelling. The variability of NGC 1068, combined with the similarities between it and NGC 4151 and 3C273 in other respects, greatly strengthens the argument that these sources also vary.

Although the most complete observations have been made at 10 μm, it seems that the 5 μm flux from NGC 1068 has also decreased. Before JD 2440800, the average flux at this wavelength was $7.3 \pm 0.6 \times 10^{-26}$ W m^{-2} Hz; since then, a level of $5.5 \pm 0.6 \times 10^{-26}$ W m^{-2} Hz has been observed. Our observations are consistent with a similar variation at 3.5 μm. At this wavelength, the observed fluxes are $2.9 \pm 0.5 \times 10^{-26}$ W m^{-2} Hz before JD 2440800 and $2.4 \pm 0.2 \times 10^{-26}$ W m^{-2} Hz since then. At 2.2 μm, the flux from the central region of NGC 1068 is predominantly due to stars. Observations of variations in the nuclear source would be extremely difficult at this wavelength[2].

Terrell[4] has considered the limits which can be placed on the sizes of astronomical objects from observations of variations in flux. Sizes considerably greater than cT (where c is the speed of light and T is the time scale of the fluctuations) are possible if the source consists of a large, optically thick sphere which re-radiates the emission from a varying central source. An optically thick shell with a diameter of the order of 3 pc and containing dust at a temperature of about 400 K would be consistent with our observations of the nucleus of NGC 1068, although the spectrum at wavelengths longer than 15 μm would have to be attributed to a larger, cooler component.

More generally, if the varying source is not optically thick or is not of an appropriate shape, the upper limit on its diameter would be of the order of $cT = 0.3$ pc. The source would have to radiate at least 7×10^{-26} W m^{-2} Hz at 10 μm, the amount of the observed variation. It would have insufficient surface area to radiate this level of flux thermally unless its temperature were greater than 1200 K. A temperature of this order is acceptable only if the emissivity of the radiating dust grains decreases rapidly towards shorter wavelengths so that the estimated flux agrees with that observed at 2.2, 3.5 and 5 μm.

The observations reported here thus place strong constraints on models for the generation of the far infrared flux from NGC 1068 by thermal means. Many other galactic nuclei also radiate strongly in the infrared[1,3]; the similarity of their spectra to that of NGC 1068 suggests that these constraints hold for them also.

Radio and optical variability have already been observed in the nuclei of Seyfert galaxies[5-7] such as NGC 1068. The fluxes modulated in these regions of the spectrum are, however, relatively small when compared with the total emission of the nuclei, most of which is in the infrared[8]. The observations reported here are the first strong evidence that a significant proportion of the nuclear emission is modulated. In the 10 μm atmospheric window alone, we have observed a change in luminosity of 2.5×10^{43} erg s^{-1} which is comparable with the total luminosity of our galaxy and about 0.5% of the total luminosity of the nucleus of NGC 1068. It can be inferred that the total change in luminosity was much greater when allowance is made for unobserved regions in the infrared spectrum.

Comments on the Evolution of the North-East Atlantic

It has been proposed[1-3] that the opening of the Bay of Biscay occurred by rotation about a pole situated near Paris (50.0° N, 3.3° E) and not about the pole proposed by Bullard *et al.*[4] (43.6° N, 1.0° E). The rotation about the first pole results in strike-slip motion along the North Pyrenean Fault during the pre-Upper-Cretaceous opening, while the rotation about the second pole results in compression there. The second rotation is not compatible with geological data[5] which indicates extension prior to Upper Cretaceous in the Pyrenean region.

We wish to show how these two hypothetical rotations agree with the magnetic data of Williams and McKenzie[6].

Fig. 1 shows a rotation of the Iberian peninsula (contour at the 1,000 fathom isobath) by 23° about the first pole. Intermediary rotated positions every 5° are also shown. Similarly, Fig. 2 shows a rotation of the Iberian peninsula by 27.8° about the Bullard *et al.* pole. If the 1,000 fathom contour represents the limit of the continent, most of the area between anomaly 32 and the western limit of Portugal (except for the southernmost part presumably related to movement of Africa) would have been created by the relative rotation of the Iberian peninsula in Fig. 1, but not in Fig. 2. The first rotation would thus seem to be in better agreement with Williams and McKenzie's data. In addition, this first rotation explains the shape of anomaly 32 as reflecting the pre-drift position of the Iberian peninsula.

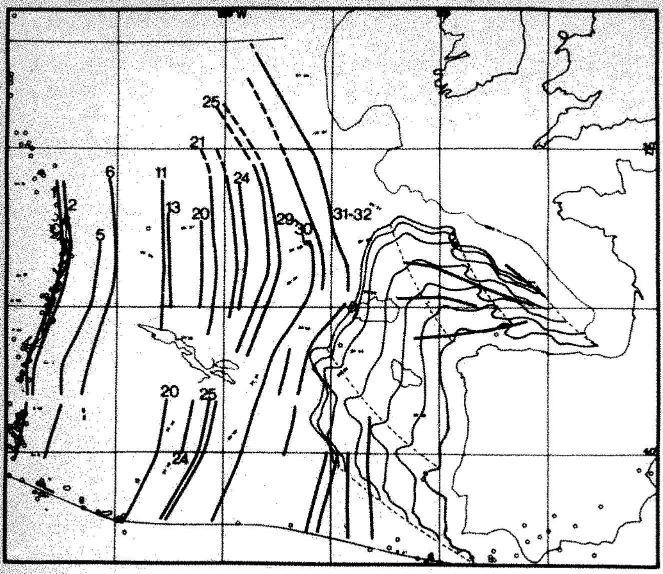

Fig. 1 Magnetic anomalies after Williams and McKenzie[6]. The Iberian Peninsula has been rotated about a pole at 50.0° N, 3.3° E. Several flow-lines are shown in dashed lines.

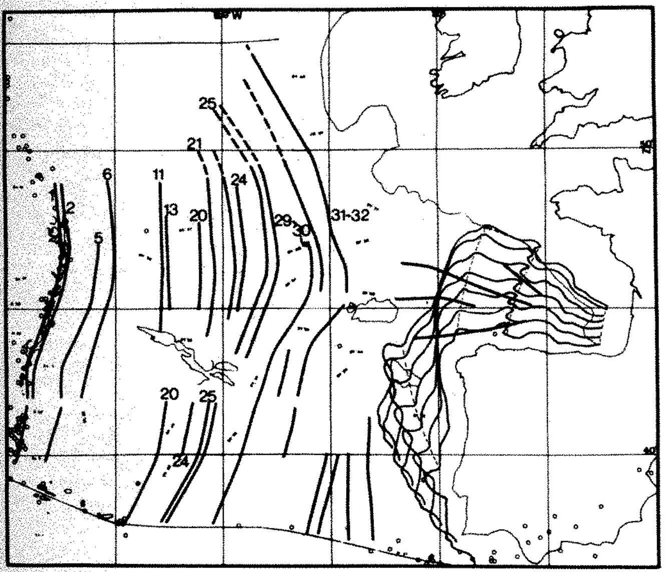

Fig. 2 Magnetic anomalies after Williams and McKenzie[6]. The Iberian Peninsula has been rotated about the Bullard *et al.* pole at 43.6° N, 1.0° E. Several flow-lines are shown in dashed lines.

But even in Fig. 1 the detailed agreement between measured and predicted magnetic anomalies is not good. This may result from inaccurate identification of the anomalies east of 32 by Williams and McKenzie, as a detailed 10 km spaced systematic aeromagnetic survey of the Bay of Biscay (ref. 7 and unpublished work of E. Le Borgue, J. Le Mouël and X. Le P.) has shown the anomalies there to be less fan-shaped than indicated by their map. In any case, an extension toward the west of the systematic detailed survey would enable a definite choice to be made between these two possible rotations.

Implied Superheavy Element Decay Lifetime from Meteorites

Schramm and Fowler[1] demonstrated that superheavy elements could be synthesized in the *r*-process. In the light of these calculations it is interesting to look at the anomalous heavy Xe isotopic composition of carbonaceous chondrites. Rowe[2] has shown that these isotopic anomalies could be caused by the fission of some unknown nucleus. The Xe isotopic composition for this carbonaceous chondrite fission (CCF) spectrum is very different from the ^{244}Pu fission spectrum measured by Alexander *et al.*[3] and observed in other types of meteorites[4-6]. A reasonable candidate for this unknown fissioning nucleus would be a long lived element[7-10].

Assuming CCF is due to the fission of a superheavy element (SH) it is possible to estimate the half life of SH using the production rates calculated by Schramm and Fowler[1] and the interval, Δ, between the termination of nucleosynthesis and the time of Xe gas retention. The value of Δ has been estimated[11,12] from ^{129}I–^{129}Xe and ^{244}Pu–Xe measurements. A current best estimate for Δ would be 1.07×10^8 yr for a "smooth" slowly varying, time-dependent model of nucleosynthesis and 1.56×10^8 yr for nucleosynthesis models with a large "spiked" event just before solar system separation. These values of Δ were calculated using the techniques of Schramm and Wasserburg[11] with the parameters shown in Table 1. Although the parameter values in Table 1 differ slightly from those used in ref. 11, the range of uncertainty estimated[11] is still valid (though possibly overcautious). Therefore the possible range of values for Δ of

$$7.5\times10^7\ \text{yr}\le\Delta\le2.5\times10^8\ \text{yr} \tag{1}$$

given by Schramm and Wasserburg will be used here. This range includes the maximum effect of large time-dependent variations in the production function as well as any uncertainties in parameter values. Carbonaceous chondrites are generally regarded as more primitive than other meteorites (compare ref. 13). Their I–Xe ages seem, however, to be within $\sim10^6$ yr of other meteorites[14,15]. Thus the limits on Δ given above should apply to the carbonaceous chondrites.

The implied abundance ratio of element SH relative to ^{244}Pu can be calculated from the values given in Table 1, *B* and *C*. For Type I carbonaceous chondrites the ratio is

$$\mathrm{SH}/^{244}\mathrm{Pu}\approx0.0012/F \tag{2}$$

where F is the ^{136}Xe fission yield for element SH. The branching ratio of alpha decay to spontaneous fission decay for SH is unimportant because all alpha decays will eventually lead to a spontaneously fissioning nucleus (see ref. 1). There may be an uncertainty of a factor of 2 at most in the constant 0.0012. That uncertainty is, however, small compared with the uncertainty in *F*. At present it is not known whether SH will fission symmetrically, asymmetrically or even tertially, nor is the precise size of the fission yield known.

Asymmetric fission was shown by Schramm and Fowler to enable a fit to the rare Earth *r*-process abundance hump. To fit the CCF Xe spectrum with asymmetric fission it would be necessary for the low mass asymmetric peak to be at $A \geq 135$ and, if the high mass peak is at $A \sim 155$, this would imply a lower average neutron multiplicity than predicted by Nix[16]. For asymmetric fission the peak yield can be estimated from systematics (see Hyde[17]) as $\sim 6\%$. Recently John *et al.*[18] found that ^{257}Fm spontaneously fissions with a small symmetric component. If this effect is extrapolated to the superheavy region (a somewhat risky procedure) it tends to imply that element SH fissions symmetrically. The symmetric peak would be at $A \sim 142$, depending on the average neutron multiplicity and the number of alpha decays preceding the fissioning of SH. For symmetric fission the $^{136}\mathrm{Xe}_f$ yield might be as high as 10%. The yield might, however, also be low ($\sim 1\%$) if the symmetric peak was far above Xe. Nix[16] has also pointed out the possibility that tertiary fission may be the dominant mode for superheavy nuclei. If this is true it would be necessary for Xe to lie on the low mass side of one of the mass peaks in order to fit the CCF spectrum. In view of the uncertainties, calculations have been carried out for

$$0.01 \leq F \leq 0.10 \tag{3}$$

allowing a full order of magnitude uncertainty in F.

The implied half life, τ_{SH}, for the superheavy element can be calculated from the equation used by Schramm and Fowler[1]. For a production function with a terminal "spike"

$$\tau_{\mathrm{SH}} = \frac{\tau_{244}}{1 - \left[\dfrac{\tau_{244}\, ln\ R\,(244,\,\mathrm{SH})}{0.693\ \Delta}\right]} \tag{4a}$$

and with a "smooth" production function

$$\tau_{\mathrm{SH}} = \frac{\tau_{244}}{1 - \dfrac{\tau_{244}}{0.693\ \Delta}\left\{ ln\,[R\,(244,\,\mathrm{SH})] + ln\left(\dfrac{\tau_{244}}{\tau_{\mathrm{SH}}}\right)\right\}} \tag{4b}$$

where (using the notation of ref 11)

$$R\,(244,\,\mathrm{SH}) = \left(\frac{\mathrm{SH}}{^{244}\mathrm{Pu}}\right)\cdot\left(\frac{P_{244}}{P_{\mathrm{SH}}}\right)$$

It was found that τ_{SH} implied from CCF is always much less than the duration of *r*-process nucleosynthesis, T_{G} ($T_{\mathrm{G}} >$ the mean age of the elements $\sim 3 \times 10^9$ yr, see ref. 11) and terms varying as $\exp[-ln(2)\,T_{\mathrm{G}}/\tau_{\mathrm{SH}}]$ have been neglected in equation (4). (This assumption might not be valid for $Z_{\mathrm{SH}} \leq 114$, because then P_{SH}/P_{244} can become small, necessitating a large τ_{SH} to fit CCF data. Experimental searches[19,20] for superheavy elements, however, indicate $\tau_{\mathrm{SH}} < 10^9$ yr.)

Table 1 Input Data (Notation defined in Ref. 11)

	Reference
(*A*) *r*-process production ratios	
$P_{129}/P_{127} \approx 1.52$	12
$P_{244}/P_{232} \approx 0.49$	11
$0.75 \gtrsim P_{\mathrm{SH}}/P_{244} \gtrsim 0.20$*	1
(*B*) Observed abundance ratios (4.6×10^9 yr ago)	
$^{129}\mathrm{I}/^{127}\mathrm{I} = 1.07 \times 10^{-4}$	24
$^{232}\mathrm{Th}/^{238}\mathrm{U} \approx 2.42$ (=3.9 now)	11
$^{244}\mathrm{Pu}/^{232}\mathrm{Th} \approx 0.0054$ ($^{244}\mathrm{Pu}/^{238}\mathrm{U} = 0.013$)	25
(*C*) Mean carbonaceous chondrite abundances	
$\langle ^{238}\mathrm{U}\rangle$ ~17 p.p.b. (now) = ~34 p.p.b. (4.6×10^9 yr ago)	26,27,28
$\langle ^{136}\mathrm{Xe}_f\rangle$ CC I $\approx 5 \times 10^{-11}$ CC STP/g $\langle ^{136}\mathrm{Xe}_f\rangle$ CC I $\approx 4 \times 10^{-11}$ CC STP/g	29

* This lower bound assumes $Z_{\mathrm{SH}} = 110$; if $Z_{\mathrm{SH}} = 114$, the lower bound goes to ~ 0.006.

Values for P_{SH}/P_{244} are given in Table 1 and values for $\mathrm{SH}/^{244}\mathrm{Pu}$ are given by equation (2) using relation (3). Thus the range taken for $R(244,\mathrm{SH})$ is

$$0.016 \leq R(244,\mathrm{SH}) \leq 0.60 \tag{5}$$

A best estimate for $R(244,\mathrm{SH})$ would probably be ~ 0.032. Using the values for Δ given previously, this yields a best estimate of $\tau_{\mathrm{SH}} \sim 2.3 \times 10^7$ yr for a spiked model and $\tau_{\mathrm{SH}} \sim 2.4 \times 10^7$ yr for a smooth production model. If the entire range of values given by relations (1) and (5) are considered, the following limits can be placed on τ_{SH} implied from CCF Xe

$$1.65 \times 10^7\ \mathrm{yr} \leq \tau_{\mathrm{SH}} \leq 6.80 \times 10^7\ \mathrm{yr} \tag{6}$$

This narrow range seems consistent with the implied $\tau_{\mathrm{SH}} \sim 3.5 \times 10^7$ yr calculated in ref. 1 from the fossil track experiment of Bhandari *et al.*[21]. Carver and Anders[22], however, have mentioned that a chemical fractionation factor of $\sim 10^4$ should be used in estimating the implied $\mathrm{SH}/^{244}\mathrm{Pu}$ ratio for the solar system from the results of ref. 21. Such a factor changes the half life implied from fossil tracks to $\sim 1.6 \times 10^8$ yr. The range of uncertainty of this number is, however, large enough to intersect the range given in relation (6). It is also important to note that Bhandari *et al.*[21] found a high superheavy element track density in the meteorite Angra dos Reis and yet Hohenberg[23] found the fission Xe spectrum to be that of ^{244}Pu not CCF. This implies that the tracks observed by Bhandari *et al.*[21] do not come from the same source as CCF, thus equality between the implied half lives would be purely coincidental. It should be mentioned that the validity of the experiment of Bhandari *et al.* is in serious question on several points (E. A. Carver and F. Anders, to be published; and P. B. Price, R. S. Rajan and E. K. Shirk, private communication) which will not be discussed here.

The half life implied in relation (6) for a superheavy element producing CCF Xe is long enough to ensure that there would be sufficient SH remaining at the time of track retention ($\sim 3.8 \times 10^8$ yr after Xe retention[4]) to produce a countable fossil fission track density. It is therefore important for observers to look at the fossil tracks in carbonaceous chondrites. Unfortunately, this is very difficult to do because of the small grain size in this meteorite class.

The half life implied from CCF Xe is within an order of magnitude of the Nilsson *et al.*[23] estimate for $^{294}110$ but it is many orders of magnitude longer than Nilsson half life estimates for other superheavy elements produced in the *r*-process. In particular elements $Z = 112$ to 119 correlated by Anders and Heymann[7] with CCF Xe, are predicted by Nilsson to be relatively less stable than $^{294}110$. Although the estimates of Nilsson *et al.* may be uncertain by several orders of magnitude, estimates of relative stability should be fairly reliable.

I thank E. Anders and R. Ganapathy for focusing my interest on this problem. I also acknowledge enlightening comments from R. Walker, C. Hohenberg, J. C. Huneke, D. S. Burnett and J. B. Blake. This work was supported in part by the National Science Foundation.

Isotopic Composition of Xenon from a Greenland Anorthosite

FOLLOWING a study of the data resulting from the lunar α-scattering experiment of Turkevich *et al.*[1], Olsen[2] pointed out that the rocks in the Mare Tranquillitatus region were similar in oxide composition to certain terrestrial anorthosites. When lunar rocks became available for examination after the Apollo 11 mission, O'Hara[3] drew attention to the possibility that terrestrial anorthosites might be re-worked slices of the Earth's primordial crust. Windley[4], in particular, supported this view proposing that early Pre-Cambrian Group III anorthosites are fragments of layered differentiates formed early in the evolution of the Earth. Romey[5], on the other hand, does not like the comparison between lunar and terrestrial anorthosites and suggests that theories of lunar petrogenesis are developing too fast.

Nevertheless Windley's Group III anorthosites do seem to be of extreme age (≃3,500 m.y.) and to represent samples from an early phase of the Earth's geological history. If positive evidence concerning the events which occurred during this period is to be found, then this class of rock may provide a source of useful information. With this approach in mind, and being keenly aware of some of the major isotopic problems present in noble gas studies, it seemed reasonable to obtain samples of these perhaps very special rocks and to study the isotopic compositions of the noble gases "trapped" within them.

Six samples of Group III anorthosites from the West Greenland Fiskenaesset region were obtained from Dr B. F. Windley of the Greenland Geological Survey. It was decided to examine only the xenon in these rocks in the first instance.

Early measurements demonstrated the presence in rock No. 86943 (Windley classification) of xenon with an isotopic composition similar to that found in North American gas wells by Butler *et al.*[6] and Clarke and Thode[7] and discussed by Bennett and Manuel[8]. This, in itself, is an observation of some interest when considered in the light of the measurements of Srinivasan *et al.* (private communication) on a New South Wales iodyrite (International Mineralogical Association classification: iodargyrite) who also report the presence of gas well type xenon. This xenon may be present on a world wide scale in suitable trapping sites.

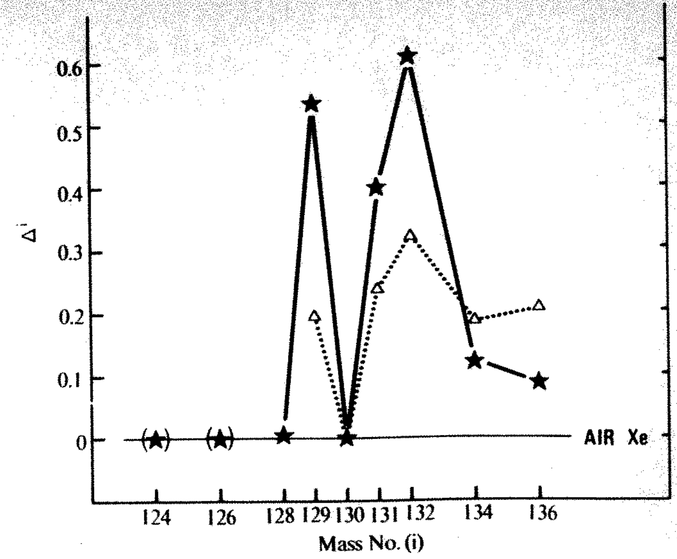

Fig. 1 Xenon ratio differences, $\Delta^i = (Xe^i/^{130}Xe)_{Sample} - (Xe^i/^{130}Xe)_{Air}$, as a function of mass number (i) for 86943 anorthosite fines (>700° C) and C-16 gas well xenon[8]. ★, 86943F (>700° C); △, C-16.

Further studies on rock No. 86943 and its mineral concentrates have resulted in the observation of xenon with an isotopic composition which seems to be necessary if the gas well pattern is to be understood. Both Bennett and Manuel[8] and Reynolds[9] have pointed out that gas well xenon must contain a contribution from ^{238}U spontaneous fission xenon, so that by subtracting this contribution from the gas well pattern it is possible to predict the isotopic composition of the remaining xenon. The isotopic composition of xenon observed in the fines of rock No. 86943 seems to approximate to that required for this component. In fact the presence of the gas well pattern in the total rock tends to support this view. The fines were produced as the result of the separation of the mineral concentrates from the total rock.

The xenon isotopic pattern observed in the fines (>700° C) from rock No. 86943 is shown in Fig. 1 together with the gas well xenon pattern as typified by C 16 (ref. 8). Here the data are presented in terms of ratio differences from air xenon using ^{130}Xe as the normalizing isotope.

In Table 1 the isotopic ratios of the fines xenon, 86943F (>700° C), are listed relative to ^{130}Xe. An estimate of the amount of anomalous ^{132}Xe in the fines, based on the assumption that all the ^{130}Xe is due to air xenon, is included. Blanks (<10% of total xenon) and air standards were run with every sample. Xenon from a number of samples of total rock No.

Table 1 Isotopic Composition of 86943F (>700° C) Xenon *

124	126	128	129	130	131	132	134	136
(0.022)	(0.021)	0.477±0.020 †	7.024±0.090	1.000	5.596±0.085	7.210±0.07	2.683±0.035	2.266±0.020

* Anomalous ^{132}Xe per gram of fines ≃ 2×10^{-12} cc NTP—assuming all ^{130}Xe due to air.
† All errors are one standard deviation.

86943, its mineral concentrates and fines has been examined. The data reported here are the best obtained so far, although the ^{124}Xe and ^{126}Xe ratios are ill defined extrapolated values.

All my attempts to produce a model to synthesize the fines xenon isotopic pattern in terms of xenon components of proven isotopic composition have been unsatisfactory. A model of particular interest would be one based on linear mass fractionation of the type of xenon found in the 1,000° C fraction of the meteorite Pesyanoe (ref. 10) but the low 134 and 136 abundances relative to the 132 mass abundance in the fines makes such a model untenable. Addition of ^{130}Xe to atmospheric xenon, but not to rock xenon, by a mechanism due to Cameron[11] is not an acceptable model for the same reason. No nuclear reaction has yet been proposed which can produce the anomalous pattern *in situ* assuming that the ^{129}Xe, ^{131}Xe and ^{132}Xe abundances are well correlated. The assumption of good correlation seems to be reasonable on the basis of the widespread observations of the gas well pattern. The low abundances of the ^{134}Xe and ^{136}Xe relative to ^{132}Xe in the fines xenon would be difficult to account for if a fission process was considered in order to explain the ^{129}Xe, ^{131}Xe and ^{132}Xe excesses.

On present evidence *in situ* production of the fines xenon component does not seem as likely as a model which accounts for it in terms of sampling, at least 3,210 m.y. ago (K/Ar age cited by Windley[4]), from a reservoir containing xenon with an isotopic composition similar to that of the fines xenon. The isotopic composition of such reservoir xenon could be the result of thorough mixing of more than one xenon component thus avoiding the difficulty associated with ascribing it to a single component. Sampling, at different periods throughout geological time, from this reservoir could account for all the gas well type xenon so far observed if suitable additions to the isotopic pattern are made by the inclusion of xenon from ^{238}U spontaneous fission.

The absence of any trace of the gas well pattern in xenon extracted from rocks of extreme age, or of supposedly deep seated origin, such as eclogites, lherzolite nodules and peridotites would then be considered to be due to their thorough outgassing during periods of metamorphism.

Thus, to summarize, first the West Greenland anorthosite No. 86943 contains gas well type xenon. Not all samples show this pattern, which is not surprising when the mineral heterogeneity of the bulk sample is considered. Second, the fines, produced during the concentration of the major minerals in the rock, contain a xenon component which seems to be essentially gas well type xenon with most of its ^{238}U spontaneous fission xenon component removed. Third, the origin of the fines xenon component is unknown . It is suggested that on the basis of present evidence it seems more likely to have originated from sampling of a suitable reservoir than to have been produced *in situ*.

The demonstrated presence of gas well type xenon in North America, Australia and Greenland indicates that it may be present on a global scale in suitable trapping sites. This observation of anomalous xenon in the fines of a Group III anorthosite substantiates previous suggestions concerning the origin of the gas well isotopic pattern. It does not, however, answer the vital question of how the anomalous xenon was produced. For example, have Group III anorthosites simply provided suitable trapping sites for the fines xenon component or has their possible presence in a primitive crust of the Earth some further significance in relation to the present day isotopic composition of gas well and atmospheric xenon?

Carbon-13 NMR Study of the Stereochemistry of Steranes from Oil Shale of the Green River Formation (Eocene)

THE presence of steranes and triterpanes in oils and sediments is especially significant as they possess the appropriate chemical stability for preservation throughout terrestrial diagenesis. They also contain a high degree of molecular order in their carbon skeleton and so the probability of their being synthesized by abiological processes is minimized. The high level of latent information in the structure and stereochemistry of these compounds renders them ideal biological markers[1-6].

The determination of true steric configuration is important in the study of both linear and cyclic fossil isoprenoids. For example, the structural information gathered on these compounds could be used in an analogous manner to the chemotaxonomic conclusions of recent flora. The biosynthesis of steroids and triterpenoids has now been shown to follow the biogenetic isoprene rule by squalene epoxide[7-11]. In steroid and triterpenoid biosynthesis it has been established that the role of the enzyme is critical in specifying the unique chain folding which allows the annelation steps to proceed along one path—a path not favoured thermodynamically[12,15]. The study of the stereochemistry of fossil steroids and isoprenoids is expected to lead to the understanding of the evolution of enzyme systems governing biosynthesis of their precursors as well as to the unravelling of the nature and kinetics of diagenetic processes in carbonaceous sediments.

The occurrence and the significance of steranes and triterpanes in the bitumen of Green River Shale has been well documented[16-22]. Gross identification of the individual biogenic compounds presented in these works was achieved on the basis of combined data from gas chromatography and mass spectrometry or X-ray crystallography[23-25].

In our study milligram quantities of high purity C_{27}, C_{28} steranes were isolated from Green River Shale using a preparative gas-liquid chromatography system developed in this laboratory for milligram-scale automatic separation of individual components from complex mixtures (see refs. 26 and 27 for details). The ^{13}C nuclear magnetic resonance (NMR) spectra of the isolated steranes were determined on a Varian HR-60 NMR spectrometer, modified for high resolution pulsed Fourier transform spectroscopy. Equipment and operational details have been described elsewhere[28,29]. Proton decoupling was performed both in the noise mode (simultaneously decoupling all protons) or off-resonance in the coherent mode to assist in spectral identification. The sample probe accommodated 5 mm sample tubes, and contained separate 15.08 MHz ^{13}C r.f. pulse coils and 60 MHz ^{1}H (proton) decoupling coils. For some spectra, the receiver coil was double tuned to allow internal locking on deuterium

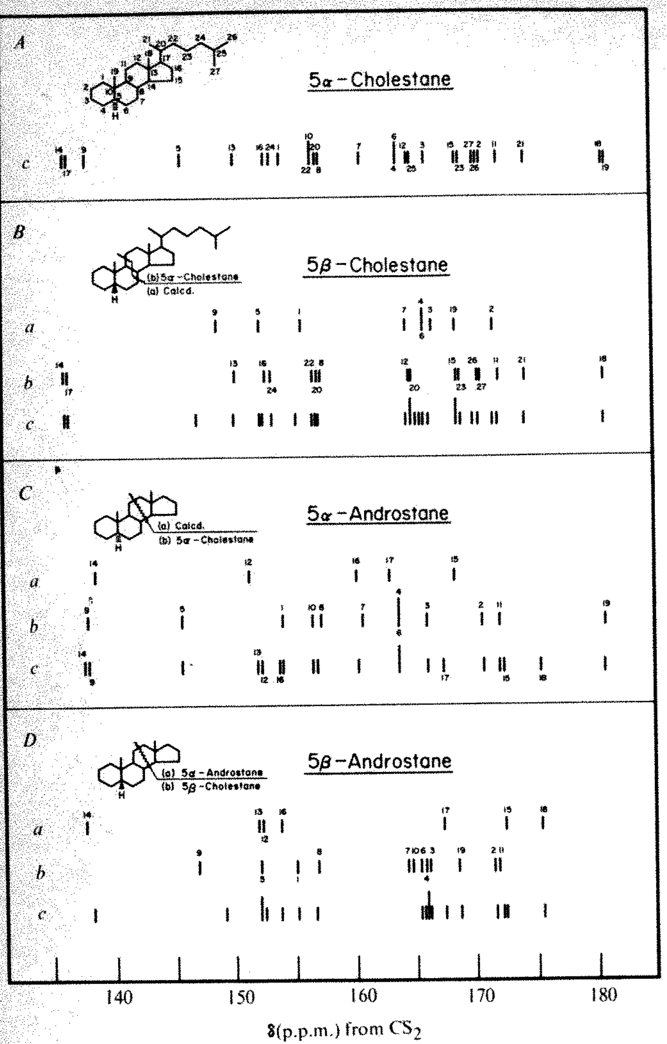

Fig. 1 Line diagram of the proton-decoupled ^{13}C resonances. *a*, Lines: resonance values calculated by additive parameters. *b*, Lines: chemical shifts taken from the appropriate part of the reference compound. *c*, Lines: experimental values. *A*, 5α-Cholestane 29 mg (Sigma Chemical Company). *B*, 5β-Cholestane 30 mg (Sigma Chemical Company). *C*, 5α-Androstane 30 mg (Mann Research Laboratory). *D*, 5β-Androstane 10 mg (Mann Research Laboratory).

(9.211 MHz). For the rest of the spectra, the ^{13}C transmitter coil was double tuned to allow coherent decoupling at the solvent deuterium frequency for a sharp reference peak, and an external ^{7}Li lock (23.321 MHz) was used which gave a limiting ^{13}C spectral resolution of approximately 0.03 p.p.m. $CDCl_3$ was used as the solvent in all cases. Due to the small quantity of the collected terpanes available (5–15 mg), both 30 µl. spherical microbulbs and normal 5 mm NMR tubes were used for spectra. The microbulbs were found to give increased sensitivity at the expense of resolution. For each spectrum, free-induction decays following 400 W r.f. pulses were accumulated on a Fabri-Tek model 1074 signal averager with a 4096 word memory. The accumulated signal was then Fourier transformed into a magnitude spectrum electronically using a Spectrum Analyser, or into an absorption spectrum numerically by a CDC 6600 computer.

The spectra were evaluated on the basis of the ^{13}C NMR behaviour of authentic tetracyclic steranes, model compounds and published data. The chemical shift assignments were aided by the extensive use of the qualitative rule of structural additivity derived for perhydrophenanthrenes[30], steroids, terpanes and carotenes[31,32].

Line diagrams of the noise decoupled ^{13}C NMR spectra of the stereoisomers cholestane (5α-cholestane) and coprostane (5β-cholestane) are shown in Fig. 1 (*A* and *B*, *c* lines). Both of these compounds have been tentatively identified in the Green River shale[21]. The difference between the two isomers lies in the manner of fusion of the A and B rings whereby the bridgehead carbons are *trans* or *cis*-substituted. To aid structural assignment, two additional model compounds, 5α-androstane and 5β-androstane, were selected and served as additive basic structural building units (*C* and *D*).

Our identification of ^{13}C resonances of cholestane followed the assignment reported by Rich *et al.*[31]. These assignments formed the basis of our extended calculations, where a part of the structure of cholestane was utilized (*b* lines). The calculations of the ^{13}C chemical shifts for the remaining portion of the molecule were performed by using the additive methyl substituent parameters obtained by factor analysis of methyl cyclohexanes by Dalling (ref. 30; *a* lines).

Although the spectrum of coprostane (5β-cholestane) seems different from cholestane, closer examination reveals that the effect of the A ring inversion on the chemical shifts can easily be traced to simple gauche-anti spatial orientation changes of the C-2, C-3 and C-4 carbons of the A ring relative to γ carbons in the B ring. As expected, the C_{19} methyl has been deshielded (−) and its resonance shifted downfield by about 12 p.p.m. The C-9 and C-7 carbons were affected the strongest by the C-2 and C-4 carbons respectively which folded into a close gauche position causing 8 and 5 p.p.m. shifts upfield. The resonances of the C-2, C-3 and C-4 carbons moved slightly upfield due to the sum of deshielding (−) and shielding (+) effects of the neighbouring carbons. The bridgehead carbons of C-5 and C-10 could be assigned with a high degree of confidence on the basis of their carbon–proton coupling behaviour shown in the coherent decoupled spectra.

The designation of the carbons of the five membered ring of the androstanes presented a particular problem because no parametric values are available to calculate ^{13}C resonances in perhydroindanes. Recourse was made to another set of parameters called "hydrocarbon parameters" developed by Dalling[30] to approximate the chemical shifts of those particular carbons. The values obtained are shown in Fig. 1, *C*/*a* lines.

† Slightly different values have been reported by Roberts *et al.*[31].

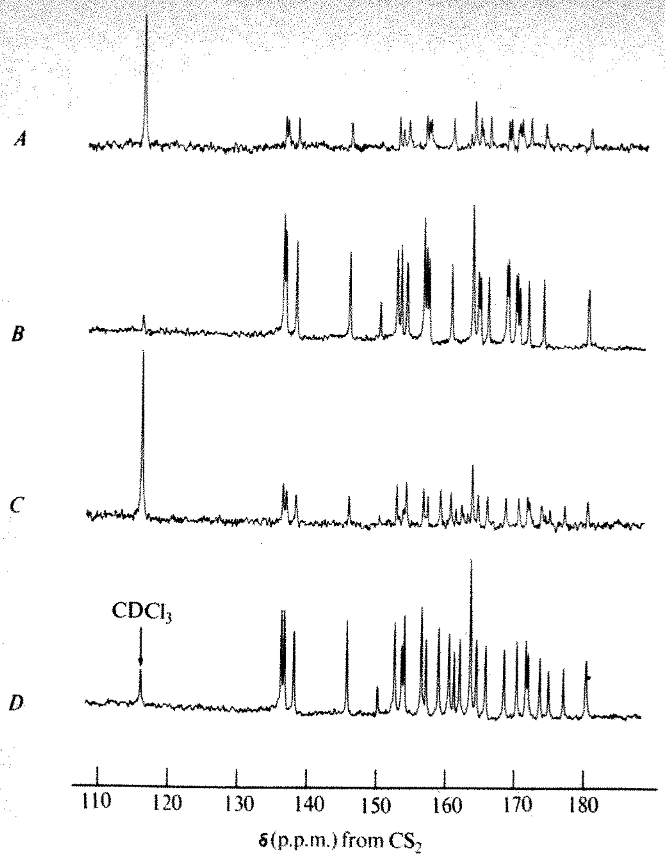

Fig. 2 Noise decoupled spectra of steranes. *A*, 12 mg sample of C_{27} sterane from Green River Shale. *B*, Authentic 5α-cholestane (Sigma). *C*, 8 mg sample of C_{28} sterane from Green River Shale. *D*, 5α-ergostane prepared from ergosterol (R & K Labs Inc.). Samples dissolved in 0.3–0.5 ml. CDCl$_3$ and placed in 5 mm sample tubes. Spectral conditions: ^{1}H noise decoupled, solvent deuterium decoupled, ^{7}Li external lock, ^{13}C r.f. pulse flip angle 50°, pulse interval 1.0 s, sample temperature 23° C, 5 kHz data sampling rate after r.f. pulse. 15,000–140,000 accumulated free-induction decays numerically fourier transformed.

Carbon resonances belonging to C-18, C-13 and C-14 positions were uniquely identified with the assistance of their proton coupling showing a quartet, a singlet and a doublet respectively.

The designation of carbon shifts of 5β-androstane provides a fine demonstration of the validity of the structural additivity principle. All assignments were derived using only the appropriate parts of 5α-androstane and 5β-cholestane molecules. ^{13}C NMR spectra possess fingerprint qualities corresponding to the multitude of factors affecting shifts, intensity and fine structure of the NMR signal. Both substituent[33] and conformational[34] effects have been shown to be very important. This quality of the ^{13}C NMR signal was demonstrated on the C_{27} and C_{28} steranes isolated from the hydrocarbon fraction of the oil shale bitumen of the Green River Formation. Their ^{13}C NMR noise decoupled spectra are present in Fig. 2 with the spectra of authentic 5α-cholestane and 5α-ergostane. There is no doubt that the spectra of the unknown steranes are identical with the spectra of the appropriate reference compounds.

On the basis of this spectral identity and study of model steranes we can state that the mode of ring fusions (all *trans*) and the geometric configuration of the side chain (17α[H]) in the isolated C_{27} and C_{28} steranes follow unequivocally from the ^{13}C NMR data. The assignment of carbon resonances of 5α-ergostane was accomplished by using the assignments of 5α-cholestane for the cyclic portion of the molecule and aliphatic additive parameters[35] to calculate the side-chain shifts. The experimental ^{13}C chemical shift values of the investigated steranes are compiled in Table 1.

We thank Dr Emilio Gelpi and Miss P. C. Wszolek for help, Dr M. P. Klein of the Biodynamics Laboratory, University of California, Berkeley, for computer facilities, the Department of Chemistry, University of California, Berkeley, for the use of the NMR spectrometer. BIOLOGICAL SCIENCES

Cellular Lipid Inclusions in the White Matter in Multiple Sclerosis

WE have obtained evidence to support the suggestion that fatty acid[1-4] and glycolipid[4-8] metabolism is defective in the white matter outside acute plaques of multiple sclerosis. Histochemical techniques show two types of intracellular lipid inclusions in such apparently normal areas.

Seventeen plaques from eight cases of multiple sclerosis and white matter from sixteen control patients, who had died from other neurological diseases, were fixed in routine saline-formol and transferred to 1% calcium acetate—10% formalin. Frozen sections were stained with haematoxylin-eosin, Sudan black, Nile blue sulphate[9], osmium tetroxide-α naphthylamine[9], 'oil red O', modified periodic acid-Schiff[9], gold-hydroxamic acid, acid haematein[9], perchloric acid-naphthoquinone[9], Holczinger's copper-rubeanic acid[9], diazotization-coupling[10], p-dimethylaminobenzaldehyde-nitrite[11], oxidized tannin-azo[12], trypan blue[13], Hale's dialysed iron[14], toluidine blue, Feulgen[15] and methyl green-pyronin[15]. Sections were also stained with 'Luxol'-fast blue either with the standard technique[15] or with the dye dissolved in 60% ethanol. Some tissue sections were extracted with acetone (4° C), chloroform-methanol (22° C; 2 : 1 v/v), or ethanol (22° C) for 1 h.

Plaques of multiple sclerosis were designated as: acute (six from two cases), showing perivenular infiltration with lymphocytes and plasma cells as well as hypercellularity throughout the lesion; active established chronic (five from five cases), with a rim of proliferating neuroglia at the edge; or inactive established chronic (six from four cases), with no evidence of cellular activity.

Two types of lipid inclusions were found in the white matter at least 2 cm away from acute plaques. The first consisted of granular or globular, isotropic droplets usually near neuroglial nuclei. The cells involved usually appeared to be oligodendroglia rather than astrocytes. These droplets were always stained with 'Luxol'-fast blue in 60% ethanol (Fig. 1) and, less frequently, with copper-rubeanic acid (Fig. 2), but not by the other methods used. They remained colloidal-iron negative after extraction with ethanol (see below). Extraction with chloroform-methanol extinguished staining with both Luxol-fast blue and copper rubeanic acid: acetone eliminated only the latter staining. The precise nature of the lipid in this type of inclusion is uncertain; the fatty acid reaction could be due to hydrolysis of phospholipids.

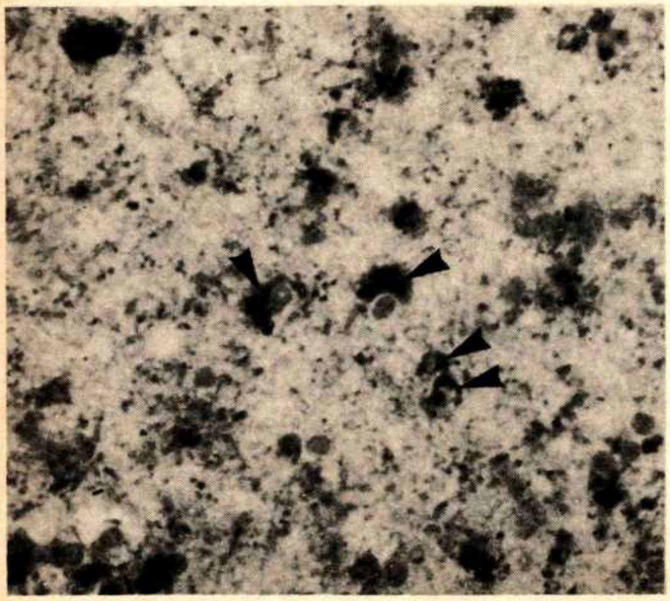

Fig. 1 Type 1 inclusion in cells resembling oligodendroglia (arrows) in the white matter around an acute plaque of multiple sclerosis. 'Luxol'-blue in 60% ethanol (× 960).

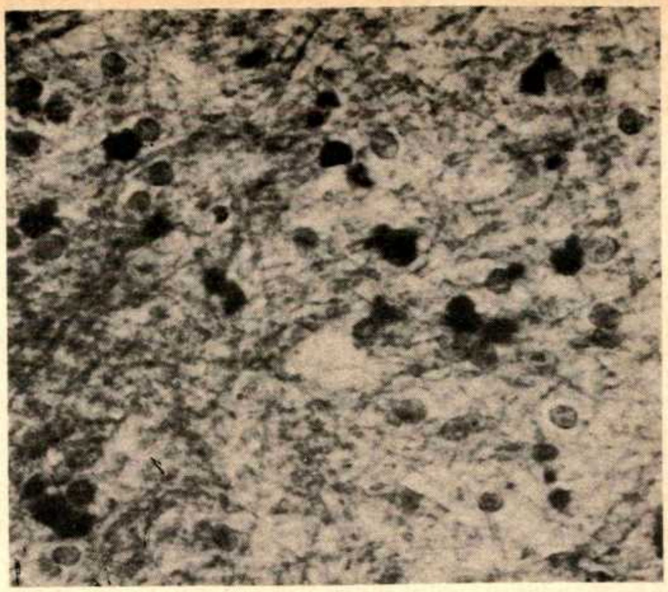

Fig. 2 As for Fig. 1 but stained by Holczinger's copper-rubeanic acid method for free fatty acids (× 960).

The second lipid inclusion in the white matter around acute plaques was a homogeneous relatively large mass usually close to or surrounding a cell nucleus. The cell type involved could not be clearly identified. The lipid mass was stained metachromatically pale orange-brown with cresyl violet (Fig. 3) and thionin (indicating sulphatide), metachromatically red with toluidine blue, moderately with 'Luxol'-fast blue, perchloric acid-naphthoquinone (cholesterol) and Alcian blue, and weakly with the modified PAS method (indicating a little cerebroside). These reactions were prevented by preliminary extraction with chloroform–methanol, but only that with perchloric acid–naphthoquinone was extinguished by acetone. The colloidal iron reaction became positive after extraction with ethanol, but not with acetone or ethanol followed by chloroform–methanol. This lipid inclusion was unstained by the other lipid methods used, the protein techniques and the methods for nucleic acids. With the exception of 'Luxol' preparations, however, it could always be identified in stained sections by its characteristic crystalline anisotropism (Fig. 3). Thus, this second inclusion seems to contain sulphatide, cholesterol and a little cerebroside, but no detectable mucosubstances. The colloidal iron reaction after ethanol recalls the staining of myelin lipids after acetone extraction[17]; the reversibility of both phenomena by chloroform–methanol extraction suggests that an acidic lipid (much as sulphatide) had been unmasked by ethanol or acetone.

Both lipid inclusions were frequently seen around acute plaques, but only occasionally around active and inactive chronic lesions. The first inclusion was never seen in control brains. Inclusions resembling the second type were noted in three control brains but were only occasionally related to cell nuclei. The nature of such extracellular inclusions is obscure[18-20]; possibly they are derived from intracellular lipid accumulations[21]. Neither type of lipid inclusion in acute multiple sclerosis resembled the Rosenthal fibre[22]: their negative reaction for protein, DNA and RNA indicates that they were not viral inclusion bodies.

The lipid inclusions within neuroglial cells are consistent with reports of abnormal proportions of lipids in white matter in multiple sclerosis[1-8]. In particular, the second lipid inclusion may be responsible for the raised sulphatide/cerebroside ratio in multiple sclerosis white matter[8].

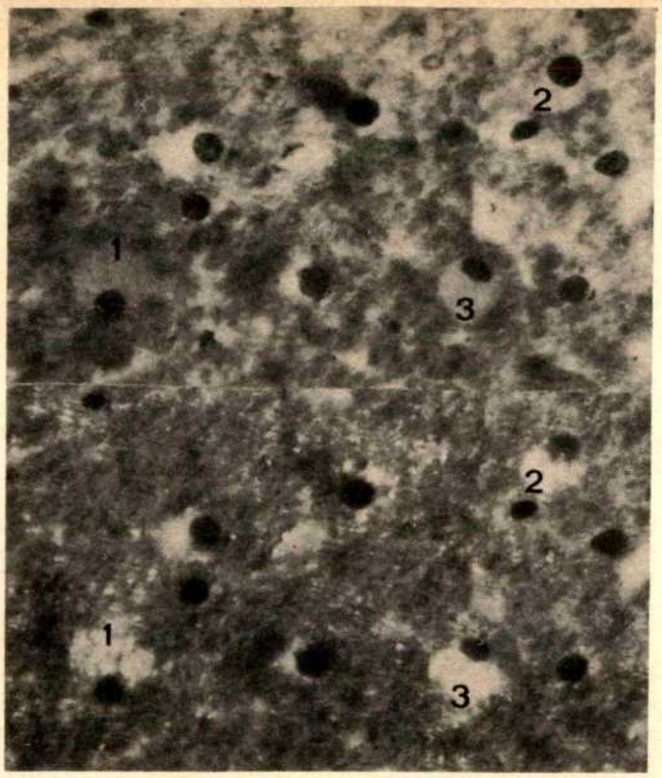

Fig. 3 Top: type 2 inclusion in the white matter around an acute plaque of multiple sclerosis. Note the intracellular site of these inclusions (1, 2, 3), which were stained metachromatically orange-brown in the section. Cresyl violet (× 960). Bottom: same field viewed in polarized light.

The metabolic interpretation of the neuroglial lipid inclusions in multiple sclerosis is speculative. They could result from defective cerebroside synthesis and increased production of sulphatide or, possibly, by failure in extrusion of membrane from the myelin–formative cell, so that lipid accumulates intracellularly.

It is unlikely that the inclusions reflect remyelinating activity, because they occur in apparently normal white matter distant from the demyelinating edge and, moreover, their histochemical characteristics do not correspond with those of the lipids that temporarily appear within interfascicular oligodendroglia during myelination[23–26].

We thank Dr David Haler, Mr Douglas High, Dr Keith Mant, Professor Keith Simpson and Dr Peter Sylvester for brain samples.

Nature of the Nerve Lesion caused by a Pneumatic Tourniquet

THE use of a tourniquet around a limb may be followed by damage to peripheral nerves. This lesion has been investigated experimentally in cats[1,2] and the results suggested that in most cases the nerve damage was limited to the portion of the nerve under the tourniquet. Nerve fibres conducted normally distal to this level, with either a conduction block or a reduced conduction velocity at the site of the tourniquet. Histological studies showed localized demyelination under the tourniquet with preservation of axonal continuity. A similar pathological change is believed to occur in many forms of human pressure palsy, and the conclusion that the nerve damage is due to ischaemia has been widely accepted.

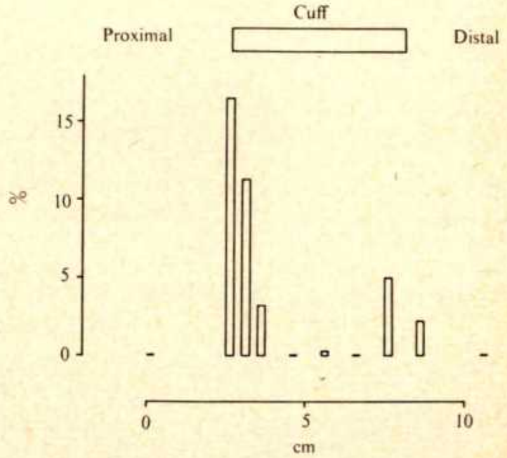

Fig. 1 Histogram to show proportion of abnormal fibres in transverse sections of medial popliteal nerve at different levels in relation to site of tourniquet (5 cm cuff inflated to 1,000 mm Hg for 75 min). Approximate position of cuff shown above. The specimen was taken 3 months after tourniquet. Nerve was fixed by perfusion with buffered glutaraldehyde and post-fixed with osmium tetroxide, 1 µm transverse sections were stained with toluidine blue, photographed, and counts made from enlarged prints[5]. Abnormal fibres (axon diameter 5 µm or greater, myelin thickness less than 1 µm) are expressed as a percentage of the large fibre population.

We have recently done some further experiments using a sphygmomanometer cuff inflated to 1,000 mm Hg around the hind limb of the baboon for 1–3 h. A brief preliminary account of the technique and of the resulting changes in nerve conduction has been published[3]. In the course of the experiments, it became clear that the role of direct pressure in producing nerve damage had been underestimated by previous workers. Two pieces of evidence for this can be cited.

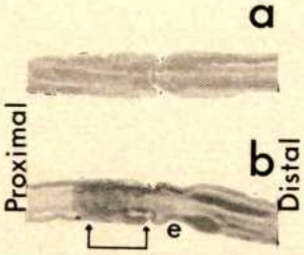

Fig. 2 Single fibres from medial popliteal nerve 1–4 days after tourniquet (5 cm cuff at 1,000 mm Hg for 90 min), to show different stages of invagination at nodes of Ranvier. Fibres were taken from a portion of nerve under the proximal edge of the cuff. Perfusion-fixation was carried out with buffered glutaraldehyde followed by post-fixation with osmium tetroxide; single fibres teased apart in 'Epon'. Symbol in *b* is as in Fig. 4.

(1) With the relatively wide (5 cm) cuff used, it has been found consistently that the nerve damage is maximal under the edges of the cuff or is restricted to these regions. This has been true of all stages of the pathological change in nerves studied for up to 6 months after the tourniquet had been applied. It has been demonstrated in single teased fibres and in transverse sections (Fig. 1). (2) The nature of the pathological change was best appreciated by examining single teased fibres by light and electron microscopy. In essence, the early change consisted of a dislocation of the nodes of Ranvier of the large-diameter myelinated fibres. The mildest form was a slight invagination of one paranode into the adjacent one (Figs. 2*a* and 3). Deeper invagination is illustrated in Figs. 2*b* and 4; it is accompanied by infolding of the myelin of the ensheathing paranode, with movement of the nodal axoplasm and axonal membrane away from the point of junction of the two Schwann cells. The dislocated nodal part of the axon could still be identified by the thickening of the axonal membrane and by the presence of characteristic transverse bands. The junction of adjacent Schwann cells was identified by their microvilli. If one assumes that the original site of the nodal axon was at the point of junction of the two Schwann cells, there must have been movement of the axon relative to the Schwann cell junction of approximately 30 µm, accompanying the invagination of the paranodal myelin.

A penetration of one paranode by another deeper than that shown in Fig. 4 may occur. In longitudinal sections of single fibres, it has not been unusual to see invagination and movement of the nodal axon which has proceeded for 100–200 µm. In such cases there is partial or complete rupture of myelin lamellae in the invaginated region.

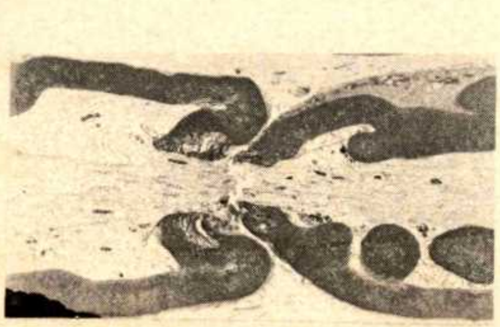

Fig. 3 Electron micrograph (LS) of nodal region shown in Fig. 2*a*.

All these changes are seen within the first few hours after the tourniquet and, by the end of the first week, invagination of myelin is beginning to be followed by demyelination. In our experience, the demyelination has usually been restricted to the region within 200 µm of the node of Ranvier. Demyelination of whole internodal segments has been rare. When teasing single nerve fibres, the striking feature of these lesions is that the changes described above have a clear polarity, the direction of invagination always being away from the cuff towards uncompressed tissue.

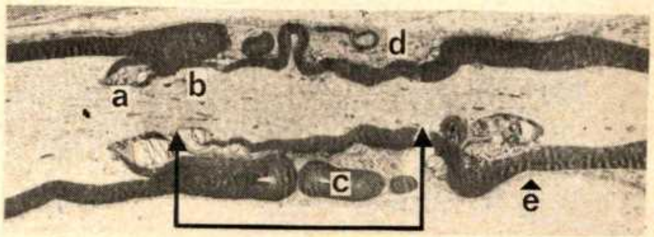

Fig. 4 Electron micrograph (LS) of nodal region shown in Fig. 2*b*. *a*, Terminal myelin loops of ensheathing paranode; *b*, terminal myelin loops of ensheathed paranode; *c*, myelin fold of ensheathing paranode cut tangentially; *d*, Schwann cell cytoplasm; *e*, microvilli indicating site of Schwann cell junction. Large arrows show length of ensheathed paranode (approximately 20 µm).

From the nature of the lesion, its polarity, and its distribution under the cuff, we therefore conclude that it is due to direct pressure and not to ischaemia. The principal evidence cited by previous authors against the possibility of direct pressure producing nerve damage is the experiment described by Grundfest[4], in which the pressure in an oxygenated chamber enclosing excised frog nerve was increased to approximately 1,000 atm before conduction was abolished. But this is a different situation from that which occurs when a pneumatic cuff is inflated around a limb. In the latter case there is a pressure gradient in the tissues between the portion under the cuff and that beyond its edge. Our results indicate that in these circumstances, longitudinal movement of the axon and its myelin occurs with respect to the Schwann cell. This change precedes demyelination.

Local Origin of Fibroblasts deduced from Sarcomas induced in Chimaeras by Implants of Pliable Disks

"THE origin of fibroblasts in healing wounds has been debated for over 100 years" according to Ross, Everett and Tyler[1], whose recent experiment indicated local connective tissue to be the source. Barnes and Khrushchov[2] had already concluded that in murine radiation-chimaeras precursor cells arose in bone marrow. We deduced from this that implants of pliable disks of adequate size, which give rise to local malignant growths (sarcoma), should in similar radiation-chimaeras produce sarcomas derived from the donor (myeloid) elements of the chimaeras and have examined such sarcomas induced by cellulose or silicone rubber. In the chimaeras the donated marrow was distinguishable from the host tissue by the presence in mitotic cells of *T6T6* chromosomes in one or other phase. The sarcomas were analysed cytologically; also, tumours arising in allogeneic chimaeras were tested genetically by their capacity for continued growth in mice of both pure strains. Both tests indicate that the tumours arose from the native host cells and not from the donated myeloid cells or their progeny.

The radiation-chimaeras used were of two kinds CBA/CBA-*T6T6* and CBA-*T6T6*/A produced as in a previous experiment[3].

Five to six weeks after the establishment of chimaerism, the mice were anaesthetized with ether. An incision was made in the mid-line of the shaved skin of the back and into subfascial pockets on each side a disk was inserted, the wound being closed with Michel clips.

In one series the disks were of 'Millipore R' filter, 25 mm diameter and 0.10 µm pore size. In the other series the disks were of silicone rubber (supplied by Dow Corning Center for Aid to Medical Research, Midland, Michigan)—2 cm in diameter and 1 mm thick[4]. Tumours once diagnosed were allowed to grow to an estimated diameter greater than 0.5 cm. Then the mouse was injected with 'Colcemid' and killed 4–5 h later. A portion of the tumour was macerated to produce cells suitable for chromosome analysis[3]. In a few mice the tumour presented not as a solid mass but as a fluctuant cyst around a rubber disk. At necropsy the cyst was aspirated of its bloodstained fluid which was then processed as a cell suspension. In each case a tumorous thickening of part of the cyst wall was identified.

Portions of solid tumour about 1 mm^3 were passed by means of a Bashford needle (or cyst fluid by syringe and needle) to suitably compatible mice. Thus tumours in syngeneic chimaeras were passed to (CBA × CBA-*T6T6*) F_1 hybrids, where the single *T6* chromosome of dividing cells of the second host would distinguish cells of the second host from tumour cells, which should contain no *T6* chromosomes if the tumour arose from the natural cells of the primary host or two or more *T6* chromosomes if the tumour derived from the donated cells. Tumours in allogeneic chimaeras were analysed by passage to CBA, A and (CBA-*T6T6* × A) F_1 mice: tumours of host origin should grow in CBA and F_1 mice only, whereas those stemming from the donated bone marrow should grow in A and F_1 mice only. A single case of a subcutaneous sarcoma arising in a syngeneic chimaera of another experiment was analysed cytologically.

The fate of fifty-five chimaeras investigated is given in Table 1.

All tumours were analysed cytologically as of host origin (Table 2). In all but five a diagnosis was made on the primary tumour (or cyst fluid). In four of the five exceptions absence or paucity of mitoses in the primary tumour was the cause of doubt. Repetition on the first passage of the tumour confirmed that the primary tumour was of host origin. In the fifth animal (A390) a small tumour was diagnosed only at necropsy; passage was successful and the passaged tumour shown (M6251) to have arisen from the host tissue of the original chimaera.

All twenty-one tumours arising in allogeneic chimaeras behaved in the genetic test of passage as host type tumours, killing CBA and (CBA-*T6T6* × A) F_1 recipients but not A strain mice.

Table 1 Fate of Radiation Chimaeras with Implants

Implant	Type of chimaera	Early death	Killed—tumour	Late death—no tumour
Cellulose	Syngeneic	4	7	0
	Allogeneic	0	13	2
Silicone rubber	Syngeneic	0	11	3
	Allogeneic	2	8*	5

*One died undiagnosed.

Table 2 Sarcomas in Subcutaneous Tissue

Type of chimaera	Code No.	Origin of tumour	Confirmation on passage Code No.	Origin
(*a*) Induced by 'Millipore' filter				
Allogeneic	M5595	—	M5625	Host

Syngeneic	M5786	—	M5864	Host
Syngeneic	M5791	Host		
Syngeneic	M5795	Host		
Syngeneic	M5796	Host		
Allogeneic	M5805	Host		
Allogeneic	M5825	Host		
Syngeneic	M5865	Host		
Allogeneic	M5915	—	(M6106) (M6153)	Host Host
Allogeneic	A390	—	M6251	Host
(*c*) Spontaneous				
Syngeneic	M5579	? Host	M5623	Host

The one spontaneous sarcoma in a syngeneic chimaera was also typed cytologically as of the host.

The results indicate that sarcomas induced in the subcutaneous connective tissues of radiation chimaeras originate in cells of the host rather than in immigrant cells derived from the donated bone marrow. Similar results had been obtained for osteogenic connective tissue[3]: sarcomas induced in bone after injection of strontium-90 were also of host-type in spite of the immediate propinquity of donor-type bone marrow.

In this experiment none of forty tumours arose from the donated tissue. Long experience in this laboratory with chimaeras induced after this lethal dose of radiation (1,000 rads) to CBA mice indicates that little, if any, reversion of myeloid or lymphoid tissues occurs, so that virtually all leucocytes were of donor origin[5]. The deduction to be made, therefore, is that these tumours, most of which were of spindle cells (fibrosarcoma), arose from native connective tissue cells, not immigrant leucocytes.

Ross *et al.*[1] came to a similar conclusion for the origin of normal fibroblasts in healing wounds of skin. This was deduced from experiments in which ^{3}H-thymidine was given to one partner of an irradiated parabiotic pair of rats dependent for their marrow function and survival on the shielded femur of the animal that was later injected. Labelled leucocytes were found in skin wounds of both but labelled fibroblasts only in the animal exposed to ^{3}H-thymidine.

The thesis of Barnes and Khrushchov[2] on which the present experiment was planned rested on the observation that, after 5–7 days' duration of a glass disk *in situ*, the predominant cell attached to the glass had the general microscopic appearance of a young fibroblast. Ryan and Spector[6] apparently consider the cells on the glass to be a continuously maintained population of macrophages derived from blood monocytes, dividing after a latent interval of several days and departing. Spector[7] concludes that macrophages, though capable of change to epithelioid cells in tissue, do not convert to fibroblasts.

The controversy that has lasted for more than a century on the origin of the fibroblast may still not be resolved and proponents of both options may be right. We deduce from the present study and that of Ross *et al.*[1] that malignant and normal fibroblasts can be derived from local precursors in connective tissue, but this does not exclude that in appropriate circumstances fibroblasts may be derived from myelogenous cells.

We thank Dr Austin Brues for advice on materials for implantation and D. Stone, M. Bland and Mrs C. Smith for technical assistance.

Induction of Zona Reaction in Golden Hamster Eggs by Cortical Granule Material

BRADEN *et al.*[1] have shown that the zona pellucida of mammalian eggs changes after fertilization so that penetration of further spermatozoa is greatly reduced. Austin and Braden[2] inferred that this zona reaction was due to the action of the cortical granule material which is released from the egg into the perivitelline space shortly after sperm entry into the egg cytoplasm. We wish to present experimental evidence to support this inference.

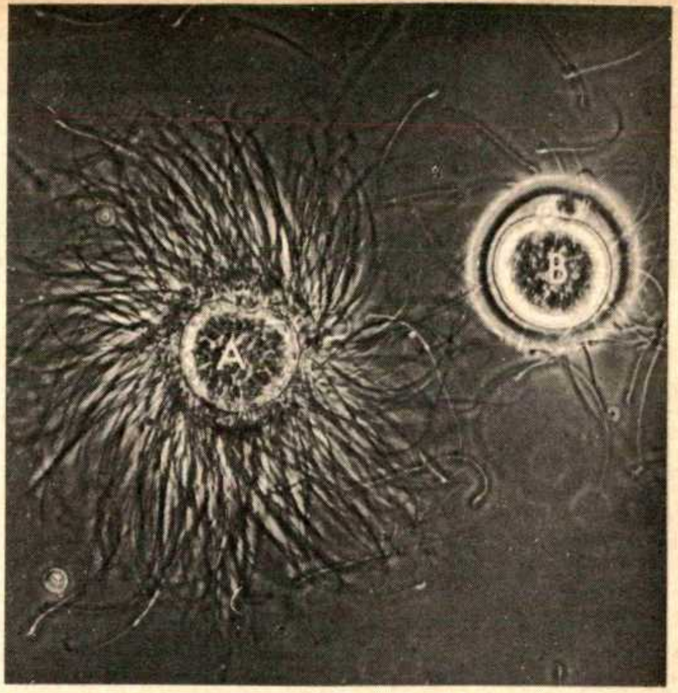

Fig. 1 Two eggs recovered from a hamster female 5 h after artificial insemination and incubated for 5 min with capacitated spermatozoa. One of the eggs (*A*) has many spermatozoa attached to the zona pellucida (negative zona reaction), while the other egg (*B*) does not have spermatozoa firmly attached to the zona (positive zona reaction) (× 450).

Adult female hamsters were induced to ovulate by injection of human chorionic gonadotropin on day 3 of the oestrous cycle[3], counting the day of the post-oestrous discharge[4] as day 1. Fourteen hours after the injection, they were artificially inseminated with cauda epididymal spermatozoa and killed at various times after insemination, from 5 to 72 h. Eggs were flushed from the oviducts with Tyrode solution and cumulus cells, if present, were removed by treatment with 0.1% bovine testicular hyaluronidase (300 USP units/mg, Nutritional Biochem. Corp.) in Tyrode solution. Cumulus-free eggs thus obtained were placed in 100 μl. of an incubation medium[5] under mineral oil in a sterile plastic dish. Spermatozoa used to inseminate these eggs were capacitated with detoxified human blood serum[6,7]. Five minutes after the eggs and spermatozoa had been mixed together, two types of eggs could be distinguished (Fig. 1). One type had a cloud of actively moving spermatozoa strongly attached itself to the surface of the zona pellucida. When these eggs were cleaned by pipetting them through a small bore pipette and examined with a phase contrast microscope, none contained a spermatozoon either in the perivitelline space or in the vitellus. Clearly no egg of this type had been penetrated by any spermatozoon before the time of recovery from the oviducts. In the other type of eggs, no spermatozoa were found firmly attached to the zona pellucida in spite of their continuous collisions with the zona surface. Examination of these eggs with a phase contrast microscope revealed that each had already been penetrated by a spermatozoon and cortical granule breakdown had taken place. When the two types of eggs were separated and incubated for 1 to 2 h with capacitated spermatozoa, the zona pellucida of already fertilized eggs was not penetrated by extra spermatozoa while unfertilized eggs became highly polyspermic. A series of observations (to be reported in full later) have indicated that the refractory state of the zona pellucida "zona reaction" develops less than 15 min after cortical granule breakdown before sperm chromatin dispersion can be seen. A similar strong zona reaction was observed throughout the cleavage stages, indicating that this is a permanent change of the zona pellucida.

If cortical granule material is responsible for the development of the zona reaction, it should be possible to induce this reaction by exposing the zona pellucida of an unfertilized egg to the cortical granule material released from fertilized eggs. The following experiments were designed to determine whether this was the case. For each experiment, 200–300 unfertilized eggs were flushed from the oviducts of females injected with human chorionic gonadotropin 14 h previously. After dispersing the cumulus oophorus cells with 0.1% bovine testicular hyaluronidase in Tyrode solution, the eggs were treated with 0.1% hog pancreatic trypsin (1–300, Nutritional Biochem. Corp.) in Tyrode solution containing 0.1% bovine serum albumin fraction V (Armour). Within 1 min the zona pellucida of all eggs was completely digested. After three thorough washings with Tyrode–albumin, the eggs were placed in 25–50 µl. of incubation medium[5], under mineral oil, and inseminated with capacitated spermatozoa suspended in 1–2 µl. of a sperm-capacitating medium (detoxified human serum). Ten minutes later (our preliminary observations had shown us that the cortical granules of such zona-free eggs break down completely with 2.5 to 5 min after insemination), the incubation medium was drawn into a capillary tube (1.4 mm inside diameter), one end of which was then sealed with flame. The tube was centrifuged at 7,000*g* for 10 min, causing eggs and spermatozoa to sediment at the bottom of the tube in a volume of approximately 1 µl. Supernatant solution (10–25 µl.) containing cortical granule material was placed under mineral oil in a dish (group *A*). Also, incubation medium with capacitated spermatozoa but no eggs (that is no cortical granule material) was centrifuged and 10–25 µl. of the supernatant were placed under mineral oil in another dish (group *B*). Seven to eighteen fresh unfertilized, cumulus-free eggs in 1–2 µl. of Tyrode solution were added to each drop Both groups of eggs were incubated for 30 min at 37° C, then inseminated with capacitated spermatozoa and incubated for an additional hour. Cumulus-free unfertilized eggs and capacitated spermatozoa were mixed concomitantly with 10–25 µl. of the supernatant solution containing cortical granule material and incubated under mineral oil for 1 h at 37° C (group *C*). At the end of the incubation, all eggs were examined with both a high power dissecting microscope and a phase contrast microscope for evidence of zona reaction.

The results (Table 1) showed that all eggs of group *A* displayed a characteristic zona reaction, while none of the eggs of groups *B* and *C* showed the reaction. The zona pellucida of every egg in these two groups (*B* and *C*) was heavily penetrated by spermatozoa.

Table 1 Effect of Cortical Granule Material in the Induction of the Zona Reaction

Group	Exp. No.	No. of eggs	No. of eggs with zona reaction	No. of eggs without zona reaction
A	1	15	15	0
	2	7	7	0
	3	15	15	0
B	1	10	0	10
	2	7	0	7
	3	18	0	18
C	1	9	0	9
	2	8	0	8
	3	18	0	18

The results reported here clearly demonstrate the zona reaction in hamster eggs and indicate that it is elicited by cortical granule material. The apparent effectiveness of this material in spite of great dilution suggests that the active agent is a very potent substance. The chemical nature of the active agent and the mode of its action on the zona pellucida must await further investigation.

This study was supported by grants from the Ford Foundation, the Population Council, the Rockefeller Foundation, and the US Public Health Service. C. B. thanks Professor Vincent J. DeFeo who made possible his appointment as a visiting professor at the University of Hawaii, and the Catholic University of Chile for leave of absence. We thank Mrs Cherrie A. Mahi for assistance in the preparation of the manuscript.

Postnatal Malnutrition and Brain Cholinesterase in Rats

Severe malnutrition, especially protein–calorie restriction, early in the life of rats[1] and pigs[2] can cause behavioural abnormalities which persist long after nutritional rehabilitation. The physiological or biochemical basis for these abnormalities is not known, although long term, irreversible alterations in total DNA[3] and brain lipid content have been found to result from early malnutrition. A part of the brain which has been demonstrated to be involved in the control of behaviour is the central cholinergic mechanism[5], and changes in brain acetylcholinesterase (AChE) and cholinesterase (ChE) have been reported to be correlated with behavioural changes in animals subjected to different environmental situations[6]. Furthermore, Sereni *et al.* found that undernutrition during the first 3 weeks of life decreased the activity of AChE in the brains of rats until they were 2 weeks old. We have now investigated the effects of early protein–calorie restriction on the activity of ChE in the brain.

Pregnant Holtzman rats were fed a purified diet containing 25% casein until the birth of their young. Eight newborn male rats were assigned to each litter and during suckling, lactating dams were divided into an experimental group fed a low protein diet (12% casein) to decrease milk production, and a control group fed on optimum protein diet (25% casein). After a 3 week nursing period, rats on the low milk intake were weaned to a low protein diet (3% casein) for the next 4 weeks. The control group received the optimal protein diet. After the restriction period all animals were fed the optimal diet until they were 38 weeks old.

ChE, DNA and nitrogen in the brain were measured at 9 days, 3 weeks, 7 weeks and 39 weeks of age. The colorimetric method[8] was used for the ChE assay and nitrogen was determined by the microkjeldahl method. To determine DNA, homogenization of brain tissues followed by hydrolysis of tissue lipids were accomplished as described by Penn and Suwalski[9]. The nucleic acid extracts were obtained by Schneider's procedure[10]. Finally, a modified method developed by Burton[11] was used for colour development.

Table 1 shows that both specific and total ChE activity increased with age. The rate of increase was most marked during the first 7 weeks of life. At 9 days malnourished rats

Table 1 Brain Cholinesterase Activities of Malnourished Rats and of Rehabilitated Rats

Age (weeks)	Group	ChE/g wet brain weight (R* × 10⁶)	Specific activity ChE/100 mg N (R × 10⁶)	ChE/mg DNA (R × 10⁶)	Total activity ChE/brain (R × 10⁶)
1+ (9 days)	Control (8)	3.92±0.22	28.5±1.17	5.21±0.70	3.71±0.34
	Experimental (8)	4.20±0.17†	29.1±1.29	5.17±0.44	3.65±0.20
3	Control (9)	6.92±0.51	37.9±2.87	9.16±1.08	11.1±0.92

* R is rate in moles substrate hydrolysed per minute.
† Significant difference ($P<0.05$) from control.
‡ Significant difference ($P<0.005$) from control.

had an increased specific activity of ChE (ChE/g wet brain weight), the mean difference from the control value being significant at the level of 0.05. When activity was expressed as either ChE/100 mg nitrogen or ChE/mg DNA, there were no differences between the two groups, which does not agree with the report[7] of lowered brain AChE activity (CμM/30 m/mgN) in undernourished rats at 6, 8 and 14 days, and no differences at 21 days. At 3 weeks of age the total ChE activity per brain in the malnourished rats was significantly lower ($P<0.005$) than that of control animals. There were no differences in the specific activity of the enzyme between the two groups, which agrees with Sereni's results on 21 day old rats[7]. On the other hand, Adlard *et al.*[12] reported that the brain AChE activity (per gram wet tissue weight) at 21 days was lower (11%) in rats undernourished during gestation and lactation.

At 7 weeks of age the total enzyme activity per brain in the malnourished group was still lower ($P<0.005$) than the control value. But the specific activity of the enzyme (ChE/g wet brain weight and ChE/100 mg nitrogen) was significantly increased ($P<0.005$) in the malnourished group. The specific activity expressed as ChE/mg DNA did not differ between the two groups. The increased specific activity of brain ChE in the 7 week old malnourished rats persisted after the animals had been given a normal diet for 31 weeks. The total enzyme activity per brain did not differ significantly between the two groups at 38 weeks. This is attributable to the smaller brain weights of the previously malnourished rats. Thus, severe protein–calorie deficiency in early life resulted in long lasting increases in the specific activity of brain ChE in rats.

It is interesting that these long lasting increases in brain ChE parallel the long term increases in the emotional reactivity observed in adult rats given identical nutritional treatment[1]. Moreover, the long term effects of early handling give similar results in that both emotional reactivity[13] and subcortical ChE[14] decrease.

Stereochemical and Vibrational Theories of Odour

ALTHOUGH many theories of odour specificity have been proposed, only two have been supported by quantitative measurements with statistical analysis. My stereochemical theory correlates the odours of various compounds with the sizes and shapes of their molecular models[1]. Wright's vibrational theory relates the odours to certain absorption peaks in their far infrared spectra[2]. It would be interesting to compare the relative success of our two theories directly, but so far this has not been possible, because we had used different test compounds and different statistical criteria.

Accordingly I have decided to apply my theory to the same set of compounds that Wright discussed. These are twenty-six homologues of benzaldehyde and nitrobenzene, originally prepared by Klouwen and Ruys[3], who reported their odours in qualitative terminology, for example, bitter almond, weak note of sassafras. As a basis for comparing our theories, however, it would be preferable to obtain quantitative measurements of the degree to which each compound resembles in odour a single standard, for example, benzaldehyde itself (which is the principal constituent of bitter almond oil).

For this purpose I used a panel of twenty-nine observers who were experienced in olfactory tests but unfamiliar with most of these compounds[4]. About 0.1 g of each odorant was presented in coded 10 ml. glass-stoppered Erlenmeyer flasks, for comparison with a standard flask containing 0.1 g benzaldehyde. The observers were instructed to ignore any differences in intensity, and to concentrate on odour quality. The scale of odour similarity runs from 0 for no similarity up to 8 for extreme similarity. The odorants were presented in daily batches of eight in randomized sequence, and each odour appeared twice. Hence the odour similarities given in the middle column of Table 1 represent the averages of more than fifty individual judgments. These odour similarity values constitute the experimental olfactory data which each theory must seek to explain.

The starting point for my stereochemical theory is a set of three orthogonal silhouette photographs of a scale model of the benzaldehyde molecule. Using the PAPA scanning computer[1], the molecular silhouette of each homologous compound was compared with the benzaldehyde silhouette as the standard. The centre of gravity of each molecular silhouette was taken as the datum point. The computer-generated scale of molecular shape resemblance runs from 120 for complete identity down to 90 or less for very dissimilar molecules. The detailed results are given at the right of Table 1.

Table 1 Olfactory and Stereochemical Similarities to Benzaldehyde

Compound	Odour similarity *	Molecular shape †
Benzaldehyde (standard)	(7.17) ‡	(120.6) ‡
o-Methylbenzaldehyde	3.79	109.0

Benzonitrile	6.29	112.0

* Similarity to odour of benzaldehyde.
† Resemblance to molecular silhouette of benzaldehyde.
‡ Omitted from statistical calculations.
§ Sample unobtainable.

These data are easier to comprehend in the form of a graph (Fig. 1). Clearly there is a strong correlation between odour quality and molecular shape. The more closely a compound resembles benzaldehyde in the shape of its molecule, the more similar it is to benzaldehyde in odour. (The only exception is *m*-methylnitrobenzene which smelled much closer to benzaldehyde than its molecular shape would indicate.) The pair of regression lines diverge mildly, indicating a relatively high correlation coefficient, $r = 0.90$. With $N = 25$ compounds, the probability was extremely low that this correlation could be fortuitous, $P \ll 0.001$. The molecular silhouette photographs were also run through the PAPA computer a second time, using the functional group (CHO or NO_2) of the molecular silhouette as datum point instead of the centre of gravity. The results were not quite so good, $r = 0.71$, but the probability level remained highly significant, $P < 0.001$. The experimental data evidently provide strong support for the stereochemical theory of odour.

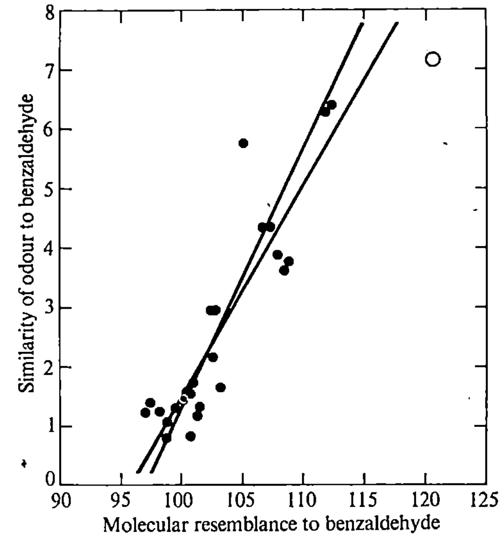

Fig. 1 The almond odour is correlated with molecular shape for 25 homologues of benzaldehyde and nitrobenzene. $r = 0.90$. (Two regression lines are shown because both variables are subject to experimental error; the open circle represents the benzaldehyde standard.)

Now it is the turn of the vibrational theory to explain the observed olfactory values for this series of compounds. In the study reported earlier[2], Wright and Robson did not have quantitative olfactory data available, so they treated the sixteen almond-like odorants as a group, contrasting them with an external control group of thirty-one miscellaneous compounds with other odours. Thus there is no basis on which to compare their χ^2 analysis with my regression analysis, even though their final probability levels appear much the same as mine.

If our two theories are to be realistically compared, it is necessary for Wright to devise a method for computing, from the infrared spectral frequencies, a quantitative measurement of how closely the spectrum of each compound resembles the spectrum of benzaldehyde itself, or some composite spectrum based on several compounds having an almond odour. This procedure would enable him to add his column of vibrational data to Table 1, and draw his graph corresponding with Fig. 1. Then, and only then, could we compare correlation coefficients, and obtain a direct measure of which theory fits the olfactory data more precisely.

I have developed one aspect among three quantitative comparisons of our theories that are in progress[5]. I thank Dr F. Rijkens of the Chemische Fabriek "Naarden" who supplied most of these compounds, and Drs R. H. Wright and J. R. Hughes for samples. Many of the aldehydes were freshly regenerated here from their semicarbazones by Dr Marvel-Dare Nutting. The measurements with the PAPA computer were furnished by Miss Silvana Vallerga at the University of Genoa.

Evidence for Inhibition by Brain Serotonin of Mouse Killing Behaviour in Rats

THERE is some doubt about the role of brain serotonin in aggression. In mice made aggressive by prolonged isolation, there is a decrease in brain serotonin turnover[1], while increased aggressiveness has been noted in cats[2] and rats[3] given *p*-chlorophenylalanine (PCPA), which inhibits serotonin synthesis[4], although the experiments with cats[2] were not confirmed later[5]. Dominguez and Longo[6] reported that PCPA attenuates irritability and viciousness in rats with septal lesions, and Welch and Welch[7] observed decreased aggressiveness in isolated mice given PCPA. The explanation for these contradictory results may be that different models of aggression are not mediated through the same areas of the brain or by the same biochemical mechanisms.

We have therefore investigated the effect of modifying brain serotonin metabolism on mouse killing behaviour induced in isolated rats with or without lesions in the anterior olfactory area[8,9]. Two operations were performed on male Wistar rats (200–240 g, Morini). In the first (bulbectomy), the cortex of the olfactory bulb and the anterior part of the olfactory nucleus were removed on both sides of the brain. A glass cannula was inserted at a right angle to the lamina cribrosa of the ethmoid bone through a hole in the frontal bone. In the second operation (bulbotomy) both olfactory stalks were cut with a needle inserted by the same route as the cannula. Cuts were caudal to the olfactory nucleus, so that most of the rostral end of the olfactory tubercle was sectioned. Sham operations were performed by inserting a needle as in the other two cases but without sectioning the olfactory stalk.

After surgery, rats were isolated in cages (26 × 20 × 14.5 cm) in a regime of light from 0700 to 1900 h. Mouse killing activity was tested after 10–15 days by putting a white male mouse into the rat's home cage. We recorded the number of rats which killed their mouse within 1 h unless otherwise stated. All tests were made at 2000 h. Killing was minimal in the middle of the dark or light period.

Table 1 Induction by PCPA of Mouse Killing Behaviour in Intact and Olfactory Bulb-Lesioned Rats

	No. of mouse-killers/No. of animals treated				
Rats	Saline	*P**	PCPA	*P*†	*P**
Intact	6/50		18/40	<0.02	
Sham operated	2/25	ns	8/20	<0.02	ns
Bulbectomized	4/40	ns	34/40	<0.001	<0.01
Bulbotomized	28/40	<0.001	35/35	<0.001	<0.001

DL-PCPA methylester HCl was injected intraperitoneally as a single dose of 400 mg/kg, 36 h before tests for mouse killing behaviour.
Tests were performed at the tenth day of isolation.
For statistical analysis chi-square test was used.
* Compared with the correspondent intact group.
† Compared with the correspondent group injected with saline.

The behaviour of the sham operated rats did not differ significantly from that of untreated controls. After 10 days of isolation, about 10% of rats in both groups were killing mice (Table 1). PCPA increased the percentage of mouse killers to 45% and 50% in the control and in the sham operated group, respectively. Contrary to previous results[10], bilateral removal of the olfactory bulb by suction induced no muricidal behaviour. PCPA, however, caused 85% of these rats to kill mice.

Sectioning the olfactory stalk produced 70% of mouse killers and PCPA increased this to 100%. Moreover, treatment with PCPA always induced killing in rats which had not been affected by bulbotomy (Table 1).

In about 30% of these animals mouse killing induced by PCPA ceased within 10 days of the last administration of the drug; once established in the remaining animals it persisted indefinitely, but the killing response occurred after a longer latency. Since PCPA, in addition to its effect on serotonin, produces a small but significant depletion of brain catecholamines[4], we investigated the effect of selective inhibition of catecholamine synthesis on mouse killing. Ten non-killer, bulbectomized rats were treated with D,L-α-methyl-tyrosine, methyl ester (HCl 250 mg/kg given intraperitoneally) and tested for mouse killing behaviour at 6 h intervals for 24 h. None of these animals turned into mouse killers.

Table 2 Inhibition by 5-HTP and Pargyline of Mouse Killing Behaviour

	No. of killers*/No. of animals treated			
Treatment	Intact	*P*†	Bulbotomized	*P*†
Saline	38/38		25/25	
5-HTP	10/20	<0.001	16/28	<0.001
Pargyline	7/30	<0.001	6/28	<0.001

Drugs were injected intraperitoneally; L-5-HTP at a dose of 30 mg/kg 20 min before test; pargyline at a dose of 100 mg/kg 8 h before test.
* Animals who killed the mouse within 15 min from presentation.
† Compared with the correspondent saline-injected group.

Since these experiments suggested that mouse killing was potentiated by selective depletion of brain serotonin, we investigated the effect of increasing this substance by treatment with L-5-hydroxytryptophan (5-HTP), its immediate precursor, or parygyline, a monoamine oxidase inhibitor. 5-HTP (30 mg/kg) or pargyline (100 mg/kg) were administered intraperitoneally 20 min and 8 h respectively, before the test, to rats which had become killers as a result of isolation or bulbotomy.

As Table 2 shows, 15 min after the mouse had been presented, only 50% of the animals treated with 5-HTP and 23% of those treated with pargyline killed the mouse. Moreover, none of the pargyline-treated animals, which had killed the mouse 12 h after presentation, ate their victims, although before treatment they ate up part or all of the mouse within 1 h.

Our studies support the idea that inhibitory influences on the mouse killing by rats originate in the anterior olfactory area[9]. Our findings may differ from those of Vergnes and Karli[10] because they removed the olfactory bulb by inserting a suction cannula in a fronto-caudal direction. This could have removed a more extensive portion of the olfactory nucleus and/or part of the olfactory tubercle.

Since in our experiments bulbectomy eliminated all the olfactory cortex but only the anterior part of the olfactory nucleus, which in turn is eliminated after bulbotomy, these results suggest that the olfactory nucleus is involved in the inhibition of mouse killing. Some inhibitory influences, however, must originate within the olfactory bulb for PCPA produced many more killers among bulbectomized than sham operated animals.

The fact that either bulbectomy or PCPA alone induced mouse killing in only a percentage of animals, while the combination of the two was effective in 100% of cases, suggests that the two procedures act through different mechanisms. PCPA probably removes serotoninergic inhibitory influences. This idea is supported by the finding that mouse killing is antagonized or suppressed in animals whose brain serotonin has been increased by 5-HPT or pargyline.

The fact that PCPA potentiates mouse-killing behaviour in rats but antagonizes other types of aggressiveness, indicates that the former is not only behaviourally[11] but also biochemically different from the others.

We thank A. Frongia for examining the histological sections, G. Puddu for making statistics and G. L. Gessa for encouragement and excellent advice. Pargyline was a gift from Guy Everett (Abbott Laboratories).

Retraction and Expansion of the Dendritic Tree of Motor Neurones of Adult Rats induced *in vivo*

Cerf and Chacko[1] found that the number and diameter of motor neurone dendrites decreased after axotomy in the adult bullfrog. The purposes of the investigation reported here are to confirm and extend these observations in a mammal, to determine whether the dendritic changes are due to loss of axoplasm or loss of effective neuromuscular transmission, to see if dendrites recover after nerve regeneration has restored contact between the nerve and the originally innervated muscle mass, and if they recover after the regenerating nerve makes contact with different denervated muscle. Quantitative assessments of the dendritic spread of developing rat and human cortical neurones have been made by Eayrs and Goodhead[2], and Schadé and van Groenigen[3]. Schapiro and Vukovitch[4] found that the number of dendritic spines of rat cortical neurones could be influenced by variety of experience during development; Jones and Thomas[5] and Matthews and Powell[6] reported a decrease in the number and length of dendrites after deafferentation. Possible neuronal plasticity in the central nervous system of adult rats has been reported by Raisman[7].

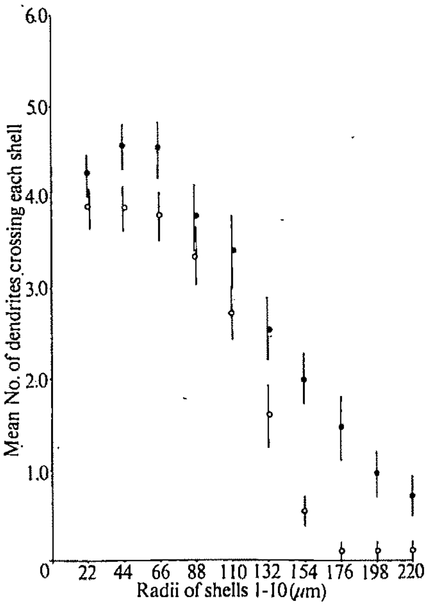

Fig. 1 The number of dendrites crossing concentric shells is expressed graphically against the radius of the shell. ●, Normal right side; ○, treated left side of a rat 6 weeks after botulinum toxin. Twenty neurones were measured on each side and the mean values are shown, with standard errors.

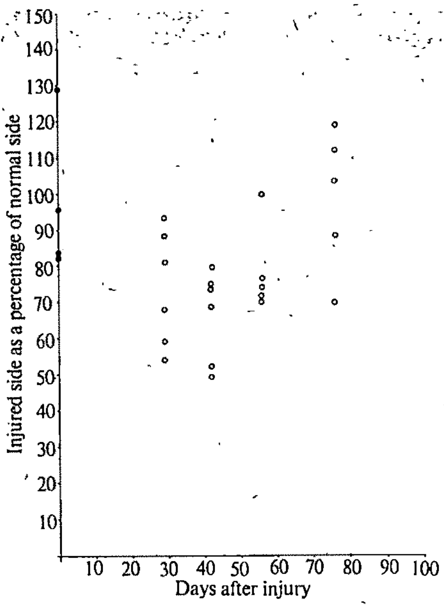

Fig. 2 Dendritic spread of hypoglossal neurones is expressed against the time since hypoglossal nerve transection; each point was obtained from twenty normal and twenty abnormal neurones of one rat. Values found between 4 weeks and 8 weeks after injury are significantly different from normal ($P<0.02$; >0.01). ●, Normal rats; ○, experimental rats.

Sholl's[8] "concentric shell" method was used to assess the dendritic fields of hypoglossal neurones in rat medullae prepared by the Golgi–Cox[8] method with 6 weeks' impregnation. Two hundred μm lateral ventricular nucleus transverse and coronal sections were used to measure the dendritic spread of twenty impregnated neurones from the left and from the right hypoglossal nucleus of each rat; the mean number of dendrites crossing each of the concentric shells was determined and expressed graphically against the radius of the shell. Fig. 1 shows mean values obtained from the normal right hypoglossal nucleus, and from the left hypoglossal nucleus 6 weeks after injecting botulinum toxin into the left side of the tongue (experimental series 2, see below). The smaller number of dendrites found passing through peripheral "shells" after injection suggests that terminal dendrites have retracted or degenerated, or failed to impregnate in these neurones. The mean dendritic spread of neurones of one hypoglossal nucleus was expressed by summing all the means from shell 2 to shell 10 (Fig. 1); this sum of means obtained from the nucleus containing the abnormal neurones was then calculated as a percentage of the sum of means obtained similarly from neurones of the opposite, unoperated, nucleus. Only in this way could variation between rats in impregnation by the Golgi–Cox method be overcome. No correction was made for planar projection of the dendrites which showed no preferred plane of radiation.

There were five experimental series of male rats aged 3 months, running in part concurrently. In the first, the left hypoglossal nerve was transected at the point where it crossed the carotid bifurcation[9], and regeneration proceeded; in the second, 250 pg of botulinum toxin type A was injected into the left half of the tongue[10] to prevent local neuromuscular transmission; in the third, the left hypoglossal nerve was transplanted into the normally innervated left sternomastoid[11]; in the fourth, the left hypoglossal nerve was transplanted into

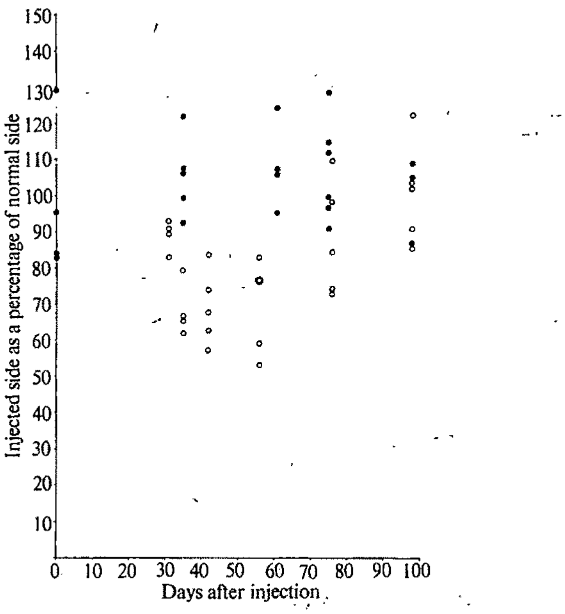

Fig. 3 Dendritic spread of hypoglossal neurones is expressed against the time since injection of botulinum toxin; each point was obtained from twenty normal and twenty abnormal neurones of one rat. ●, Normal rats, and those injected with toxin previously subjected to prolonged boiling; ○, rats injected with toxin. Values found between 5 weeks and 8 weeks after injection are significantly different from normal and control rats ($P<0.001$). No significant change is found in rats injected with boiled toxin.

the normally innervated left sternomastoid, and 70 days later the spinal accessory nerve innervating this muscle was transected and diverted[11], permitting the previously implanted hypoglossal nerve to innervate this "foreign" muscle; in the fifth, the procedure of the fourth series was followed, but the afferent nerves from the sternomastoid passing to the cervical plexus were transected at the same time as the spinal accessory.

Nerve injury (experimental series 1) caused a reversible decrease in dendritic spread (Fig. 2) closely resembling that found after botulinum toxin (experimental series 2) (Fig. 3). This suggests that the changes are not due to loss of axoplasm or to direct cell injury as such. The re-expansion of dendritic field found between the fifth and tenth weeks need not be due to re-establishment of functional contact between nerve and muscle but could be due to intrinsic late neuronal events; but, if regeneration is impeded by surrounding the transected nerve with normally innervated muscle (experimental series 3) no dendritic re-expansion occurs at this time (Fig. 4). The neurones of the implanted nerve remain quite capable of responding, however, for if this muscle is then denervated (experimental series 4), the dendritic fields grow out (Fig. 5). This late induced expansion is therefore independent of the initial loss of neuromuscular contact, but depends directly on its re-establishment and shows no specificity for the muscle originally innervated. Combined sensory and motor denervation of the recipient muscle (experimental series 5) did not influence the response obtained from motor denervation alone.

It therefore seems that dendritic retraction is due to loss of effective neuromuscular contact and that re-expansion is a direct consequence of re-establishment of such contact; failure of sensory denervation of the recipient muscle to influence the response obtained with muscle denervation alone does not show definitely that the effect is mediated to the perikaryon by the axon involved, for too many unaffected collateral sensory pathways exist which could convey information about sternomastoid contraction.

Preliminary results obtained from ultrastructural stereology indicate that the volume of hypoglossal dendrites changes in a manner closely corresponding to the dendritic field alterations reported here. It is therefore unlikely that the results indicate altered neuronal impregnation by the Golgi–Cox method in these circumstances.

The fate of preganglionic synaptic endings originally terminating on dendrites which are then caused to retract by axonal events, and the origin of synaptic endings appearing on re-expanded dendrites, are currently under investigation.

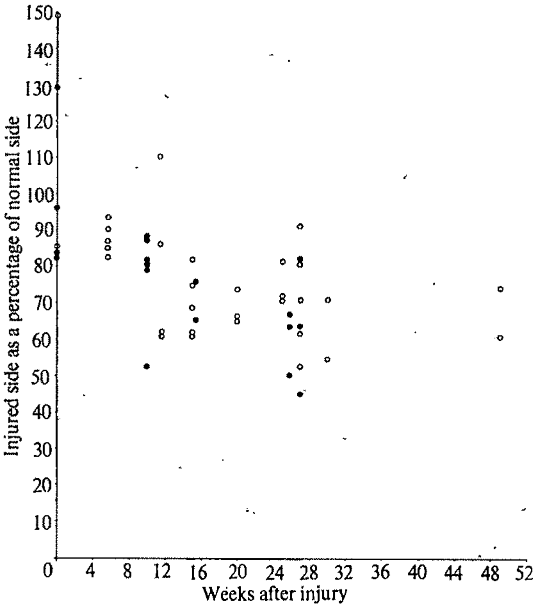

Fig. 4 Dendritic spread of hypoglossal neurones is expressed against the time since implanting the hypoglossal nerve into the normally innervated sternomastoid. ●, Transverse sections of medulla; ○, coronal sections of medulla. Note the failure of the dendritic tree to re-expand after the sixth week. The retraction is statistically significant ($P<0.02$; >0.01).

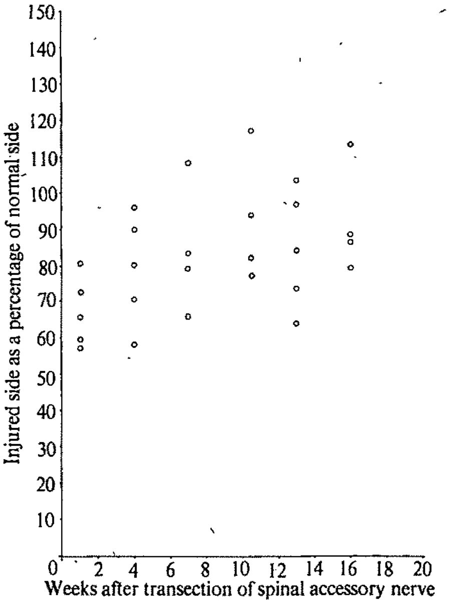

Fig. 5 Dendritic spread of hypoglossal neurones is expressed against the time since transection of the spinal accessory nerve 10 weeks after implanting the hypoglossal nerve in the sternomastoid. Zero time therefore corresponds to the 10 week point on Fig. 4. The dendritic field re-expands, and the points between 7 and 16 weeks after transection of the spinal accessory nerve are significantly different from those in the comparable period in Fig. 4, where the spinal accessory was not transected ($P<0.01$; >0.001).

We thank Mrs K. Grant and Mrs J. Anderson for technical assistance, and Dr Keppie for botulinum toxin; financial support was provided by the National Fund for Research into Poliomyelitis and other Crippling Diseases, and by the Medical Research Council.

Fluid Balance in the Sahara

IT has often been said that the inhabitants of arid regions seem to require far less fluid than non-indigenous visitors[1], but opinions vary as to whether this discrepancy is attributable to ethnic differences in the inherent physiological mechanisms which are concerned with sweating and water metabolism, or to cultural-adaptive factors such as diet, clothing and mode of activity[2-4]. In an attempt to elucidate this problem, I and a Toureg nomad undertook a 500 mile journey in the Central Sahara, and I present here the observations which were made of our respective fluid requirements during this trek.

To ensure that the physiological observations were directly comparable, I chose clothing that was similar in style and colour to that of my companion and I followed an identical régime of activity. We were alike in age and physique and shared the same food supply. In this way external factors which might have affected water requirements had the same influence in both of us. In the following account I refer to myself as subject 1 and to the nomad as subject 2.

Subject 1 was a member of the 1970 British Air Mountain Expedition which carried out a multidisciplinary research programme in the southern Sahara. At the start of the journey he had already been in the desert for more than 2 months and was therefore fully acclimatized. At this time he was 35 yr old, weighed 73.25 kg and was 1.79 m tall. Subject 2 was a 38 yr old Toureg nomad of the Kel Etedale clan. Although measurements were not obtained, he was similar in height, weight, physique and body fat to subject 1.

The journey began in March 1970 in the village of Iferouane (latitude 19° 20′ N; longitude 8° 10′ E) and ended in the oasis of Tamanrasset (latitude 22° 50′ N; longitude 5° 20′ E), in the Ahagger Massif of southern Algeria. Water and food were carried on two camels and two others were ridden intermittently. The 500 mile trek was completed in 20 days at an average rate of 25 miles per day.

Snacks were taken at dawn and noon, with a more substantial meal after sunset. Both subjects shared a mixed diet of millet, dried cheese and British Army "compo" rations. Their average 24 h intake was 2,200 calories, composed of 280 g of carbohydrate, 80 g of protein and 85 g of fat. Salt was added liberally to the food. Subject 2 preferred millet to meat, and it is likely therefore that his protein intake was somewhat less than that of his companion.

The water camel carried four 32 pint plastic jerry cans and a goat skin which held 42 pints. Wells were encountered intermittently throughout the journey and water was only once in short supply. On this occasion (day 12) an isolated well was found to be blocked by a dead camel. This emergency was resolved by a 4 day forced march to the next water point.

To facilitate the accurate measurement of fluid intake, all water for drinking was decanted into the subject's personal water bottle. A record was kept of the number of bottles of water which were consumed in each 24 h from sunrise to sunrise The quantity of drinking water remaining in a bottle at the end of the 24 h was measured, and because the total volume of the bottles was known, the individual's fluid intake could be calculated.

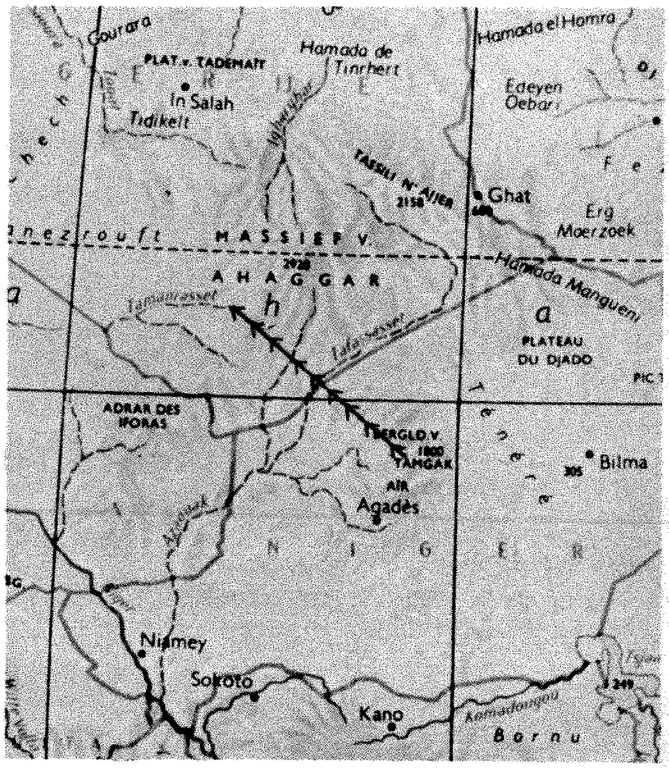

Fig. 1 The route that was followed from Iferouane in the Aïr to Tamanrasset in the Ahagger.

Apart from the 4 day period of water shortage, water was never rationed. The subjects were always able to drink their fill, according to the dictates of their thirst. It was noticeable that a considerable proportion of the water intake was drunk in the evenings when the day's march was over. The first morning specimen of urine was collected in a graduated plastic container and the volume and specific gravity were recorded. The Fantus test was carried out on this specimen to demonstrate the presence of urinary chloride. Because of the language barrier, attempts at collection of the total urine output met with incredulity and hilarity and this aspect of the investigation was therefore regretfully abandoned.

The daily fluid intakes are shown in Table 1, together with the early morning urine volumes and specific gravities. The distances covered and the noon air temperature and humidity, as measured by a whirling hygrometer, are also recorded.

The usual 24 h fluid requirements varied from 4 to 8 l. and were very similar in both subjects. The Toureg's intake was usually lower than that of subject 1, but only by a factor of a few per cent.

On day 9, which was largely spent in watering the camels and collecting fodder, the fluid intake was reduced. On days 13 14

Table 1 Daily Observations

Day	24 h fluid intake (l.)		Early morning urine Volume (ml.)		Early morning urine Specific gravity		Noon meteorological data			Estimated distance covered (km)
	Subject 1	Subject 2	Subject 1	Subject 2	Subject 1	Subject 2	Dry bulb °C	Wet bulb °C	Relative humidity

and 15, because of the blocked well, the remaining water supplies were rationed and shared. The fluid intake on day 16, when the next water point was reached, was almost double that of the normal day. The subjects were probably still somewhat dehydrated on day 17, as their fluid intakes on this day remained high.

The urinary specific gravity observations and the morning urine volumes were within expected limits and indicated that the subjects were not in a state of chronic dehydration. Similarly, the tests for urinary chloride showed that they were never salt deficient.

Fig. 2 Toureg of the southern Sahara.

At an early stage of the journey it became obvious that the Toureg's mode of activity was optimal for life and survival in the desert. He avoided heat gain by spending the hottest part of the day in rest, by riding the camels during the moderately hot period and by walking during the relatively cool morning and evening. Similarly, his traditional dress was efficient in the prevention of heat gain from solar radiation and the facilitation of heat loss by convection.

The Toureg's diet was comparatively low in calories and moderately low in protein. A diet of this nature requires a relatively limited quantity of water for metabolism and it would prevent the accumulation of body fat and thus facilitate heat exchange. It must be stressed that this diet was eaten from choice rather than from any lack of food. In this context, it is of interest that the members of the Toureg race tend to be very tall, thin and angular in physique[5]. This somatic configuration facilitates heat loss from the body in a hot dry environment. (Compare the short fat Eskimo who is equally well adapted to the conservation of heat.)

Although water was frequently consumed during the heat of the day, a considerable proportion of the daily intake of fluid was drunk in the evening. This is in accordance with the observations of Adolph[6] and of Leithead and Pallister[7], who suggested that in a hot environment a water deficit of several litres could be accumulated, without noticeable effect on the thirst.

In my investigation the two subjects were alike in age, height, weight and physique. During the journey their pattern of activity, diet and clothing were almost identical. For this reason all the external factors which might have influenced their water metabolism were directly comparable. Their 24 h fluid intakes were very similar; that of the Toureg was consistently minimally lower than that of the Englishman.

These findings suggest that the fundamental water requirements of a Toureg nomad and an acclimatized European are the same. Discrepancies which have been observed previously have probably been caused by cultural–adaptive factors rather than by any difference in basic physiological mechanisms.

I thank Colonel J. Adam, RAMC, for his support during the planning of the expedition, and Dr K. Collins and Professor C. H. Wyndham for guidance during the preparation of the manuscript. This work was financed by a grant from the Medical Research Council.

Experimental Study of Mimicry in Salamanders involving *Notophthalmus viridescens viridescens* and *Pseudotriton ruber schencki*

THE aposematically coloured eft stage of the red spotted newt, *Notophthalmus viridescens viridescens*, is both toxic and noxious to potential predators. The black chinned red salamander, *Pseudotriton ruber schencki*, is the most common red-orange salamander other than eft *N. v. viridescens* in the vicinity of the Highlands Biological Station in North Carolina. This study provides experimental evidence that *P. r. schencki* is a Batesian mimic of *N. v. viridescens*.

Because wild potential avian predators were found to be partially preconditioned to avoid both efts (model) and *P. r. schencki* (mimic), feeding experiments were carried out with domestic chickens to determine the behaviour of naive birds[1]. The chickens were maintained collectively in an outside enclosure but were individually isolated for testing. Each trial involved either a model or a mimic and a non-mimic salamander; this procedure is similar to that used by Brower[2]. Drab coloured, palatable salamanders of the genus *Desmognathus* (*D. monticola*, *D. quadramaculatus*) were used as controls (non-mimics). The feeding order of birds, the size of the salamanders, and the order of presentation of the controls were all randomized; two trials were made each day.

Seven chickens were divided into two experimental groups. The four chickens in group I were each offered ten models; after conditioning (consistent visual rejection of models), six mimics were offered to each chicken. The three chickens of group II were each offered six mimics before and after presentation of ten models. For both groups, the trials were discontinued for 7 days, after which mimics were again offered to each chicken. All the salamanders used in the trials were anaesthetized in separate solutions of 'Finquel' (tricaine methanesulfonate) to eliminate behavioural differences or similarities; they were offered to chickens dorsal side up in a shallow plastic dish. Each chicken was allowed 5 min to react to each salamander, and its response (characterized as: eaten, pecked but not eaten, and not touched) was measured to the nearest second.

The chickens in group I initially seized, but did not eat, the noxious model; rejection of models on sight, without contact, occurred after one to seven trials ($\bar{x}=5$). All the chickens in group I rejected all mimics after conditioning with efts (Table 1). Before conditioning with models the chickens in group II ate all mimics offered and seized, but did not eat, the first models presented; models were not touched after two to five trials ($\bar{x}=3.3$). After conditioning with ten efts, two chickens in group II rejected all mimics; one chicken ate all mimics (Table 1). The mean seizure times for the latter chicken were as follows: mimics before conditioning with models, 2.0 s; mimics after conditioning with models, 3.5 s; non-mimics, 1.3 s. When models were again offered to this chicken, one was pecked and five were not touched; when offered, mimics were again eaten. All non-mimics, *Desmognathus*, were eaten rapidly by all chickens, the mean seizure time ranging from 1.3 to 15.7 s for individual chickens in both groups. The mean seizure time for mimics eaten ranged from 2.0 to 22.2 s for group II. Analysis of variance revealed no significant differences in seizure times.

Table 1 Responses of Chickens to Model, Mimic and Non-mimic Salamanders

	Non-mimic	Model	Mimic before conditioning	Mimic after conditioning
Group I				
Eaten	83	1		0
Pecked, not eaten	0	13		1
Not touched	0	26		42
Group II				
Eaten	86	0	18	8*
Pecked, not eaten	0	11	0	1
Not touched	0	25	0	23

* All eaten by one chicken.

Statistically significant differences exist between number of mimics eaten after conditioning and number of non-mimics eaten during the same trials: group I, $\chi^2(3 \text{ d.f.})=43.0$, $P<0.005$; group II, $\chi^2(2 \text{ d.f.})=24.0$, $P<0.005$. There was no difference between the number of mimics and non-mimics eaten before conditioning ($\chi^2=0$). We conclude that the palatable mimic (*P. r. schencki*) derives a selective advantage over non-aposematically coloured salamanders due to their similarity in colour to the noxious model (*N. v. viridescens*), and that this relationship is clearly the result of Batesian mimicry.

We thank S. A. Gauthreaux, H. T. Coss, and M. Hare for their help. This work was supported by National Science Foundation grants to the Highland Biological Station, and a Clemson University FRC grant.

Standing with a Bent Knee

I AM currently investigating knee forces by techniques similar to those already successfully used on the hip joint[1]. Although this work is not yet complete, it is difficult to reconcile Dr Roberts' article[2] with my observations and I should be glad of the opportunity to comment on this from an engineering viewpoint.

From the lever factors y/x in Fig. 3 of the article, the reader is given to understand that the equilibrium of the knee is produced by the force in vastus crureus (of the quadriceps group) acting directly about the joint centre. But this force acts on the patella which functions rather like a pulley attached to the femur and the equilibrium of the knee in the position shown must be due to the force in the patellar ligament. While the forces are similar in magnitude, they have different lever arms and the patellar ligament lever arm should surely replace y in the figure.

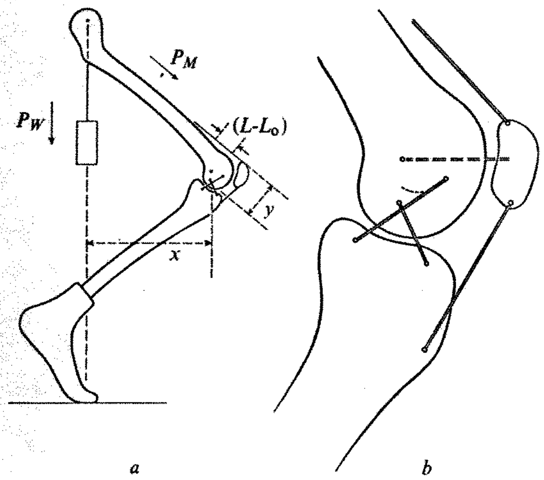

Fig. 1 *a*, Diagram of model leg to show how the offsets x and y were measured. *b*, Detail of the pivot points at the knee. The dotted line shows the bone profile round which the posterior ligament becomes wrapped in full flexion of the knee.

The model configuration shown in Fig. 2 (shown here as Fig. 1) is a most unusual position to adopt when standing on one leg. The superimposed body weight is shown acting through the hip so that the trunk must be approximately erect to bring the centre of gravity above the hip joint; the knee is flexed at right angles while standing on the tips of the toes. I have tried to assume this posture and invited several of my colleagues to do so with almost complete lack of success except among the young and athletic who, if they could do it, found the position most uncomfortable. The natural tendency when trying to assume this position on one leg is to incline the trunk forward, thereby moving the line of gravity toward the knee to reduce the force required from the knee extensors. A good example of this forward inclination of the trunk occurs in the common and similar activity of rising from a chair without assistance from the arms. Ciné film records, taken in the laboratories here, show that in extreme cases subjects bring their trunk practically horizontal when rising in this way.

Observation confirms that one-legged support is normally confined to smaller angles of knee flexion than that depicted. Yet, at very small angles of knee flexion, the line of gravity passes behind the joint, bringing the flexors into action and causing the conditions assumed by Dr Roberts to break down. It follows that the simple spring action postulated can only normally occur over quite a small range of knee angles. A further assumption implicit in the theory is that the centre of gravity will only move vertically but, in all normal activities, including balancing, horizontal movements also occur, since the centre of gravity is always free to move over a region equal to the support area of the foot. Such movements, which are likely to be as frequent as vertical movements, would require immediate compensation by the knee muscles, but would not of course affect the length of quadriceps so that spring action could be of no assistance.

In an activity such as walking, it has been known for many years that complex changes in the moment of the resultant force about the knee occur all the time[3]. The prop and paddle concept and the linear spring concept are surely an oversimplification of the real situation.

R. D. McLEISH

University of Manchester
Institute of Science and Technology,
PO Box 88,
Sackville Street,
*Manchester M*60 1*QD*

Received May 4, 1971.

[1] McLeish, R. D., and Charnley, J., *J. Biomech.*, **3**, 191, (1970).
[2] Roberts, J. D. M., *Nature*, **230**, 499 (1971).
[3] Bressler, B., and Frankel, J. P., *Trans. Amer. Soc. Mech. Eng.*, **72**, 27 (1950).

DR ROBERTS writes: In considering the lever factor, Dr McLeish looks at the force exerted by the muscle on the patella. I am looking at the forces on the femur. We are both neglecting the turning moment exerted by the compressive force between the patella and the end of the femur because the line of action of this force is offset by only a small distance from the axis of the joint. It is this force, however, that accounts for the difference between the actions of the muscle force above and below the patella.

The limb posture in Fig. 2 (shown here as Fig. 1) is less unusual than Dr McLeish maintains. The trunk does not have to be upright, if it is balanced by the free leg, neither does the line of the compressive force really have to be vertical, although in a model where a known force is to be applied at a point whose position is indeterminate it is convenient to use a hanging weight and thus to employ the vertical force of gravity.

Dr McLeish treats my article as though I had maintained that the resistance to compression is the only function to be served by the muscles acting at the knee. He thus takes no account of my treatment of the contribution of the two-joint muscles. Their action in exerting a turning moment at the hip is sufficient to account for all the situations that Dr McLeish adduces in refutation. My thesis, that it may be profitable for purposes of analysis to examine the prop and paddle actions separately, is not affected by his argument.

Mechanism of Absorption of Phosphate from Soil by *Endogone* Mycorrhizas

ECTOTROPHIC mycorrhizas have often been shown to benefit the growth of their host plants, and similar results have also been found for endotrophic mycorrhizas formed by *Endogone* species[1,2] which are widespread on agricultural crops and are of considerable importance. Several workers have concluded that these growth responses are caused by an increased uptake of phosphate from the soils and possible mechanisms have been suggested[2] to account for this increased uptake. The purpose of our work was to distinguish between some of these possibilities, and we report preliminary results here.

A sandy loam soil of low phosphate status was labelled with ^{32}P and partially sterilized by γ-irradiation to eliminate indigenous fungi. Onions were grown in the soil in pots and half of these plants were inoculated with *Endogone mosseae* (yellow vacuolate spore type) by the method of Hayman and Mosse[4]. Onions were harvested on four occasions during a period of 4.5 weeks; at each time we measured dry and fresh weights and phosphorus (P) contents of root and shoot, count rate of plant tissue, total root length and the phosphate concentration in the soil solution. Infected plants were clearly larger after 2 weeks and had five times greater dry weight, and two times greater P percentage, than control plants at the final harvest. Infected plants were shown by microscopic examination to have endotrophic mycorrhizas and the hyphae extended into the soil around their roots.

The specific activities of P in the plants (corrected for P in the seed), were almost identical for mycorrhizal plants and controls at all harvests (Table 1). The specific activity of P in equilibrium with the soil solution was measured before, during and immediately after the end of the experiment. The mean of the three determinations, 35 c.p.m., is so close to the mean for the specific activity of P in the plant that it is likely that both groups of plants absorbed their phosphate from the soil solution or forms in rapid equilibrium with it. Neither roots nor hyphae seem therefore to solubilize non-labile inorganic phosphates or hydrolyse organic phosphates.

It is well known that phosphate ions have small diffusion coefficients in soils, and that there is likely to be a serious depletion of phosphate in solution immediately around absorbing roots[5,6]. The more actively the roots absorb, the greater this depletion will be. A root cannot, however, reduce the concentration of ions in solution at its surface below zero, and the rate of diffusion to such a cylindrical "zero sink" in the soil thus sets an upper limit to the uptake rate of a simple root. No process which occurs solely within the root can affect this.

Table 1 Specific Activity of Phosphate absorbed by Infected and Uninfected Onion Plants, Measured at Four Harvests

Plant age (days)	Infected plants	Uninfected plants
	c.p.m. × 10^8/mol P	
23	44	44
37	38	39
44	36	36
54	35	35

Table 2 Inflow of Phosphorus into Mycorrhizal (M) and Control (C) Onion Roots during Three Successive Growth Periods

Growth period	Duration (days)	Inflow mol/cm root/s × 10^{-14}	
		M	C
Harvest 1–2	14	17	5
Harvest 2–3	7	22	1.6
Harvest 3–4	10	13	4.2

The calculation of this maximum possible rate of uptake into a root system in a soil with defined properties is possible, but it is particularly difficult for phosphate. First, the diffusion coefficient for phosphate in the soil depends on concentration so that an average value has to be used[6]. Second, most phosphate diffusion occurs within a very short distance of the root, and it is uncertain whether the soil properties, such as water content and bulk density, are the same there as in the whole soil. Our estimate of the maximum inflow (uptake per unit length of root per second) is thus approximate, but is unlikely to be in error by more than a factor of 2. Using the simple model of Brewster and Tinker[7] with an average phosphate concentration in the soil solution of 5×10^{-6} M, an estimated mean diffusion coefficient of 3×10^{-9} cm^2 s^{-1} and an impedance factor of 0.3, we calculate it to be 3×10^{-14} mol/cm s^{-1}. The measured mean inflow to the control plant roots (Table 2) calculated by the formula in ref. 7, could thus be accounted for if all roots were active, but it is highly unlikely that the inflow to mycorrhizal roots could be transported by diffusion alone (Table 2). Because mass flow in the soil solution transported less than 1% of the absorbed phosphate, we conclude that entry into and subsequent transport through mycorrhizal hyphae occurred. Mechanisms which postulate a more active root cylinder cannot account for the results, because all the control plant roots were already functioning at near maximum efficiency. The hyphae may, of course, always produce extra absorbing surface, but the distribution of this surface with respect to the root is crucial—if it is immediately adjacent to the root surface, it merely competes with this for the diffusion-limited supply, but if it is dispersed away from the root, it is outside the root depletion zone, and its uptake is a net gain to the plant. This distinction may be particularly important in similar work on ectotrophic mycorrhizas, where the fungal sheath lies on the root surface.

These results thus support the simplest theory of the mycorrhizal effect, namely, that the hyphae form a better distributed surface for absorbing P from the soil solution than the root alone. If our results are confirmed with other crops and soils, they may be of value in deciding where *Endogone* infection can improve phosphate nutrition in crops. It is implicit in our explanation that this improvement should occur on soils where the maximum P inflow to a "zero sink" root is less than that required by the plant for maximum growth rate.

We thank Mr P. H. Nye, Professor J. H. Burnett, Professor J. L. Harley and Dr B. Mosse for discussion and advice, and Dr Mosse for samples of infected plant material. This work was financed by the Agricultural Research Council.

Rapid Leaf Closure of *Mimosa* in Response to Light

VARIOUS higher plants make rapid movements in response to stimuli[1–3], among them *Mimosa* which rapidly closes its leaves when touched. We wish to report a series of experiments demonstrating such fast closure in response to light alone. Usually, light causes opening of the leaves, although it is known that after a few hours in the dark, light (< 550 nm) will cause the petiole to fall rapidly[4,5].

Mimosa pudica was grown in soil from seed, raised in a greenhouse with a cycle of 16 h light and 8 h dark under natural and fluorescent lighting. When the plants were 3 months old, they were changed to a cycle of 14 h light and 10 h dark under incandescent lighting. Experiments were run when the plants were 4–9 months old. From each plant, leaves (with at least ten pinnule or leaflet pairs per leaf) were excised and floated in distilled water. This treatment produced results no different than those obtained for the entire plant. The leaves were illuminated for 30 min (to open the leaflets fully) with an incandescent (white) light source (45 mW/cm²/s) 35 cm from them. A water filter was used to absorb heat and in no case did the temperature of the air around the leaflets increase more than 0.1° C. Experiments were begun at least 3 h into, and finished more than 2 h before the end of, the photoperiod. After the 30 min opening period, a variety of light–dark presentations was used in an attempt to elicit a fast closing response of the leaflets. For each cycle of light and dark, twelve plants were chosen randomly as to the order they were to be run in each cycle. Two different leaves from each plant were used for each cycle tested. After the initial period of illumination the leaves were given dark periods from 1 to 20 min followed by a 10 min illumination from the same white light source. The treatments used and the results are presented in Table 1. A dark period of at least 5 min followed by light is necessary to produce rapid leaf closure, defined as movement of at least two of the pinnule pairs, initiated and completed within 3 s. The latency of closure is the time elapsed before the rapid movement begins. By Wilcoxon tests, there is no difference in latency among the D20, D10 and D7 treatments ($P > 0.05$, two tailed), but the D5 and D6 treatments have a significantly longer latency ($P < 0.01$, two tailed). This suggests that the response is becoming weaker as the dark period approaches D5; below this point, there seems to be no gradual increase in latency, but rather a sharp cutoff in the response. Because of variability in the sensitivity of leaflets, as Fondeville *et al.*[5] noticed, the exact point between closing and remaining open between D4 and D5 is difficult to determine. Those treatments that produced rapid closure could be repeated at least three times with rapid closure continuing and with no significant change in latency on the third presentation. But, when switched to D1, the leaves remained open during the light. Similarly, the D1 treatment followed by light would not produce closure even when repeated three times, but when switched to D10, rapid closure occurred during the light period.

Table 1 Response to White Light

Treatment (min) with dark (D)	Response (latency in s) to light of 10 min	
	First presentation	Third presentation
D20	Close (61)	Close (70)
D10	Close (54)	Close (49)
D7	Close (52)	Close (59)
D6	Close (79)	Close (77)
D5	Close (94)	Close (90)
D1, D2, D3, D4	Open	Open

Twenty-four leaves were used for each treatment.

To determine what wavelengths of light might be effective in producing this behaviour, interference filters were used with coloured filters and an incandescant light source to produce sharp peaks of light with known spectral characteristics. Two leaves from each of twelve plants were used again exactly as in the above experiment but only with a D10 treatment followed by light of 10 min duration. At an intensity of 0.3 mW/cm²/s, peak wavelengths of from 420–900 nm produced no closure. As the intensity (or energy level) was raised gradually to catch the peaks of the action spectrum, only certain wavelengths produced closure. At an intensity of 0.4 mW, peaks at 460–520 and 620–660 were the only wavelengths producing closure. Raising or lowering the intensity did not discriminate any further among these wavelengths.

We cannot say how these treatments produce rapid closure, which presumably involves changes in the permeability of the cell membrane of the motor cells in the pulvini with a subsequent change in turgor pressure[3]. It has been suggested, however, that pigments, phytochrome in particular, act, either directly by being bound to membranes or indirectly through some mediating substance, to control permeability change[6].

We thank Dr Ruth Satter for her assistance and encouragement.

A New Neandertal Child Mandible from an Upper Pleistocene Site in Southern Italy

A NEW mandible of a Neanderthal child was found by chance by Mr Adolfo Berdar on September 6, 1970, during the opening of a motorway at the Upper Pleistocene site at Archi, near Reggio Calabria, in Italy.

The geology of the site can be summarized as follows. The hill south-west of the town of Archi (Fig. 1), a remnant of one of the lowest terraces of the Aspromonte and cut by the valley of the River Torbido, consists of a sandy gravel series of Upper Pleistocene age. This terrace contains four complexes—*A*, *B*, *C* and *D* (see Fig. 2, I). Grey clays containing Pteropoda, *Dentalium*, *Nucula* and cyathoid corals from the higher Pliocene (*A*) are overlapped by a clinostratified sandy-gravel formation (*B*). The *B* formation which dips gently is younger than Calabrian and is probably Sicilian in age. It has abundant neritic malacological fauna (*Pectunculus*, *Modiola* cfr. *modiolus*, *Arctica islandica*, *Lucina glacialis*, *Cardium norvegicum*, and the like). A sharp unconformity separates this group from the overhanging fluvio-deltaic gravels and sands, the *C* series. Three subdivisions of *C* can be distinguished. First, horizontally layered coarser gravels from crystalline and metamorphic rocks (*C*-1), with iron oxidation on the cemented top. Second, "grey sands" (*C*-2), which consists of gently inclining lenses of sand and sandy gravels, some with ochraceous oxidation, with scattered marine shells (for example, *Spondilus gaederopus* and very rounded *Pectunculus* fragments, *Patella ferruginea*, *Anomya*, *Mytilus*). These may be remnants of reworked shells of the subjacent Sicilian, and of a destroyed Tyrrhenian (that is to say, *Strombus*) beach. In the higher levels there are frequent pumice fragments (*V*), which are evidence of volcanic activity in the Northern Sicilian area at that time. Third, after a crossed-bedding layer of fluvial origin, there is a layer of gravels and sand (*C*-3) 3–4 m deep, in which the human mandible was collected (*M*). Various other embedded bones of mammalian fauna were also found—*Paleoloxodon antiquus-italicus* of great size (for example, molar teeth, femur, vertebrae), *Dicerorhinus merckii*, *Bos* cfr. *primigenius*, *Cervus elaphus* of large size and *Megaceros* sp. Among the very scarce avifauna, a proximal extremity of tibia of the great auk, *Alca impennis* Linn. was found. Fossils of the great auk have also been discovered in the Mediterranean area at the Romanelli cave (Otranto)[1,2] and at Devil's Tower (Gibraltar)[3].

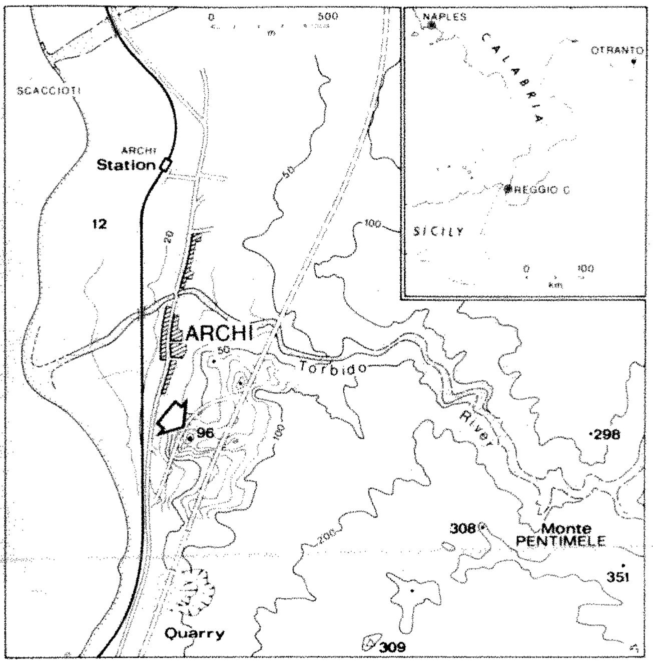

Fig. 1 The site near Reggio Calabria (height in m).

The Archi series continues with a very thin silty layer (*S*) containing freshwater and terrestrial molluscs (*Limnaea*, *Paludina*, *Bythinia*, *Anodonta* and *Buliminus*), and a sandstone with silicified wood and other badly conserved remnants of fossil flora. Next, there is a conglomerate which contains brackish oligohaline facies fauna (*P*), rich in *Tapes decussata* and *Cardium edule lamarki*, together with *Cardium papillosum*, *Solen*, *Venus* and Ostracoda (*Cyprideis*, *Xestoleberis*). The presence of this fauna suggests that there was a marine transgression which was followed by a rise of about 92 m in this part of the coast, so creating the terrace. The series ends with marls which contain traces of flora and gravels (*D*-1). An unconformity separates *D*-1 from the topmost "red gravel formation" (*D*-2), which also contains *Paleoloxodon antiquus-italicus*. A sizable cut and a deepening of the valleys resulted therefore from this considerable neotectonic rise, while an opposite movement of the same size took place on the side facing the sea.

This analysis of the Archi series has a bearing on the Pleistocene history of the Messina Strait area. A more recent origin must now be attributed to layers such as *C*, which have previously been regarded as probably Sicilian or even older[4-6]. Many radial valleys in the Aspromonte must now be considered to be very young. A considerable isostatic rise in the land must have occurred in the late Pleistocene with continuation in the Holocene and this must have measured more than 100 m in Calabria and north-east Sicily. As observed in Sicily[7], neotectonic movements in Southern Calabria were not uniform or contemporary. It seems that there were two important general changes in the palaeogeography of this region—between the Sicilian (marine, *B*) and the late Pleistocene (fluvial, deltaic and brackish facies, *C*), and between (*C*) and the uppermost continental (*D*).

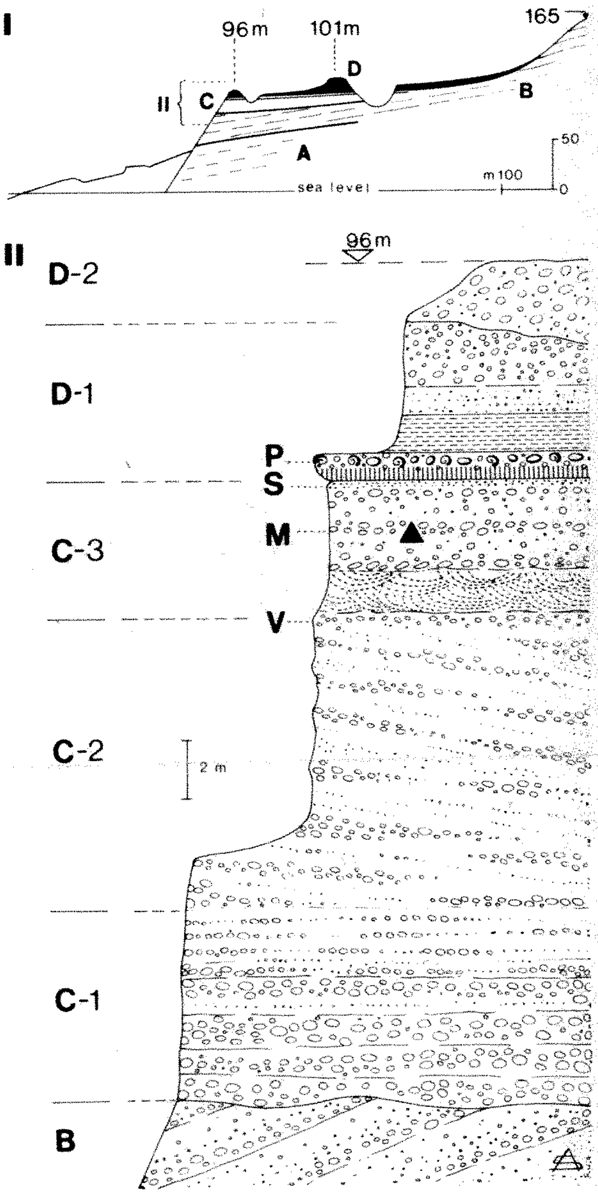

Fig. 2 Stratigraphy of the Archi Hill deposits—the 90–100 m terrace. I, Generalized section; II, the Upper Pleistocene series. Explanation in text.

The Neanderthal mandible reached our laboratories embedded in a hard concretion deposited by lime-impregnated water. When fully cleaned it was seen to be a highly mineralized and an incomplete child's mandible (Fig. 3). Both the ascending rami had been broken away long since by a fracture behind the alveolus containing the crown of the unerupted first permanent molar. All the deciduous incisors and the canine of the right side are missing, but the other deciduous teeth—the canine on the left side and all the molars—are in position. X-ray examination revealed the presence of the germs of all the permanent teeth from I_1 to M_1 which suggests that the mandible belonged to a child aged between 5 and 6.

The mandible is markedly massive and there is little doubt that it is male. The front of the jaw contains some interesting features (Fig. 3*b*). The chin definitely recedes, that is, the alveolar border projects and the basal margin falls back. But the slightly inward curve of the outline which corresponds to the alveolar part suggests an initial incurvatio mandibulae anterior. In the basal margin a low triangular elevation in the median line, the trigonum mentale, is visible and can be felt when the finger is passed over the bone. At the lower margin of the symphysis the trigonum continues into the interdigastric spine, so that it has a rhombic shape.

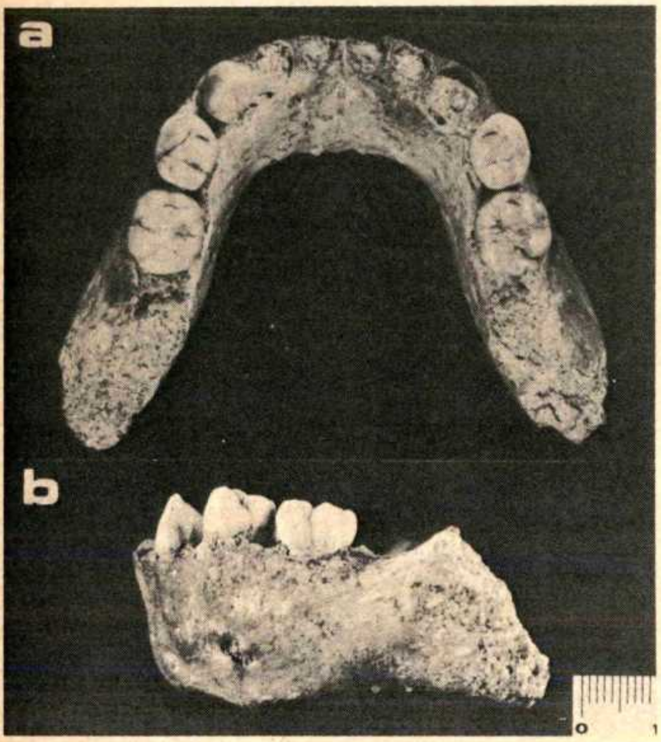

Fig. 3 *a*, Profile view (left side); *b*, occlusal view in alveolar plane orientation of the mandible.

The inner surface of the frontal part immediately below the alveolar border rises to a flat, smooth, diffuse swelling, the torus superior. Below this and without any break the muscular area is very clearly developed. It consists of a faint rough surface with two spine-like formations, one on each side. The spine on the left is long and narrow, whereas that on the right is very small. In the mid-line at the boundary between the torus superior and the muscular area there is one foramen supraspinosum.

The outline of both the inner and outer surface of the symphysis is given in Fig. 4*a*. The drawing was obtained using Sergi's diagraph and by making a cast of the jaw and cutting it at the required point. Measurements of the angle of symphysis (according to Weidenreich[8]), the angle of the chin (see McCown and Keith[9]) and the height and the index of the position of the foramen supraspinosum were taken from the drawing (Table 1).

On the lateral surface of the body of the mandible the foramen mentale is found opposite the first molar, about 10.2 mm to the right and 11.8 mm to the left of the alveolar border, and about 5.6 mm to the right and 6 mm to the left of the lower margin. The opening is of a long oval form, with an incipient septum between the front and back parts. The prominentia lateralis is well developed but, as would be expected in a child of between 5 and 6, it is found in the posterior alveolar part, that is to say, on the labial side of the place to be occupied by M_1.

On the inner surface of the body of the mandible there is no fossa sublingualis as a separate anterior part of the fossa subalveolaris beyond the linea mylohyoidea. The fossa subalveolaris itself ends at its lower boundary in an appreciable elevation which strengthens the inner surface of the lower margin of the jaw.

A drawing was made of the alveolar arch—the horseshoe-shaped area occupied by the alveoli—with the labial and lingual limits of the alveoli taken as boundaries. From this drawing the length and breadth of the arch and the mandibular index were measured (Table 1).

Table 1 Measurements of the Mandible (Linear Measurements in mm)

Height of the symphysis		22	
Height of the foramen supraspinosum		9	
Height of the body	20.7 (R)		20.9 (L)
Height of the body at M_2	18.4 (R)		19.2 (L)
Thickness of the body	11.8 (R)		12 (L)
Thickness of the body at M_2	13.4 (R)		13.7 (L)
Bimental width		40.6	
Width between buccal margins of M_2		50.1	
Width between lingual margins of M_2		34	
Length of the anterior alveolar arch		27.8	
Breadth of the anterior alveolar arch		44	
Index of robustness	57 (R)		57.4 (L)
Index of the foramen supraspinosum		40.9	
Index of the anterior alveolar arch		63.2	
Angle of the symphysis		65°.5	
Angle of the chin		81°	

R, right side; L, left side.

The crowns of the teeth are well preserved, and the cusps are only slightly abraded. The measurements are given in Table 2. The left canine has a strongly convex buccal surface bordered by a slight basal arch-like swelling which rises on each side. This basal structure can be considered a typical cingulum. The lingual surface is slightly concave and is bordered on all three sides by a thickened rim. The mesial side looks like that of an incisor. In the first milk molar the trigonid which has three cusps and both mesial and distal crests is markedly higher than the talonid. The talonid is an oval basin separated from the trigonid by the distal trigonid crest and the slope of the metaconid. The buccal surface is bordered at its base by a pronounced cingulum, but no definite tuberculum molare can be seen. In the second milk molar the trigonid is not higher than the talonid and is not retained in its entirety. In particular there is no longer any direct connexion between the protoconid and metaconid. The talonid is large and has some fine furrows in it which indicate the boundaries of the cusps and the presence of some wrinkles on the lingual side. X-rays of the teeth revealed a marked degree of taurodontism in the molars.

Table 2 Measurements (in mm) of the Crown of the Teeth

	C (L)	M_1 (R)	M_2 (R)	M_1 (L)	M_2 (L)
Mesio-distal length	7.2	9	10.6	9	10.4
Bucco-lingual breadth	6.6	7.7	9.3	7.4	9.2
Height	8.2	5.8	5.6	6	5.8
Robustness of the crowns	47.5	69.3	98.6	66.6	95.7

R, right side; L, left side.

A survey of all the anatomical features leads to the conclusion that this mandible possesses the primitive features found in Neandertals. A reliable comparison with other Neandertal specimens is difficult because so few are available, especially in this age group—there are only the mandibles of the Devil's Tower (Gibraltar) child[3] and of Skhūl I and Skhūl X[9].

The resemblance of this mandible with that of the Devil's Tower child is very striking in many respects—the angle of the symphysis (68°), the height of the symphysis (21 mm), the height of the body at M_2 (19 mm), the width between the buccal margins of M_2 (54 mm), the width between the lingual margins of M_2 (33 mm), and the length (27.5 mm), the breadth (46 mm) and the index of the anterior alveolar arch (59.8). The angle of the symphysis reported here for the Devil's Tower mandible was measured using the median section through the symphysis, according to Garrod *et al.*[3] (Fig. 4*b*). Moreover, it was assumed that this section was correctly oriented to the alveolar plane, and the position of the incision was deduced from the height of the symphysis (21 mm). The value obtained in this way does not correspond to that obtained by Weidenreich[8] (75.5°), who used a drawing of the section quite different from the original one. Finally, the angle of symphysis in our mandible is very close to that of the child of Ehringsdorf[10] (65°) according to Weidenreich[8].

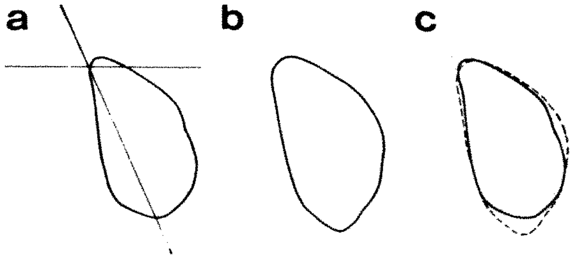

Fig. 4 Drawings in natural size of the section through the symphysis mentis in the mandible of Archi (*a*) and in that of Devil's Tower (*b*). Superimposition of the two drawings for comparison (*c*).

We thank Dr Laura Bonfiglio for assistance in fieldwork, and Mr Alessandro Benvenuti for technical assistance in cleaning the bone material. This work was supported by the National Research Council of Italy.

Submillimetre Wave Sensing of Nocturnal Moths

THE development of insects resistant to chemical pesticides has created a strong need for optical traps to control populations of economically important insects. But first it is necessary to understand their response to electromagnetic radiation. In 1968 preliminary tests indicated that pulsed coherent radiation of 337 µm wavelength might be attractive to insects. We have now made a behavioural and theoretical study of this phenomenon, using the fall army worm (*Spodoptera frugiperda*), the corn earworm (*Heliothis zea*), the Indian meal moth (*Plodia interpunctella*) and the codling moth (*Carpocapsa pomonella*).

Behavioural experiments were conducted using hydrogen cyanide and water vapour lasers providing signal at wavelengths of 28, 118, 311 and 337 µm and power levels between 16 and 50 mW to evaluate the frequency dependence of response. We used male *S. frugiperda* and *H. zea*, between 12 and 72 h old. All the tests were conducted during the period of peak nocturnal activity (8.00 p.m. to 1.00 a.m., EST). The experimental setup is illustrated in Fig. 1; the observation procedure has been described already[1]. The test chamber was a plastic cylinder of 4.5 inches in diameter and 80 inches long and most moths were at the end opposite the laser before the power was turned on. The number of moths attracted to the laser was counted as a function of time after the laser was switched on.

Precautions were taken to insure that the moths responded to the submillimetre wave radiation and not to any other stimulant. Experiments were conducted in a darkened room (21° C) and moths were counted using a red filtered flashlight. To reduce the visible and ultraviolet radiation emitted from the lasers, the ends of the test chamber were covered with black polyethylene with zero transmission in this region of the spectrum. The test cage was also covered with a black cloth to screen it from the visible radiation emitted from the laser plasma tube. To eliminate any doubt with regard to the test room bias the laser was detuned for 10 min and behaviour was observed before each experiment. (When the laser is detuned, the output power drops to zero while the visible and ultraviolet radiation remain at the same level.)

A strong attraction of both species to 337 and 311 µm radiation was observed, but, the response at 311 µm was less pronounced than at 337 µm (Fig. 2). *S. frugiperda* was not attracted to 28 or 118 µm radiation. The response of male *S. frugiperda* to an attractant light (7.5 W BL lamp) in similar environmental conditions is included for comparison. Chopping the radiation at a rate between 600 and 3,000 min^{-1} did not affect the response at 337 µm, but the attraction of *H. zea* to 118 µm increased slightly with a chopping rate of 2,400 min^{-1}. Further experiments indicate that the 337 µm radiation induces changes in the activity of the moths and reduces mating potential. Exposure of both species to 337 µm (50 mW) for 0.5 h inactivated them for the rest of the night although the experiment was conducted at the beginning of nocturnal activity period. The effect was more noticeable with *S. frugiperda*. Also, when fifteen virgin female *H. zea* were introduced in a cage containing

Table 1 Physical Dimensions and Propagation Characteristics of Nocturnal Moths

Moth species	D_{max} (µm)	D_{min} (µm)	D_{av} (µm)	*R*	λ_1 (µm)	λ_{op} (µm)
H. zea	216	109	167	0.705	266	328
S. frugiperda	210	116	160	0.8	220	347
C. pomonella	163	137	150	0.73	190	380
R. interpunctella	110	75	94	0.71	130	224

D_{max}, maximum outside diameter; D_{min}, minimum outside diameter; D_{av}, average diameter; *R*, ratio of inside to outside diameter; λ_1, cut-off wavelength of H_{01} mode; λ_{op}, optimum operating wavelength.

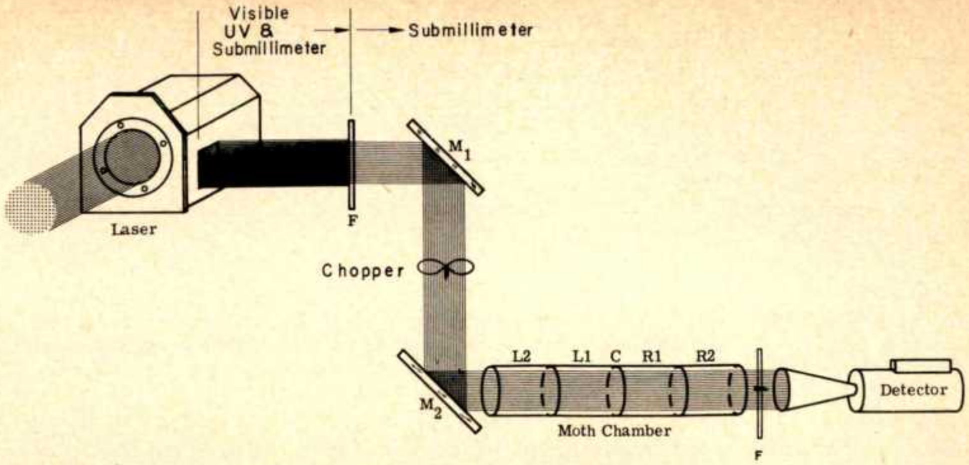

Fig. 1 Diagram showing laser and moth test chamber. M_1 and M_2 are mirrors and F is a polyethylene filter.

twenty-nine males, one each 5 min (10.30 p.m. to 12.30 a.m., EST) in the presence of 16 mW at 337 μm wavelength, fourteen out of them were attracted to the laser and no mating was observed. These effects may be similar to respiration changes induced by a BL attractant lamp[2].

Looking for a theoretical basis for these responses, we conducted experiments which show the failure of incoherent infrared sources[3], and coherent radiation from Klystrons (0.8 to 3.5 cm) and a Gallium Arsenide diode (0.85 μm) to elicit the response of the moths. This indicates the absence of electromagnetic thermal detectors in the moth system and suggests that moths respond to invisible radiation through tuned structures. Macroscopically the main spines of these moths' antennae are hollow thin walled tubes with tapered cross section and periodic variation in the outside diameter. This structure is suitable as a dielectric antenna coupling electromagnetic radiation between the moth and its environment.

An antenna would function properly if the radiation pattern was highly directive and the dielectric tube able to propagate electromagnetic waves over the useful bandwidth. Since pure E or H modes can be excited in dielectric tubes only in the case of perfect circular symmetry, it is reasonable to assume that only hybrid modes exist on moth antennae. Since all the modes except the HE_{11} mode are characterized by a cut-off wavelength[4] and the radiation pattern is highly directive when only one mode is excited; therefore dielectric tube antennae perform properly over the frequency band where only the HE_{11} mode can be propagated. (The subscript numbers indicate the number of half wavelengths which the interference pattern of the mode possesses in the plane of the tube cross section.)

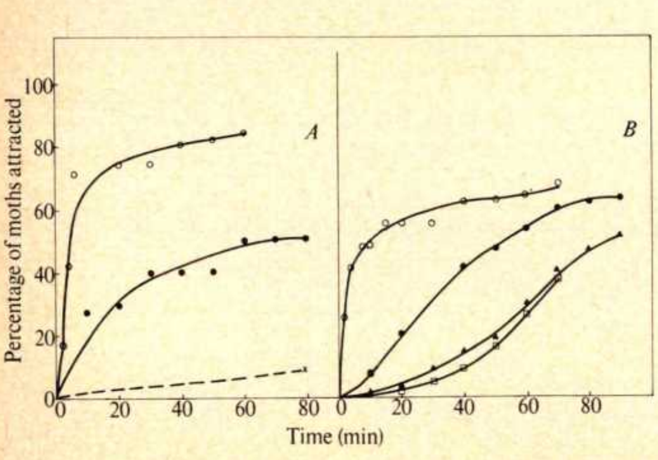

Fig. 2 Response of male *S. frugiperda* (*A*) and male *H. zea* (*B*) to electromagnetic radiation. The radiation wavelengths are 337 μm (○), 311 μm (●), 118 μm (▲) and 28 μm (□). The dashed line is the response to incoherent BL source. *S. frugiperda* did not respond at 118 and 28 μm.

The average of the pertinent physical dimensions of several moth antennae, together with their propagation characteristics, using a value of 2.5 for the relative dielectric constant[5], are listed in Table 1. The optimum wavelength λ_{op} is based on the criteria by Thourell[6], which compromise between antenna gain and directivity. Measured values of D_{min} were used to calculate the cut-off wavelength of H_{01} modes (lowest order cut-off mode). The previous discussion shows that electromagnetic radiation of wavelength λ_{op} could be efficiently coupled into the moths. As the wavelength deviates from λ_{op} the ability of the moths to respond to radiation drops gradually.

In conclusion, insects are strongly attracted to a submillimetre radiation source. Theoretical study on the moth antennae together with the frequency dependence of their response strongly suggests that the antennae may be the receptor through which insects are stimulated to respond. The response is very pronounced and has strong potential for optical traps to control the population of pest insects.

We thank Dr Kenneth Evenson and Mr Thomas Limperis for their help. This work was supported by US Department of Agriculture contract.

Lymphocyte Sensitization to Basic Protein of Brain in Malignant Neoplasia: Experiments with Serotonin and Related Compounds

IT has been found that blood lymphocytes from patients suffering from malignant neoplasia (even in an early stage) are sensitized to a basic protein[1] (encephalitogenic factor, EF) derived from human brain[2]. They react even more markedly (but to a strikingly similar degree) with a basic protein derived from a variety of human tumours[3]. During a visit to Dr Carnegie's laboratory some months ago one of us (E. J. F.) was shown the complementary structure of the serotonin molecule and the antigenic determinant (since published[4]) and realized that since the electrophoretic method[1] depends on interaction of EF with sensitized lymphocytes, structures complementary to the EF determinant might be able to mask it and so block the reaction.

In EF from human brain the main encephalitogenic determinant is associated with the sole tryptophan residue and the equivalent synthetic (eleven amino-acid) peptide[5] is known to be a potent inducer of experimental auto-immune encephalomyelitis[5,6]. Carnegie[4] further suggested that the encephalitogenic determinant might function as a receptor site for serotonin (5-hydroxytryptamine) and so be important in the pathogenesis of both experimental encephalitis and multiple sclerosis.

Here we examine the ability of serotonin and sterically related compounds, as well as other materials with well marked neuropharmacological activity, to block EF-lymphocyte interaction. The "goodness of fit" of these materials to the antigenic determinant has also been assessed.

From patients with cancer (lung, stomach, bowel, breast) 20 ml. of venous blood was removed and lymphocytes separated after preliminary defibrination as described elsewhere[7,8]. Sensitization of lymphocytes to EF was determined by the cytopherometric method and confirmed previous results. In principle the method depends on the interaction of sensitized lymphocytes with antigen (EF) resulting in the production of a material (dependent on protein synthesis by the lymphocytes[9]) with the property of slowing the electrophoretic migration of normal guinea-pig macrophages. The latter are thus used as a marker system for lymphocyte-antigen interaction. As before, the normal guinea-pig peritoneal exudate was subjected to 100 γ radiation to eliminate the potentiality of the 10–20% admixed guinea-pig lymphocytes to take part in a "mixed reaction" with the added human lymphocytes. Experimental details have been given elsewhere[7,8]. In brief, the lymphocytes to be tested were incubated together with the irradiated macrophages and antigen for 90 min and mobility of the macrophages measured (t_e). As control the mobility without antigen was estimated (t_c). When the blocking effect of a material was to be examined it was added to the cells and allowed to incubate at room temperature (20° C) for 30 min. The antigen was then added and after 90 min at room temperature the cytopherometric measurements on the macrophages were carried out. In the control experiments antigen was added first and after 1 h incubation the blocking agent added. After a further 30 min measurement of macrophage mobility was made.

Results were expressed as percentage increase in migration time. Thus if t_c = mean migration time of ten cells in each direction of the potential difference (twenty readings) over a given distance under control conditions (that is, lymphocytes + macrophages and no antigen), t_e = mean migration time with antigen added, then $\frac{t_e - t_c}{t_c} \times 100$ was calculated in each case. As in previous work[1,7,8] all specimens were numbered, scrambled and studied "blind". Results were later decoded.

In general EF produced about 15% reduction in migration rate of macrophages through interaction with lymphocytes from patients with malignant neoplasia[1]. A synthetic eleven amino-acid peptide of known encephalitogenic capacity[5,6] was also found to produce a similar reduction (Table 1). Thus the determinant on EF which reacts with lymphocytes from patients with malignant neoplasia seems to be antigenically similar to the encephalitogenic factor and should (if Carnegie's[4] speculation is justified) be susceptible to blocking by serotonin. While 10 μg/ml. of serotonin failed to influence the migration rate, 33 μg/ml. added before EF resulted in a 10% reduction (as compared with 17.2 when added after EF), and 18.2% when no serotonin at all was present. In later experiments 66 μg/ml. or 132 μg/ml. serotonin was used, the former producing 6.6% slowing and the latter 3.9%. A similar effect was produced by incubating 33 μg EF with 66 μg/ml. serotonin for 30 min at room temperature before adding to the cell mixture. In these conditions 3.4% reduction resulted. Because of the small scatter of the individual migration time readings, analysis showed that this was significantly different ($P < 0.001$) from the 6.6% obtained when serotonin was added at the beginning. In all subsequent experiments 132 μg/ml. serotonin was used and gave a reduction of below 4%, that is in the range obtained in normal (non-sensitized) subjects. Other neuropharmacologically-active or serotonin-related drugs were also tested. These included adrenaline, noradrenaline, acetylcholine, tryptamine, histamine, succinyl choline. None was found to be active in blocking EF-lymphocyte interaction in cancer patients. The protocol of typical experiments is shown in Table 2. It is apparent that serotonin alone has the capacity to block EF. Only D-lysergic acid diethylamide has a capacity to block partially—a result expected on grounds of steric arrangement of the molecule (as would be expected if we were dealing with a steric fit).

Table 1 Blocking Effect of Serotonin; Illustrative Protocols

	A	B	C
EF (*a*)	17.0	16.3	18.2
Serotonin + EF	3.9 (*b*)	1.1	10.0 (*c*); 18.6 (*d*)
EF + serotonin	17.3	16.4	17.2 (*c*); 18.6 (*d*)

	D		E
Synthetic peptide (3.3 μg/ml.)*	16.3	BP (33 μg/ml.)	16.1 ($P < 0.001$)
Serotonin + peptide	0	Serotonin + BP	10.4 ($P < 0.001$)
Peptide + serotonin	16.5	BP + serotonin	16.3

	F		G
PPD (33 μg/ml.)	—	BSA (33 μg/ml.)	13.6
Serotonin + PPD	14.0	Serotonin + BSA	13.8
PPD + serotonin	17.9 (*e*)	BSA + serotonin	13.1

	H
F1 (33 μg/ml.)	—
Serotonin + F1	17.4
F1 + serotonin	18.8

(*a*) 33 μg/ml. unless otherwise stated.
(*b*) 132 μg/ml. serotonin—the amount unless otherwise indicated.
(*c*) 33 μg/ml. serotonin instead of the normal 132 μg/ml.
(*d*) 10 μg/ml. serotonin instead of the usual 132 μg/ml.
(*e*) Both healthy and diseased subjects show PPD values between 15–20%.

Patient		Sex	Age

* Ser-Arg-Phe-Ser-Trp-Gly-Ala-Glu-Gly-Gln-Arg (SF 13a obtained through the courtesy of Dr F. C. Westall[4]).

Having established that serotonin could block the interaction of EF and sensitized lymphocytes in cancer we studied its blocking capacity with other antigens. To do this we took advantage of the fact that all subjects studied both in health and disease have lymphocytes sensitized to the F1 fraction (thyroglobulin) of thyroid gland[7] and that patients suffering from sarcoidosis are sensitized to a number of antigens including bovine serum albumin[10]. Attempts to block F1-lymphocytes inter-reaction by means of serotonin were

Table 2 Blocking of Antigens by Drugs other than Serotonin: Illustrative Protocols

	Patient E	Patient B	Patient D
EF	17.0	16.3	17.4; 16.3*
Acetylcholine	0.8	—	—
Acetylcholine+EF	16.0	16.1	16.9*
EF+acetylcholine	16.7	15.0	—
Histamine	0.4	—	—
Histamine+EF	16.3	—	16.3*
EF+histamine	16.9	—	—
Succinyl choline	0.0	—	—
Succinyl choline+EF	15.1	—	—
EF+succinyl choline	14.6	—	—
Noradrenaline	0.0	—	—
Noradrenaline+EF	18.2	15.7	—
EF+noradrenaline	17.8	15.1	—
Adrenaline	−0.2	—	—
Adrenaline+EF	17.6	—	—
EF+adrenaline	17.3	—	—
Tryptamine+EF	—	15.0	17.2*
EF+tryptamine	—	14.7	—
D-Lysergic acid diethylamide	—	—	7.8*

* Peptide (3.3 μg/ml.—see Table 1 note) substituted for EF (33 μg/ml.).

Patients E, B and D are those listed at foot of Table 1. All drugs were at a concentration of 132 μg/ml. except D-lysergic acid diethylamide 50 μg/ml.

unsuccessful. In a typical experiment serotonin (132 μg/ml.) followed by F1 gave 17.4%; and F1 followed by serotonin, 18.8%—results not significantly different. Similarly in a case of sarcoidosis BSA alone gave 13.6%; serotonin (132 μg/ml.) followed by BSA 13.8%; and BSA followed by serotonin 13.1%. It is thus apparent that serotonin has no capacity to block F1 or BSA interaction with lymphocytes. Its blocking effect is specific for the encephalitogenic determinant of EF.

Table 3 Illustrative Protocol of Blocking Experiment with Concanavalin

Patient	Antigen		Concanavalin* + antigen	Antigen + concanavalin
E.A. aged 10 erythema nodosum	EF	16.8	3.8	14.9
J.H. aged 57 sarcoidosis[9]	EF	17.9	—	—
	BP	16.4	1.3	16.5
	Muscle	14.1	2.1	—
	PPD	18.9	0.9	17.0
	Kveim reagent	13.5	1.0	—
	Ovalbumin	13.6	1.9	—
	BSA	13.7	1.9	—
	F1[6]† (thyroglobulin)	18.2	2.0	17.4

* 30 μg/ml.

† F1 values both in health and disease centre on 20%.

EF, BP, PPD, ovalbumin, bovine serum albumin and thyroglobulin were at a concentration of 33 μg/ml. Kveim reagent was from Public Health Labs, Colindale; 0.1 ml. was used in each test. A supernatant from centrifugation (250g, 10 min) of a 20% suspension of human muscle was prepared and 0.1 ml. used in each test.

Concanavalin was tested for blocking capacity. It was found to block all antigens both in neoplasia and sarcoidosis (Table 3) in the same way as antilymphocytic serum (ALS)[11]. This blocking activity is thus general and not specific. Both concanavalin and ALS differ from serotonin in that the blocking activity of the latter is limited to EF. It is known that a basic protein which may be extracted from human sciatic nerve (BP) has some antigenic determinant(s) in common with EF (made from human brain)[12–14]. Indeed in patients with malignant neoplasia (but with no evidence of either central or peripheral nervous system involvement) lymphocyte sensitization to BP is present though at a lower level than to EF[1]. On theoretical grounds it would be expected that serotonin might block BP less well than EF. This was found to be the case (Table 1). Whilst serotonin reduced the result with EF from 16.3% to 1.1%, with BP it was reduced from 16.3% to 10.4%. It may be supposed that the antigenic determinant centred on tryptophan may also be present in BP but modified sequence on either side may result in a less close fit.

Circulating antibody studies have indicated[15] that EF shared antigenic determinant(s) with purified protein derivative (PPD) of *M. tuberculosis*. Unpublished studies of lymphocytes from patients with severe active tuberculosis by the electrophoretic method have shown that these cells are sensitized to both PPD and to EF, confirming the original suggestion. The degree of sensitization to PPD (as shown by the percentage inhibition under the standard conditions of the cytopherometer test) always lay between 16 and 20% in all subjects examined. Serotonin was found to afford a partial block of PPD. In a typical experiment, for example, a subject giving 17.0% reduction with PPD, gave 17.9% if PPD was followed by serotonin (that is no change) but 14.0% if serotonin was added before PPD ($P<0.001$). There would thus appear to be a descending order of "goodness of fit"; serotonin blocking EF most effectively, BP less well and PPD least, whilst other unrelated antigens are not blocked at all. Both BP and PPD are blocked by ALS and by concanavalin, again indicating that the mode of action of these two materials is different from that of serotonin.

These experiments support the concept that the encephalitogenic determinant is a binding site for serotonin and open up possibilities of using molecules of known shape as potential blocking agents to study the conformation of receptive antigenic determinants. A further series of drugs related to serotonin is under test.

We thank Dr F. C. Westall for a sample of synthetic (eleven amino-acid) peptide, and our clinical colleagues for access to their patients. The cytopherometers used were purchased by grants from the North East Multiple Sclerosis Society and the Multiple Sclerosis Research Fund Limited. P. R. C. holds a research fellowship of the Multiple Sclerosis Society of Great Britain and Northern Ireland.

BOOK REVIEWS

Scientific Medicine

The Emergence of Scientific Medicine. By W. P. D. Wightman. (Contemporary Science Paperbacks No. 44.) Pp. 109. (Oliver and Boyd: Edinburgh, 1971.) 37½p.

ANYONE who has studied the reference literature of medical history will know how few books there are that really compel the reader to think beyond the commonplace. Dr Wightman's book belongs to this small group. Its text, based on lectures given over many years to medical undergraduates at Aberdeen, is dense and compressed with not a wasted word. In these days of verbosity it is to be welcomed for that reason alone.

More than anything, Dr Wightman dislikes the kind of prejudices that spring from perverted logic or ignorance of history. One of his particular hates is the fallacy that the Church impeded the progress of science and medicine in the Middle Ages and he quite obviously takes the greatest pleasure in setting the record straight, following the lead set by Dr Talbot in his *Medicine in Mediaeval England* (1967). He also delights in shaking us out of our arrogance, as for instance when he claims that a belief in the procedures of temple incubation is not *ipso facto* irrational "provided that . . . the opinion . . . as to right action . . . is based on a conscious relation of ideas".

His chief concern is with plotting the course of non-magical attitudes to the body, from Greek times to the seventeenth century. This he does by interposing his own comments between cleverly chosen extracts from the works of a dozen or so seminal writers. Here he explains their apparent contradictions; there he marks out the line that divides true originality from high competence. No hero worshipper, he gives credit to Aristotle for "imposing system upon the flux of experience" and yet recognizes, in respect of logic, the philosopher's debt to his teachers and predecessors; while Galen is praised not only for his experimental genius but in addition for the persuasive consistency of his humoral theory. In a sense, as Wightman points out, the latter can be said to prefigure the modern theory of endocrine balance.

As for Harvey, even he, in his Aristotelean view of the blood, is shown to be a product and disciple of tradition; whereas that sworn enemy of the orthodox, the "God-intoxicated ranter" Paracelsus, emerges almost as a blood brother of Francis Bacon, at least insofar as both men followed similar methodical lines of thought. Again, Fracastoro was a scientist in the modern mould, not so much because he formulated a contagion theory as because of the "critical manner in which he confronted theory with facts".

This short book should be read twice over, and not only by newcomers to the subject. It helps us to glimpse some of the conceptual difficulties that faced our forebears and it arouses admiration for the experimental methods evolved by men such as Richard Lower.

E. GASKELL

On Being Neurochemical

Methods in Neurochemistry. Edited by Rainer Fried. Pp. xi+374. (Marcel Dekker: New York, 1971.) n.p.

THIS book's preface claims neurochemistry as one of the fastest growing of the life sciences, and this is probably true: the *Journal of Neurochemistry* is now as large as was the *Biochemical Journal* of a previous generation. The contents of *Methods of Neurochemistry* suggest that one of the methods of growth of the subject is by capture. It is to cover "all important areas of the neurosciences, mainly in the fields of biochemistry and pharmacology". Of the book's six chapters, that by Donough O'Brien on biochemical screening in mental retardation could equally count as clinical biochemistry; while that of Krnjević on microiontophoresis embraces much physics and pharmacology. The neurochemical aspect of each contribution is nevertheless undoubted; the neurosciences by their nature encourage interdisciplinary work and thinking. Thus O'Brien's account, which is the largest in the book, gives both clinical and technical commentaries on some twenty metabolic abnormalities in man which are related to mental dysfunction. It lists briefly seventy to eighty such conditions and avoids discussion of those which are adequately recounted in books of reference; it also demonstrates well the need for expanded laboratory facilities in this field.

The stated editorial intentions regarding *Methods in Neurochemistry* are to present several distinct areas of research, rather than obey a unifying concept, and the book begins with accounts of the purification and properties of myelin isolated from neural systems (L. C. Mokrasch), and of the purification and properties of phospholipids (G. B. Ansell and S. Spanner). Methods of determining catecholamines and their metabolites are also described (D. F. Sharman); the three contributions include excellent experimental details.

Of very different character is the final and second largest contribution, which is by the editor and a co-worker and is a tabulation of "compounds of importance to neurochemistry". Errors in this section include the relatively harmless mis-spelling of names of substances, but also mistakes among less well known compounds. Saccharopine, an amino-acid derivative found as a urinary constituent in a form of mental disorder, is given the structural formula of a C_{10} compound and the molecular formula of a C_{11} compound. Three successive entries are: chlorpromazine, depicted with triply-bonded chlorine in a 6-membered ring; cholesterol with structure lacking angular-bonded methyl groups; and cocaine, with the molecular formula of a C_{17} compound and the structural formula of a C_{18} compound. Neurochemistry: important, expanding, should be able to command better service.

H. MCILWAIN

Blastocyst Biology

The Biology of the Blastocyst. Edited by R. J. Blandau. Pp. xi+560. (University of Chicago: Chicago and London, March 1971.) £12.40.

THE current publication explosion has produced torrents of books on almost every conceivable aspect of reproduction. Prospective readers are thus likely to scan new books very carefully for quality, price and comprehension before being tempted to invest their money. *The Biology of the Blastocyst* sets a high scientific standard, covers a comprehensive set of topics (perhaps too wide) and has a price that even by current standards is not cheap. It is obvious that this book will prove of considerable value to the rapidly increasing number of researchers engaged in reproductive physiology. It should serve as a valuable reference for data for some years before it is inevitably superseded by a later publication.

Reports of conferences seldom debate in detail a major advance in a particular topic; they tend to cover broad aspects of a subject, with chapters penned by authorities in these different areas. This book is no exception, for there are more than thirty authors involved in thirty-one chapters. In this area of biology the comprehensive description of the subject matter demands an interest in a wide variety of subjects such as endocrinology, differentiation, ultrastructure, tissue culture, immunological reactions between mother and foetus, teratology and uterine musculature. At implantation, as at certain other stages in pregnancy, many events occur simultaneously in the embryo and the mother. There can be no doubt that a full and fair treatment of these events is provided in these chapters, which are well written by authorities in each topic. Naming names would be tedious and unfair: let it suffice to state that almost every conceivable topic touching on the blastocyst is covered somewhere in the volume. Inevitably some authors have chosen to write a brief review of their topic while others have described their own experiments, and this inevitably leads to some unevenness in the book. Yet every chapter offers a wealth of detail or something interesting and stimulating, and it is a pleasure to browse through the pages, picking up ideas or comments. Discussions in the conference have been omitted, which is in many respects a relief from pet ideas or theories unsupported by critical material or analysis.

My major criticism concerns the repetition of subject matter in various chapters. This repetition obviously permitted more contributors to state their views in the symposium, but the combination of some chapters or the exclusion of others could have provided a more streamlined presentation. Some of the chapters contain material of peripheral interest, such as fertilization or the biochemistry of the cleaving embryo, and one chapter could have sufficed for these. Other chapters are somewhat superfluous because two or more contributors cover essentially the same subject matter, for example, there are three on immunology. More rigorous selection of speakers, or even joint chapters, would have led to a more concise and easily presented book.

The book is well produced in a handsome size, contains detailed references and is well illustrated. The editing has been done with care. It will prove a most valuable source of material.

R. G. EDWARDS

Bioelectromagnetism

Electromagnetic Fields and Life. By A. S. Presman. (Translated from the Russian by F. L. Sinclair.) Edited by Frank A. Brown, jun. Pp. xix+336. (Plenum: New York and London, 1970.) $25.

EVER since Franz Mesmer, the Austrian doctor and mystic, started some two hundred year ago to treat patients with iron magnets, controversy has continued over the question of whether magnetic fields can affect biological systems. In this book A. S. Presman, a biophysicist at Moscow University, sets out to review the experimental evidence for biological effects of electromagnetic fields with frequencies below 10^{12} Hz (thus excluding visible and shorter wavelengths, where quantum effects are important) and proposes a new hypothesis to explain them.

In the first part of the book the author describes the naturally occurring electromagnetic fields to which all organisms are continuously subjected. The electrical properties of living organisms are discussed briefly, and various physical mechanisms by which such fields could affect biological systems are listed.

In the second part the author reviews the experimental evidence for electromagnetic field interactions. Especially useful is the extensive bibliography, although references are only listed up to 1967. The principal effect is heating of tissue which leads to death if the heat cannot be quickly dissipated. Surprisingly, however, effects seem to occur at field intensities which are too low to cause appreciable heating. One reads, for example, of the good correlation between the incidence of cerebrospinal meningitis in New York and solar activity, and between magnetic storms and mortality from nervous and cardiovascular diseases in Copenhagen and Frankfurt. Planaria, bees, wingless termites and many flies can orientate themselves relative to the Earth's magnetic field. Seeds of corn and wheat sown with the radicle pointing south germinate one to three days earlier than those with the radicle pointing northwards, though the effect apparently depends on the phase of the Moon. Magnetic fields of greater intensity (120 kg) prove lethal to *Drosophila* if exposed for sixty minutes, while a combination of magnetic field (600 g) and microwaves is very effective in treating tumours in mice.

The fact is, of course, that no known physical theory can explain these low-intensity phenomena because the energy involved in the fields is far too small. There are thus two alternatives: either the experimental results are inconclusive, and the statistical correlations are misleading, or, alternatively, new processes are occurring about which nothing is yet known. Presman argues that the latter is the case, and thinks the evidence indicates a transfer of information from the environment to the organism which is independent of the amount of energy carried by the waves. The field may produce its effect by modifying the subtle neural interactions between the various parts of the organism, although there are no clues yet as to how this might be accomplished.

Finally, Presman speculates on the consequences of his hypothesis. Animals, for example, may be able to communicate using electromagnetic signals, and the simultaneous changes in the direction of motion of birds in flocks and fish in shoals could be initiated in this way. Eels may sink to great depths in the Sargasso Sea to protect their young from terrestrial electromagnetic waves, and it may prove necessary to protect hospital patients from such fields using suitable metal screens. Intriguingly, telepathy and other parapsychological phenomena may at last have a physical foundation.

It would be pointless to quibble over the many controversial statements made in any book as speculative and wide ranging as this. Two points should be mentioned, however. There is an error in the equivalent circuit of a typical cell (page 35) which leads the author to conclude, wrongly, that no electric current flows through a cell in a static electrical field. Second, the statement (page 85) that the minimum theoretical electric field strength which can affect a biological system is 10^6 V m^{-1}, is difficult to reconcile with the fact that such a field, established in normal pond water, would cause it to boil within 0.01 seconds, and would rapidly be detected by any biological system. Nevertheless, this is an interesting and readable book, and "the author's modest hope, that the ideas which he presents will stimulate further critical discussion and researches" should certainly be fulfilled.

ALUN M. ROBERTS

Living Together

Aspects of the Biology of Symbiosis. (Proceedings of a Symposium held in Boston.) Edited by Thomas C. Cheng. Pp. x+327. (University Park: Baltimore; Butterworth: London, July 1971.) £7.

THE title of this book might mislead some people into believing that this is a text-book, but it is not. It is a collection of twelve papers given at a symposium of the American Association for the Advancement of Science in December 1969.

There is no universally agreed definition of the term "symbiosis". Some restrict its use to clearly mutualistic associations, while others extend it to include many examples of parasitism and commensalism. This book tends to the latter use of the term, and its bias is strongly zoological, as exemplified by the selection of topics discussed: penetration stimuli for schistosome cercariae; schistosomules and mouse skin; communication between fishes in cleaning symbioses; nubibranch associations as symbioses; respiratory metabolism of a trematode metacercaria and its host; enhanced growth and shell deposition in parasitized molluscs; a new hypothesis on the goodness of parasitism; nutritional aspects of a symbiosis between a crab and a Hawaiian sea urchin; effect of external factors on host–symbiont interactions in green Hydra; blue-green algae in echiuroid worms; immunity in invertebrates and protection of anemone fishes from sea anemones.

The best aspect of this book is that all the articles are concerned with the experimental study of symbiosis, and mostly lack the rambling, vague speculation that has bedevilled some of the earlier writing about the subject. As in most books of this type, the articles are rather uneven in quality. For example, it is most surprising that the article on nudibranchs does not mention chloroplast symbiosis. The very long article by Lincicome on the experimental evidence for his hypothesis on the goodness or parasitism certainly presents a concept new and unfamiliar to most biologists concerned with symbiosis: "Parasitism, one of life's great phenomena, possesses a quality of goodness that has largely been overlooked because man has been so possessed with the disease aspects of this association". Kawaguti's very short but fascinating paper on blue-green algae in echiuroid worms states, in the discussion and conclusions, that *Ikedosoma* can consume ammonium and that its proboscis has a reduced oxygen consumption. Unfortunately, the experimental basis for such a statement is not mentioned in either the results or the materials and methods sections, both being exclusively concerned with microscopy. There are some articles, however, such as that by Lytle, Epp and Barthalmus on green Hydra, which manage to maintain a uniformly good standard of competence.

Most of the articles in this book are concerned chiefly with describing the results of research into rather narrow fields. I am therefore perplexed that the authors publish them in this book rather than in a journal. Books take much longer to be published than journals, and this can be important in fields which are rapidly advancing. Further, some of the articles (and hence, the reputation of their authors) would have been noticeably improved by the rigorous refereeing characteristic of the better journals, but lacking in most books of this type.

In spite of the flood of recent research into symbiosis, the really good book on the subject remains to be written: perhaps the subject has now grown so large that such a book has become impossible to write.

D. C. SMITH

Electrochemistry Now

Modern Electrochemistry: an Introduction to an Interdisciplinary Area, Vol. 1. By John O. M. Bockris and A. K. N. Reddy. Pp. xxxii+622. (Plenum: New York, 1970.) $19.50.

Modern Electrochemistry: an Introduction to an Interdisciplinary Area, Vol. 2. By John O. M. Bockris and A. K. N. Reddy. Pp. xxvii+623–1432. (Plenum: New York, 1970.) $19.50.

THE publication of another book by Professor Bockris is an event in the world of electrochemists and the present large two-volume effort, with Dr A. K. N. Reddy as co-author, certainly justifies the interest which it is commanding from that fraternity. The latter may have expected something rather different and it is important therefore to establish at the outset the purpose and philosophy of the book. Certainly it is not a research treatise, it is not a chemists' handbook to the theory and practice of electrochemistry, it is not even perhaps a chemistry students' text. What is it? The answer is contained in the sub-title and preface—"An Introduction to an Interdisciplinary Area" and ". . . a book which outlines the field at a level which can be understood by people entering it from different disciplines . . .". The authors see electrochemistry not as a branch of chemistry but as an emerging discipline groomed to the present age in which the solution to the problems of pollution and power supply together with so many appurtenances of modern civilization will be electrochemical. To this end "modern electrochemistry" emerges as a fusion of ideas at present scattered throughout the various branches of physical science, a fusion albeit at a comprehensive theoretical level. Thus the first volume deals essentially with theoretical considerations leading up to and relating to physical processes within the electrolyte phase. It includes structural and non-structural treatment of ion-solvent interactions, solvation numbers, dielectric constant of water and ionic solutions, ion-ion interactions including the Debye-Hückel equations and extensions, activity coefficients, ion-transport (including the laws of diffusion, and Laplace transforms), conduction and ion migration, and concludes with chapters on protons in solution and ionic liquids (fused salts, liquid oxides, and so on). The second volume has electrode phenomena ("electrodics") as its principal theme and covers the establishment, thermodynamics and structure of electrified interfaces, charge-transfer processes of simple and complex electrode reactions and electrode kinetics. The final two chapters deal with electrode reactions of special interest (for example, electro-catalysis, electro-crystallization) and those of technological importance (such as corrosion and electric power storage).

The electrochemist will undoubtedly appreciate having together in one publication so much of the fundamentals of his subject, but more so perhaps from the point of view of refurbishing his basic knowledge than in providing any detailed information on current research methods and practices. Thus there is no reference to a.c. impedance techniques and only brief reference to galvanostatic, potentiostatic and other experimental methods. Polarography is represented chiefly by a derivation of the Ilkovic equation, and present day amperometric and chronopotentiometric methods also receive scant attention. The absence of reference to practical procedures is a notable omission in a work of this importance, even accepting the authors' concentration on fundamentals, and we feel that a better balance would have resulted from such inclusion at the expense of many fringe topics. The inclusion of a section on batteries and fuel cells fits in with the authors' aims, but is too brief to do more than scratch the surface of one of those areas which is the *raison d'être* for the books. Even more surprising is the relegation of the section on galvanic cells to quite late in the second volume, where it receives rather limited selective treatment, a result no doubt of the constraint imposed by the authors' electrolyte-electrodic divison of the subject.

The bulkiness of the two volumes is in large measure a result of the praiseworthy efforts of the authors to provide the maximum of help to the reader, and this is exemplified by numerous informative diagrams, frequent essay-type summaries and a question/answer presentation. To the more advanced reader, however, much of this might well be regarded as seeking clarity at the expense of brevity and such readers may now, like us, hope one day to see a more succinct condensed version. This style of presentation is of course shared by other American writers of textbooks and is therefore more likely to be acceptable to readers from the United States. Certainly it increases the price to a level which must make possession by most undergraduates unlikely and possibly by many postgraduate workers too. Words like "electronation" (for cathodic reduction) irritate but neither this, nor our other criticisms, should mask the fact that the authors have produced the most comprehensive theoretical text so far, quite apart from their thesis that electrochemistry should be regarded as a new interdisciplinary subject. The two volumes are a must for any university/research library and those individuals who might be able to have their own copies should be agreeably satisfied with their purchase.

Learning in Bed

Learning and Sleep. By F. Rubin. Pp. xi+138. (John Wright and Sons: Bristol, June 1971.) £1.75.

IF one mentions "sleep learning" to an academic psychologist one is likely to meet the same sort of defensive disbelief elicited by ESP. Fifteen years ago Simon and Emmons established that retention of material presented to a sleeping person is negligible unless he is in only very light sleep. Since then, outside the Soviet Union and Eastern Europe, the idea of sleep learning has been treated with scepticism, and criticism of studies has almost entirely been centred on electro-encephalographic evaluation of whether subjects were "really asleep". The baby has been thrown away with the bathwater: the idea that people might be able to learn in bed, at times when they are not soundly asleep, has been almost entirely ignored by professional psychologists.

This book therefore may serve an excellent purpose, bringing to the attention of those involved in teaching language courses, for example, the possibility of facilitating learning while we are in bed and not yet sound asleep. The opening chapters dispel misconceptions many people have about hypnopaedia (the term the author prefers). No wild claims of using all eight hours of sleep are made: learning is restricted to a period immediately after retiring and shortly before rising in the morning. The author lays great stress on the fact that here is no quick, easy short cut to knowledge. He discusses at length Soviet and Czech experiments (chiefly in language tuition), which present words or phrases, with their mother-tongue equivalents, to highly motivated students who simultaneously receive daytime tuition in the language. The crucial point is that the presentation of material during the drowsy state can facilitate learning, in properly structured courses. The experiments he describes have often not been rigorously designed: only three experiments with control groups are reported; nevertheless, the theory and evidence are sufficient to warrant practical tests of the scope and usefulness of hypnopaedia in the West.

A paperback aimed at the popular market would seem a good way of putting these points across: a pity therefore the book is priced so high. There are other annoying things, such as a pair of tables describing sleep stages which are blatently inconsistent (pages 19 and 21). This might not worry the casual reader, but there are more infuriating points: at times the author hardly makes sense (page 39, for example), and he is fond of quoting and requoting references, as if to impress the reader. The organization of the book is particularly frustrating. The fourth chapter is a study by the author which belongs with the other experiments discussed at the end of the book. Why does he proceed to practical details of which tape recorders to use and how to intone lessons in the fifth chapter only to return to the experimental evidence that sleep learning really works in the eighth chapter?

In spite of these serious faults I would still recommend this book to those not prone to irritability, who want a fresh look at a subject neglected by "serious" psychologists.

HUGH FIRTH

Underwater Acoustics

Underwater Acoustics. Edited by R. W. M. Stephens. Pp. vii+269. (Wiley Interscience: London and New York, December 1970.) £6.75.

THIS book comprises eight articles on various aspects of underwater acoustics, which are based on a series of lectures given at Imperial College, London, in 1967. The contributors are either physicists or engineers who are actively engaged in research in the different specialist topics presented in the book.

The purpose of the introductory chapter by the editor is to provide the reader with background information on the sea as an acoustic medium. In thus setting the scene for the specialist contributions that follow on topics such as sound velocity, sound attenuation, noise, reverberation and cavitation are briefly reviewed.

The first specialist chapter is a mathematical study of the propagation of acoustic waves underwater, when the effects of the medium boundaries and the medium's velocity profile are included. The limitations of solutions by ray theory methods in these circumstances are discussed. The approach favoured by the author is the method of normal modes which arise from the solution of the wave equation in cylindrical co-ordinates with the appropriate boundary conditions applied. The general complex solutions obtained are presented and discussed in some detail. Space is also devoted to the "not so spherical cow", that is the effects on the solutions when factors such as the "real" sea surface and bottom cause departure from the mathematical model analysed. The sea surface is in general nonspecular in its behaviour, and so the next chapter, which is an authoritative review of the back and specular scattering of acoustic waves from the sea surface, follows quite naturally. The discussion involves a fair degree of mathematical content, the scattering theory being developed from the Helmholtz–Kirchhoff integral. Frequent comparisons are made between theory and experimental results. A comprehensive reference list is also provided.

The fourth chapter is basically a review of the sonar equation and some pertinent aspects of signal processing in relation to acoustic exploration. In particular the discussion is based on the recognition differential and noise terms in the equation. Factors such as detection threshold, processing gain and visual integration are briefly examined. A fairly detailed review on background noise is presented which includes such aspects as reverberation, self noise, cavitation noise and ambient noise. The next chapter may be regarded as based on the target strength term in the sonar equation. It is essentially a detailed and lengthy review of experimental results associated with the echoes from simple geometrical objects and from more complex objects, in particular—fish. The information presented is extensive and the topics covered too numerous to detail here.

Non-linear acoustics form the subject of the sixth chapter. The emphasis is on the basic physical mechanism behind the non-linear effects within the range of validity of perturbation theory. A brief discussion of some of the applications of non-linear effects in underwater acoustics is also included. The next chapter is a review of underwater instrumentation. Subjects briefly discussed include transduction, telemetry, wave measurement and acoustic navigation systems. The final chapter is concerned with the audio communication between free divers. Physiological factors, such as hearing and word formation are discussed in addition to a number of the technical problems.

Although an attempt is made to retain a theme throughout the book, probably because of the diverse authorship, the book in general is a mixture. Consequently it is difficult to see for whom the book is intended. A number of the chapters are suitable for the more general reader but the remainder are specifically aimed at the research worker.

CORRESPONDENCE

Elitism in Astronomy

SIR,—I have followed the various discussions about British astronomy, and have been surprised that the chief factor we would consider in the US has remained unmentioned in public.

I refer of course to a critical number of first rate scientists. Between the two Royal Observatories and Pretoria, as an outside observer I count six first rank astronomers. In Pasadena associated with the Hale Observatories, I count fourteen astronomers of distinctly higher average performance. The UK group is split between three locations and three establishments. In quantity of first rank people at one location, all three are operating at a sub-critical level.

It has been suggested that to set up a national centre with a critical number of high calibre astronomers is elitism. The question is not whether the UK wants an elite. It is whether it wants one place alive, or many half dead. Such a centre would not be a third centre. It would be a first centre. Its physical location should in the absence of special constraints be preferably chosen on logistical grounds. But the good reasons for avoiding existing institutions are that the petty inter-institutional squabbles and prior staff commitments of existing institutions might create a sickening home for a healthy baby organization.

Yours faithfully,

NEVILLE J. WOOLF

Conquest of Cancer

SIR,—I would like to clarify some aspects of the Conquest of Cancer Bill, S.1828, recently passed by the Senate and now awaiting House action. As the director of a cancer hospital and research institute, I am vitally interested in the conquest of cancer, and as a member of the National Panel of Consultants appointed by the US Senate, I participated in the recommendations that led to S.1828.

Unfortunately, there is considerable confusion about the provisions of S.1828. This confusion, understandably, comes about because S.1828 evolved from several other bills and proposals with identical or similar names.

S.1828 provides for increased emphasis on cancer research within the framework of the National Institutes of Health. The National Cancer Institute will remain a part of NIH, but will have greater autonomy. It will not become a separate agency. Nor will its relationship to NIH be a "name only" affair as has been mistakenly stated by those who confuse it with other proposals. Under S.1828, the National Cancer Institute remains in its own buildings on the NIH campus. The NCI personnel will continue to interact with the other institutes within the NIH. The NCI will continue to use the Clinical Center of NIH for studies on patients. It will continue to use the NIH computer facilities and the NIH laboratory animal breeding and holding facilities just as it does today. The NCI will continue to use the NIH study sections for peer review of research grant applications, but will be able to supplement them with additional study sections concerned with specific aspects of cancer. For example, I hope to see a breast cancer study section added. The major change in the relationship of the Cancer Institute involves greater budgetary and planning freedom. Instead of the present arrangement that requires six (6) layers of officials above the Cancer Institute to study and approve all major plans and budgets, the Director of the Cancer Institute will report directly to the President. This administrative change will speed up the conquest of cancer considerably.

In every other respect the Cancer Institute will retain its present connexions with the other institutes and with NIH.

Furthermore, to be certain of good coordination with the NIH and other government agencies, S.1828 provides that the Advisory Council of the Cancer Institute must include, as ex-officio members, the director of NIH, the Secretary of Health, Education and Welfare, and the director of the Office of Science and Technology.

Some charge that S.1828 will break up the National Institutes of Health. But NIH is not so fragile that a change to increase efficiency and give greater autonomy to an operating institute will destroy it. Businesses and other government agencies are frequently reorganized for greater efficiency.

Another criticism is that other Institutes within NIH will want similar arrangements for themselves. Perhaps they will. Let's try it with one: the Cancer Institute. If cancer research moves ahead more rapidly under the new arrangement (as most of us who studied the situation believe it will), and if other institutes then wish to have a similar arrangement, why not give it to them? After all, we are primarily concerned with improving the people's health, not with maintaining any specific administrative pattern. If, on the other hand, cancer research does not progress more rapidly under the new arrangement, the other institutes would not want to copy it.

Some fear that the increased emphasis on cancer research implies a promise of a cure for cancer in a few years. No one associated with S.1828, the National Panel of Consultants, or the American Cancer Society has ever made or implied such a promise. We do believe that the time has come for an accelerated and intensified assault on cancer, and that the eventual conquest of this disease can be brought nearer.

Would passage of S.1828 result in neglect of basic research? Exactly the opposite is true! S.1828, and the Report of the Panel of Consultants both call for expanded basic research.

Finally, there is the point that the bill cannot guarantee a cure for cancer. There is no doubt about that and, indeed, no one would suggest there is a guarantee of a cure for cancer in any kind of legislation. There is the assurance in this bill that progress will be faster and that the cures will come sooner than they would without it. That is reason enough for its enactment and that is the reason my colleagues and I support it.

Yours faithfully,

SOLOMON GARB

Research and Development

SIR,—Your review of Dr Duncan Reekie's survey for the Centre for the Study of Industrial Innovation of abandoned industrial R and D projects complains that it is "rich in detail and poor on analysis and generalization". We would be the first to admit that the survey is short on the kind of loose ill-defined and often unsupportable generalization from which the discussion of innovation greatly suffers. Your reviewer provides a number of new illustrations—for example, that "even successful research and development projects in Britain are understaffed". One major object of the centre is to study in detail what happens in firms so that general conclusions can rest on an adequate basis of knowledge. It is perhaps because firms realized the relevance of this approach (rather than because of "luck" as your review suggests) that they cooperated so fully in Dr Reekie's study.

Your reviewer writes as though the report suggests that projects should not be abandoned. On the contrary, it refers to the inevitability of this. But your review is altogether too complacent to claim that none of the cases Dr Reekie reported should cause surprise and that all of them merely represent "unavoidable ups and downs of commercial life". In no fewer than seven of the twenty firms visited development projects had been abandoned because they had been unwittingly duplicated within the same organization. In other cases, there had been several years of successful technical development before any market assessment had been undertaken. Surely no management could claim that such cases were unavoidable? In regard to the timing of abandonment your reviewer appears to agree with the centre—though with an odd twist he suggests that he is saying something different.

We appreciate your having paid so much attention to our first report. But we must advise those of your readers who wish to know what the report says to read it in the original.

Yours faithfully,

DUNCAN BURN

Chairman,
Centre for the Study
of Industrial Innovation,
162 Regent Street,
London W1R 6DD

Those who collect information but who neglect to analyse it must surely not be surprised if others draw lessons from it which may sometimes be unwelcome—Editor, *Nature*.

Erratum

Last week's News and Views editorial "Haemoglobin Synthesized in *Xenopus* Eggs" (233, 161; 1971), contained the erroneous statement that AUGpolyU is translated when injected into *Xenopus* eggs. Of course, as Gurdon *et al.* reported in their article on page 177 of that issue, this messenger does not promote the incorporation of phenylalanine.

NATURE Volume 233 OCTOBER 1 1971

Public Money for University Research

UNIVERSITIES are notoriously proud of their independence, both individually and collectively, which is why it is such a great surprise that the Science Research Council has been able to keep its friends in the universities while persuading them to change their ways quite fundamentally. Within three years, the council has established the principle that the pattern of university research should be determined not by the statistical aggregation of the inclinations of university teachers but by a more deliberate process of planning in the course of which the council itself has assumed responsibility for picking out desirable directions for research. At the beginning, to be sure, a great many academics were up in arms, saying that academic freedom would be in jeopardy if the Science Research Council chose to head people off certain lines of enquiry or even to concentrate desirable work in selected universities. Some mathematicians are still complaining (see *Nature*, **233**, 225 ; 1971), but that protest has all the appearance of a rearguard action. Most university departments in Britain are resigned and even glad of the Science Research Council's initiative.

This is why one of the biggest dangers now facing the Science Research Council is that of complacency. The most recent annual report (see page 298) is a vigorous document, but there is a mild suspicion that the council may be more ready than is strictly necessary to compromise with unpleasant truths.

The chief of these is money. In the past year, it has been made known by the present government that the funds available for university research would grow less quickly than the numbers of students in higher education and therefore, by definition, that the proportion of university teachers able to recruit financial support from the research councils would diminish. This simple truth was spelled out clearly enough at the conference organized by the Science Research Council in Manchester last January. To everybody's surprise, the universities have raised no audible protest. By now the policy is accepted, and it is entirely appropriate that the Science Research Council, the principal source of grants for university research, should have decided that the time has now come to end the automatic but cumbersome procedure by means of which funds are transferred from the council to the University Grants Committee at the end of each university quinquennium (the next comes in July 1972) so as to keep in being research projects begun by the research councils. Under the new system, discrimination will be easier. Universities will be under less pressure to institutionalize research groups. To the extent that these effects are consonant with what the Science Research Council has been looking for, it is clear that the grand design can be implemented even more efficiently in the years ahead.

It is therefore proper to ask whether the assumptions on which the new policy is based are as appropriate as everybody supposes. One of the Science Research Council's objectives is to create a greater sense of liveliness in university research and so far, with some success, it has sought to do this by providing not merely research grants but also facilities—laboratories for high energy physics or for astronomy, contributions to organizations such as CERN and even arrangements for making sure that universities have access to computing machinery. Yet the Science Research Council remains only one of the four organizations responsible for channelling money towards science departments in universities. The three other research councils are smaller in aggregate but just as influential in their somewhat narrower fields. It is all very well for the Science Research Council to boast in its most recent report that all four of them have been able to put their names to a document in which four separate statements on pollution appear within the same cover, but that is a far cry from the coordinated policy on research which British universities now require. Why, after all, should it be the Science Research Council that makes grants for research on high pressure physics but the Natural Environment Research Council that gives out money for closely related topics in geology? Why should it be that the Science Research Council administers central facilities for high energy physics but that the Natural Environment Research Council looks after oceanography (with all its sea-going vessels)?

Another problem concerns the scale on which university research should be carried out. In past decades, the conduct of university research in Britain has been bedevilled by self-justifying prophecies about the capabilities of university departments to look after their own affairs. Large items of equipment have frequently been placed on extramural territory not merely because sharing among several universities is intended but also because it has been held that universities are unable to manage large installations (a notion easily disproved by the radio astronomy observatories which, by historical accidents, are in the pockets of university departments). As the policy of selectivity and concentration succeeds, however, there will be more and more arguments in favour of letting British universities do what American universities have done for the past three decades—to take managerial responsibility for large laboratory installations. When that time comes, the budget of the Science Research Council and its smaller associates should increasingly be spent within universities. That tendency is not merely something to be stomached—it is itself desirable.

A third class of problems stems from graduate education in British universities For years now, the Science Research Council has been saying that it wishes to encourage a different pattern of postgraduate teaching. Courses should be more relevant to the needs of industry, and students should be more alert to them, but at the same time there is a need somehow to broaden the base of postgraduate teaching so that graduates emerge as more flexible people. So far, these declarations have gone little further than wishful thinking. Yet the fact remains that British graduate education, good though it may be as an intellectual training for enquiring minds, is unsuited to the needs which taxpayers hope to meet by keeping universities in the state of grace to which, quite properly, they say they are entitled. What the Science Research Council should now do is to back up promises with performance.

Publish and be Damned a Second Time

Now that Mr Herman Kahn has made it respectable to think the unthinkable, it may be appropriate to ask what virtues still attach to the convention that reports of original scientific research should not be published more than once. Most scientific journals, *Nature* included, take a stern view of breaches of this convention and most scientists seem first of all to approve of the convention and then to do their best to live by it. The arguments for a rigid rule against multiple publication are of course familiar. The literature is full enough already, and if multiple publication became common practice, the speed with which libraries are forced to throw up their hands in despair would be enormously increased. But multiple publication can also cause bibliographical chaos. The problems of knowing whether two apparently similar titles by the same authors refer to substantially the same original article would turn every working scientist into a textual analyst. At the same time, it is only fair to recognize that there have grown up practices which consist of variations of the strict convention that those who publish the same article twice are guilty of dishonourable conduct. By now, for example, preliminary communications are widely recognized to be useful ways of making public important discoveries, but there are good reasons for complaint if the fuller version of the discoverer's report does not eventually materialize. More reprehensible, there has been a tendency in the past few years for reports of original research, once published, to pop up again in closely related forms as contributions to symposia, international conferences and other occasions on which professional scientists have been persuaded to travel. The equation between the seminar paper and the airline ticket is now uncomfortably precise.

In all these circumstances, it would of course be overzealous of a journal such as *Nature* to follow too rigid a policy, but there are some circumstances in which multiple publication is not merely an offence against accepted conventions but an assault on ordinary standards of decent behaviour. Earlier this year, there appeared in *Nature Physical Science* an article of some importance which was described by the principal author as "an extremely important breakthrough into the new field of . . .". With all despatch, the article was sent to a referee and published in the usual way. Only afterwards did it become known that the same article had been submitted to two other journals. By all accounts, it seems that the article was rejected by one journal but published, in a format substantially the same as that which appeared in *Nature*, by the second. Since then, the hapless authors have been assailed by several editors and the senior author has actually written to say "We were all very excited at the time and I would like you to think that my apparent breakdown in publication ethics was the result of overenthusiasm." With some regret, it has been decided not to publish the names of those concerned in this shabby business, but to scrutinize with immense care their claims to originality for other publications. In the long run, however, a public register of such offenders may turn out to be the best method of keeping authors on a straight and narrow path. No doubt such a record would have some of the attractions of a gossip column as well.

Another issue involving a form of alternative publication is much harder to resolve. In the past two decades, newspapers have become increasingly enterprising sources of scientific news. In the long run, of course, this is of public benefit, but there have been times when the editors of journals have been embarrassed to discover that the essence of some cherished article has been given to the daily press in such detail that full publication seems a mere formality. Thus there has grown up a running battle between some journals, with *Physical Review Letters* at their head, and those newspapers and magazines which have such a flair for seizing on important discoveries that they are, almost by definition, the best newspapers. It is only fair to say that the distinction between proper and improper practices is extremely hard to make in this connexion. Certainly there can be no rigid rule. It is also unreasonable to expect that the authors of an important discovery should keep this strictly to themselves for months on end while waiting for the solemn processes of formal publication to be completed. Not merely is this unnecessary but impractical as well, now that journalists habitually turn up at scientific meetings. And it would, of course, be altogether too toffee-nosed to ask that news of scientific discoveries should be kept even from the audiences at scientific meetings until the mills of the publication process have begun to grind. So it seems to follow that journals, *Nature* included, can ask authors to refrain from telling newspapers their good news only if the process of publication is reasonably swift. What matters is that the relationship between an author and the editors of the journal in which he seeks to publish should be open and courteous. And even then, there are bound to be occasions when news leaks out. In short, although journals are right to ask that their contributors will not call a press conference whenever a manuscript is accepted for publication, their best insurance against being scooped by the newspapers is to publish quickly.

---

100 Years Ago

THE First Commissioner of Works and Public Buildings announces that he intends again to distribute this autumn, among the working classes and the poor inhabitants of London, the surplus bedding-out plants in Battersea, Hyde, the Regent's, and Victoria Parks, and in the Royal Gardens, Kew. If the clergy, school committees, and others interested, will make application to the superintendents of the parks nearest to their respective parishes, or to the director of the Royal Gardens, Kew, in the cases of persons residing in that neighbourhood, they will receive early intimation of the number of plants that can be allotted to each applicant, and of the time and manner of their distribution.

From Nature, **4**, 453, *October* 5, 1871

OLD WORLD

EUROPEAN LABORATORY

ESRIN in Trouble

A PROPOSAL to close down the European Space Research Institute (ESRIN) is widely regarded as a setback to the cause of European collaboration. The laboratory is one of several established by the European Space Research Organization. It was originally intended as a centre for fundamental research relevant to ESRO's activities in space, and has been particularly concerned with plasma physics. If a resolution introduced at the ESRO council meeting in July should be adopted in November, the laboratory will be run down in 1972 and 1973.

The ESRIN laboratory is at Frascati, south of Rome. It has a permanent staff of about 70 and an annual budget of $2 million. In the past months, the institute has attracted a steady stream of visitors who add about a dozen to the professional complement. The director of the institute, Dr Nicola D'Angelo, succeeded Dr H. L. Jordan in 1970. He is thought to have received many expressions of support in the past few weeks, especially from university scientists, but there are fears that these may not be sufficient to distract ESRO from its present preoccupation with applications satellites.

Apart from purely budgetary considerations, it is possible that ESRIN has been threatened because the work it does might just as well be done in universities, although one of those involved says that the institute was originally set up to tackle problems beyond the reach of university departments, and much of its equipment reflects this intention. Evidently the peripheral role of ESRIN within ESRO has weakened its claim on public funds, but its supporters claim that it is one of the few examples of an international laboratory which has been an entire success.

Present and former members of ESRO complain that it will be a great waste if the laboratory is closed down just when it has been built up to full strength. Younger scientists who have recently left apparently secure positions in their own countries to work at an international laboratory are likely to be left with a great sense of frustration. Investment in ESRIN so far amounts to $10 million. The annual running cost is 2.5 per cent of ESRO's total budget of $80 million. Although it may be held that ESRIN was not strictly necessary, closing it down is certain to be widely regarded as a setback.

DETERGENTS

Phosphates to Stay?

COMFORTING remarks about the effects of detergents on the environment have become a feature of the annual reports of Procter and Gamble Ltd. In a special section in the report for 1970–71, the company says, for example, that the work carried out in Procter and Gamble's laboratories on enzyme washing powders shows that they are "safe for consumer use" and it quotes the British Government's Standing Technical Committee on Synthetic Detergents as support for its contention that enzyme detergents do not pose any problems in rivers or in sewage works (*Twelfth Progress Report of the Standing Technical Committee on Synthetic Detergents,* HMSO, 1971; £0.22½).

As far as phosphate residues are concerned, the Procter and Gamble report again quotes the Standing Technical Committee and says that it is wrong to assume that the eutrophication problems experienced in the United States are applicable in Britain. In the United States, much more sewage is discharged into lakes where there is little water movement and the largest single cause of eutrophication is thought to be compounds such as sodium tripolyphosphate which are included in detergents as water softeners and emulsifying agents. A recommendation by a United States congressional committee in April 1970 sent detergent manufacturers hurrying off to develop alternatives, but three government agencies last week declared in favour of phosphates because they seem to be less of a hazard than some of the substitutes, such as sodium nitrilotriacetate, about which there are still unresolved doubts on health grounds (*Nature,* **233,** 229; 1971).

According to the Water Pollution Research Laboratory at Stevenage, only 46 per cent of the phosphate content of sewage in Britain is in any case attributable to detergents, the remainder arising from human excreta and from industrial effluents (chiefly from metal finishing processes). Only about 70 per cent of the phosphate content of detergents could be replaced without seriously impairing the detergent function, so the advantage to be gained from the introduction of other compounds—whose properties are relatively unknown—would only be a decrease of about 30 per cent in the proportion of phosphate in sewage. It looks as though phosphate detergents are here to stay, at any rate until the alternatives have been proved to be safer.

The report of the Standing Technical Committee also says that even if phosphate-free detergents were manufactured in Britain, it is unlikely that the growth of algae would be very much inhibited.

INTELLIGENCE

Who Watches Whom?

from a Special Correspondent

THE first international conference on Communication with Extraterrestrial Intelligence on this planet was held at the Byurakan Observatory in Soviet Armenia from September 5 to 11. A joint project of the US and USSR Academies of Sciences, the conference was attended by fifty-six official delegates with one representative from each of Czechoslovakia, Hungary and the United Kingdom. There were present not only astronomers and communications experts, but biologists, historians, anthropologists, linguists and others, including two Nobel laureates, Charles Townes and Francis Crick. The subject, once treated as a bemusing speculation, is increasingly respectable.

At the symposium, much attention was given to the abundance of technical civilizations in space. Some old uncertainties were disposed of. In particular, the neurophysiologists painted a clear picture showing that one should expect everywhere the development of a complex central nervous system leading to an intelligent brain. The historians showed that this in turn leads to a highly systematized and organized society which inevitably develops technology. Ignorance in key areas, however, haunted the discussion. Although the first steps in the evolution of complex organic molecules from the simple molecules of the primitive planetary atmospheres have now been traced, these experiments have not come close to producing the key molecules of contemporary life such as DNA, and have not demonstrated that the development of such molecules is inevitable. The uncertainty prevents the transfer of the origins of life from the realm of miracles to that of statistics, to paraphrase Philip Morrison. We fall back on subjective probabilities of great uncertainty.

The abundance of detectable civilizations should be proportional to their longevity as power emitting entities. Fears have grown that civilizations only slightly ahead of those on this Earth will be so good at conserving energy that there is none wasted for us to detect. Indeed, it may be possible to detect only those that want to help us, and even those may be few; as Carl Sagan put it, they may have little interest in conversing with a species as antique, in their view, as we are. Compounding the probabilities, both statistical and subjective, the feeling developed that it was probably thousands of light years to the nearest detectable civilization.

It was noted that we might first detect other civilizations through evidence of astro-engineering activities such as the construction of devices to capture all the energy of a central star, this energy eventually appearing as thermal pollution in the far infrared.

But it was still quite generally agreed that the most likely route to detection of and communication with other civilizations is through electromagnetic radiation particularly at radio frequencies, where some existing systems could detect themselves across half the galaxy. There is still a search for syllogisms which would lead to optimum frequencies and places to search. Surprisingly, what had been a simple situation has become complicated. Where once there was one special radio wavelength on which to listen for other creatures, the 21-cm wavelength of hydrogen, there is now a multitude, including spectral lines of water, the stuff of life, more intense than any hydrogen line. There is no clear choice among them. Once there was a microwave frequency where the cost of transmission was minimal, with the cost increasing at lower frequencies due to cosmic noise, and at higher frequencies due to quantum noise. Now the existence of the universal 3° black body radiation has added a new noise source which spreads the most economical frequency from 1,200 MHz to 60,000 MHz. To make things worse, it no longer even makes much sense to examine the nearest stars first. It has been shown that if there is a range in the luminosities of civilizations in which only a small percentage are much more luminous than the rest, then the ones most visible to us will not be the nearest but the intrinsically brightest. These may lie in any direction, and so there is no guidance as to where to look. Such a situation is not unprecedented; the radio galaxies exhibit just this behaviour.

Despite these new uncertainties, the much discussed conclusion that success would lead to great scientific and social benefits, and the striking potentialities of the existing instruments, produced a remarkably strong consensus that major efforts should be made to search for extraterrestrial intelligent life. It was recommended that existing instruments make the valuable and promising searches they can make. Among other recommendations, it was also suggested that studies should be made of the design of giant instruments for searches: a radio telescope 1 km or larger, a 100 metre millimetre wave telescope, a thirty metre submillimetre wave telescope and a ten metre infrared telescope. The first of these, which has many other uses, could cost billions of dollars, a figure thought, after all, not out of keeping with the importance of the subject, and consistent with the sums spent on space and nuclear research. The Soviet workers at Gorky, under V. S. Troitsky, have in fact recently initiated a search for signals, so far testing a dozen stars, and watching for pulsed emissions from anywhere in the sky; the work continues.

The conference set up a committee to organize future conferences and meetings to coordinate research, if desirable. So far, such organizational activities and actual research have been confined entirely to the United States and the Soviet Union for no profound or good reason. It was expected that participation in the discussion and research in extraterrestrial intelligent life will spread elsewhere.

HUMAN ECOLOGY

Hopes Balance Fears

OPTIMISTS and pessimists were evenly matched at the annual symposium of the Eugenics Society in London last week. The subject was the now familiar population and pollution and Dr Eliot Slater of the Institute of Psychiatry, University of London, began with a warning that population growth, which meant that "a man does his neighbour more harm than good just by staying alive", was forcing society to adopt new standards of behaviour which were to him distasteful. Population pressure was undermining people's natural benevolence. The maintenance of social order requires more and more state intervention, with the result that human identity will be "increasingly translated into a set of digits on a computer". More crowding means more arousal—then drugs and even greater dangers, rage, despair and organized violence. The nuclear family has already been reduced and the pace of social change is such that "we are like a man racing down a mountainside whose legs cannot keep up with his centre of gravity". Does the encouragement of suicide follow the encouragement of abortion? Is it possible to avoid disaster if we regard man as a measure of all things?

The anthropologists took a longer view. People, even primitive people, have always damaged the environment. They are only worried about it now because they can no longer escape the results. The moors of Yorkshire and Wales, like the deserts of North Africa, are monuments to previous occasions on which people have been able to upset the delicate ecological balance. Pollution is not new, only the perception of it.

The environmentalists tended to the view that pollution is a problem in public administration. The urgent need is for collaboration at the level of local, national and international government. The herrings are disappearing from the North Sea, but DDT is probably not the explanation. So far as this symposium is concerned, the moral seems to be that the fight against pollution must and should begin at home.

The geneticists were more worried by chemicals than by radiation. Dr Mary Lyon, Girton College, Cambridge, argued that the radiation from nuclear fall-out is likely to be less mutagenic than the medical use of X-rays. Dr M. S. Legator of the United States Food and Drug Administration, on the other hand, took the view that respectable investigations of the mutagenic effects of certain chemicals had only just begun.

The sociologists opened with a new warning that it is affluence and not technology or over-population that spells pollution. In the maddening manner of their discipline, they argued that research tends to be concentrated not on the important problems but on those which can be solved, however trivially. To them, to be practical, zero or even negative population growth would be a worthwhile goal.

The capstone of the symposium was the Galton lecture by Dr C. L. Carter, an optimist. The new eugenics, he implied, is the amalgam of social work and genetics which makes it possible to avoid needless misery while allowing people freedom. Dr Carter argued that once family planning is effective the more intelligent parents will have the larger families, resulting in a higher average IQ. He looked for an even more rapid adaption in the future of "genetic endowment to fit society".

PATENTS

Inventions Incorporated

PLANS for the establishment of a European patent office are finally taking shape and the first European patents will probably be granted in 1973. The intergovernmental conference that has been sitting since 1969 has recently published a draft agreement and it is hoped that final recommendations will be made by June 1973.

The notion of a European patent was first put forward in 1955 by the Council of Europe, which agreed on a system of classification of patents that was eventually accepted in 1968. In 1962, the European Economic Community set up a working party to prepare a draft European patent but the plan was shelved until 1969, when the present conference of nineteen European countries was set up.

The European patent is being welcomed by the British Patent Office and Mr J. D. Fergusson, assistant comptroller, estimated this week that the setting up of a European patent office will decrease the number of annual applications from 60,000 to 155,000 or 20,000. He added, however, that the reported date of achieving the European patent was highly optimistic and that 1976 would be more realistic. The decrease in the number of applications to the British office would be reflected by a decrease in staff but it would not lead to redundancy as the European office would need qualified people. The site of the European office has not been decided although Mr Fergusson said that it must be within an EEC country.

The advantages of a European patents office are that it will avoid duplication of applications and work. Ideally, national patent offices should cease to exist when the European office is working, but Mr Fergusson said that it was not planned to close the British office and that a substantial number of applications would still be received as the cost of obtaining a European patent would be high. Most of the overseas applications, now about 60 per cent of the total, would go to the European office but a trickle of applications from the United States would still be received. The British Patent Office is planning to carry out a market research survey in 1972 to see how many of the British applications will be channelled through the European office.

The standards to be set by the European office are more stringent than those now in force in Britain and most European countries and comparable to those of West Germany. Agreement has already been reached by the nineteen countries presently negotiating that if the European office finds a patent invalid then it will also be declared invalid in the member countries. If an application is made simultaneously to the British and European offices, Mr Fergusson said that the British application would be suppressed until the result of the European patent is known.

The logical step to take after setting up a European office would be to obtain world-wide standardization of patents. Mr Fergusson said that this was not feasible because of the different concepts—now standardized in Europe—of the essential ingredients of a patentable idea. It seems, however, that this would be a laudable aim and the Patent Cooperation Treaty set up last year (see *Nature*, **226**, 888 ; 1971) goes a long way towards achieving it. This treaty eases the work on patent offices by sharing the exploratory work, but applications have still to be made to individual countries to register patents.

COMPUTERS

Profit the ERA Way

WITH declining sales and profits rapidly turning into losses in the computer service industry, it is surprising to find the Electrical Research Association launching a new company, Electra Computer Services. But this is a logical development of ERA's activity in the computer field over the past two years, and points the way for future profitable developments in the industry. The organization of the ERA is more like that of comparable American research institutions than of British research associations—more than 90 per cent of its activities are carried out under contract without the aid of government funds. There is no government support for the computer unit, which was established two years ago, chiefly for the benefit of members of the ERA.

Why has the ERA been successful when other computer service companies are falling by the wayside every week? The association says that it provides a personal service. The managing director of the new company is Mr Paul Addison who has headed the Association's computer activities since they started. He emphasized that customers are not really concerned with how a computer bureau solves their problems but only the accuracy of the solution. Whereas most bureaux fall into one of two categories—providing solutions to scientific and technical problems by the flexible use of their hardware, or selling off the peg packages to solve standard problems such as payroll calculations—the bureaux of the future must provide a complete data processing service to be credible. It is the aim of the ERA to provide such a service with Electra, solving unique problems or providing standard services as required, so that the customer has the same sort of close contact and versatility which he could expect from his own in-house computer.

The association claims that its customers have been persuaded by experience that it is often better to buy computer time rather than a machine. In one case, for example, it says that a customer was able to reduce his annual expenditure from £70,000 to £15,000 by forsaking his machine for the association's service. The association also claims its reputation with industry now allows it to give potential clients a feeling that the provision of computer services is not another way of robbing them of cash. For customers new to the use of electronic computers the ERA says that its services are a useful intermediate step to the purchase of a machine.

Appointments

MRS MARGARET THATCHER, Secretary of State for Education and Science, announced last week the appointment of new members to the Natural Environment Research Council, Medical Research Council, Computer Board for Universities and Research Councils and the Advisory Committee for Scientific and Technical Information.

Four new members are appointed to NERC: Professor P. Allen, University of Reading, Professor R. B. Clark, University of Newcastle upon Tyne, Professor K. M. Clayton, University of East Anglia, and Dr H. C. Pereira, East Malling Research Station. From October 1, 1971, NERC will be composed of the new members together with Professor F. H. Stewart as chairman, Professor Sir Edward Bullard, Professor R. W. Edwards, Lord Howick of Glendale, Rear Admiral Sir Edmund Irving, Dr C. E. Lucas, Mr T. A. L. Paton, Professor F. W. Shotton and Sir Owen Wansbrough-Jones.

The Medical Research Council also has four new members: Professor D. A. K. Black, University of Manchester and Manchester Royal Infirmary, J. P. Bull, MRC Industrial Injuries and Burns Unit, Birmingham Accident Hospital, D. G. Davey, Imperial Chemical Industries, and Professor R. B. Welbourn, University of London, Royal Postgraduate Medical School and Hammersmith Hospital. The non-retiring members of the council are: His Grace the Duke of Northumberland (chairman), Professor Sir Richard Doll, L. Pavitt, Professor W. S. Peart, Professor D. A. Pond, Professor R. R. Porter, Professor T. Symington, Professor P. M. B. Walker, Professor R. E. O. Williams and Dr J. A. B. Gray.

The Advisory Committee for Scientific and Technical Information is increased to twelve members by the appointment of Professor G. Black, University of Manchester, Professor L. Maunder, University of Newcastle upon Tyne, and Dr R. Weck of the Welding Institute to the committee. The other members are: Dr L. Rotherham, chairman, Dr J. W. Barrett, Mr J. G. N. Brown, Dr G. M. Dyson, Mr. H. J. Habakkuk, Professor J. B. Jepson, Mr N. Mackenzie, Mr D. T. Richnell and Professor G. D. Sims.

Professor G. A. Barnard, University of Essex, and Professor J. C. Gunn, University of Glasgow, are appointed to the Computer Board for Universities and Research Councils. The other members of the board are: Professor D. J. Finney, chairman, Mr A. H. Duncan, Dr J. Howlett, Dr K. W. Morton. Professor D. J. Newell and Professor M. H. Rogers.

Gesture of Independence

THE Science Research Council has given the government a clear hint in its report for the year ending on March 31 (HMSO, £0.65) that the present review of arrangements for spending public money on scientific research should not be completed without full consultation. In particular, the council says that it "looks forward to the publication of the Dainton report and the opportunity to discuss its findings before any decisions are taken on the reorganization of civil science". The Dainton report, commissioned by the Council for Scientific Policy, was completed in May this year, and has since been regarded as a part of the material with which the Rothschild review should be provided.

The Science Research Council is also as open about its wishes as any official body might dare. The report says that the council reaffirms "its belief in the present role of the research councils and stresses the need for close collaboration and cooperation between all the bodies contributing to the support of civil science". It also asks for closer links between "those in industry and government who are concerned with the role of science in national life". Although the council can boast only of the somewhat lukewarm collaborative document on pollution research as evidence of the way in which the research councils might collaborate, it promises more studies of other common interests.

In its own defence, the Science Research Council says that autonomous organizations are best able to judge the "intrinsic merit" of proposals for expenditure in education and research. It draws attention to the way in which its position outside the government proper enables it to call on the voluntary services of people "with the experience and qualifications to advise how public funds can best be used", pats itself on the back for its policy of selectivity and concentration and promises that it will be increasingly vigilant in trying to match the directions in which research and education are supported with what are called national needs.

The council says that the diminished pace of growth of expenditure will begin to restrict the council's activity in the coming financial year. The report says that "beyond March 1972, it is certain that the funds available will be such that it will not be possible for the council to carry out in full the programme which could be justified on educational scientific grounds". The council is worried that the university population will be growing more quickly than its own resources and it says that there will be an even greater need for the determination of priorities in different fields of the council's work. The council is particularly anxious about long-term capital projects now urgently needed in Britain.

On strategy for research, the report says that it will continue to give priority to engineering and the applied sciences as well as to areas of research which have been picked out for their promise of intellectual and practical benefit. The council says that it will do what it can for astronomy and in particular help to build an observatory in the northern hemisphere, but that the cost of participating in the project to build a 300 GeV European accelerator will have to be accommodated, as every high energy physicist has known for more than a year, by reducing the cost of the domestic programme. On relationships with the universities, the council says it wishes no change in the present division of responsibility for government support of university research between itself and the University Grants Committee, but that in future the practice will be abandoned of transferring funds from the Science Research Council to the University Grants Committee for the support of research projects begun under the council's auspices.

There is also to be a relaxation of the rules which have so far restricted the numbers of people employed as research assistants with the help of research grants, although the council says that the duration of these research posts will be limited so as to persuade both the universities and the people concerned that more permanent arrangements would be in their best interests. In spite of the council's previous attempts to divert research students from PhD courses to other courses of advanced training, possibly as preliminaries, the number of new research studentships increased by seven per cent to 2,158 in 1970 and the number of awards for advanced courses by two per cent to 1,568.

The report says that for the first time the council had to turn away qualified applicants in engineering departments. In 1970, 32 per cent of its research studentships were awarded to people in applied science departments, but since 1969 the pace of growth has been faster in the pure-science departments (10 per cent) than in the applied science departments (5 per cent). There has, however, been a substantial increase (from 180 to 200) of the cooperative awards in pure science by means of which people working in industry are enabled to carry out research at a university. The council is also pushing hard for different kinds of PhD courses, preferably with a broader base. The Engineering Board of the Science Research Council seems to have been especially active in the past year in assessing what it calls the "total technology" needs of young engineers.

Expenditure by the SRC in 1970–71 amounted to £51 million, an increase of £4 million on the previous year. The Rutherford Laboratory remains the largest of the council's domestic pensioners (£8 million in 1970–71), the Daresbury Laboratory with its electron accelerator comes next (£4.5 million) and the Atlas Laboratory and the Radio and Space Research Station cost £1.16 and £1.63 million respectively. Grants to universities cost a total of £9.65 million, with engineering the most generously treated (£3.89 million), nuclear physics still keeping its head above water with £1.56 million and the Astronomy, Space and Radio Board generously increasing its expenditure by more than 20 per cent to £1.12 million.

The report welcomes the international collaboration which allows British scientists to use facilities abroad and enabled 220 foreign scientists to spend up to a year in Britain last year.

The report is also enthusiastic about collaborative programmes, drawing particular attention to the UK interest in the Institut des Hautes Etudes Scientifiques, the proposed use of the Franco–German High Flux Beam Reactor at Grenoble and the Radio and Space Research Station link with the Italian satellite project SIRIO, and the SRC is particularly delighted that the government—at the SRC's consistent recommendation—has agreed to UK participation in the CERN 300 GeV project.

Disappointment is expressed that the discussions on the future of the European space programme have so far been unproductive, no agreement being reached on either a future European programme or on European involvement in NASA's post-Apollo programme. But the SRC is encouraged by Britain's individual involvement with NASA, citing the presence of American experiments in the payloads of the UK-4 and UK-5 satellites, the provision of experiments for the American programme by British scientists and the continuing analysis of lunar samples in Britain. The SRC also welcomes the possible future involvement in the ultraviolet astronomy satellite SAS-D.

NEW WORLD

DDT Nailed Again

by our Washington Correspondent

A SCIENTIFIC advisory committee appointed by William D. Ruckelshaus, Administrator of the Environmental Protection Agency, has added its voice to the chorus of opposition to the use of DDT in the United States. Five top level scientific committees in almost as many years have recommended that the pesticide be phased out of domestic use as soon as possible, but in spite of the armoury now available to pesticide critics, the battle of words over the safety of DDT is far from finished.

So far this year, DDT has been the subject of two decisions of the US Court of Appeals, its use in the United States has been cancelled by the Environmental Protection Agency (EPA), that decision has been appealed against by chemical manufacturers, a lengthy public hearing has been started and a scientific advisory committee has issued a report. These skirmishes are, however, the result of a skilful rearguard action being fought by pesticide manufacturers to delay a ban on DDT, and there seems little likelihood of anything other than final victory for the anti-pesticide forces.

The first indication that the tide had turned against DDT came in November 1969 when the Department of Agriculture cancelled four major uses of the pesticide in the United States—on tobacco, shade trees, over water and in the home. Spurred on by the taste of blood, environmental groups led by the Environmental Defense Fund initiated a sequence of court actions which culminated in a decision of the Court of Appeals in January this year directing the EPA to cancel all remaining uses of the pesticide, and to consider suspending its registration (immediate suspension would prevent DDT from being marketed while the cancellation process takes place).

The EPA obediently cancelled all uses of DDT in the United States but concluded that suspension is not warranted, thereby setting in train a public hearing, another court action and a study by an advisory committee. The public hearing and the setting up of the advisory committee were requested by manufacturers exercising their rights under the Federal Insecticide, Fungicide and Rodenticide Act to appeal against a cancellation order, and the court action was brought by the Environmental Defense Fund in protest against the EPA's decision not to suspend registration of DDT. The upshot of the bureaucratic manoeuvring so far is that the advisory committee has recommended rapid phasing out of all uses of DDT, but that the pesticide should continue to be made available to the public health service for "control of disease-bearing insect vectors until satisfactory alternatives are developed", the appeals court has instructed Ruckelshaus to reconsider his decision not to suspend registration of DDT and to make a final decision by November 1, and the public hearing is likely to drag on until next year.

Ruckelshaus has ninety days in which to respond to the advisory committee report, and with two court decisions to back him up, he is unlikely to revoke the cancellation order. But if he is looking to the report for inspiration to help decide the vexed problem of suspension he will be disappointed, for on the imminence of the hazards associated with use of DDT, the advisory committee is skilfully ambiguous. It suggests that present use of DDT "does not present an imminent hazard to human health, in terms of bodily functions and safety", but continued use of DDT is "an imminent hazard to human welfare in terms of maintaining healthy desirable flora and fauna in man's environment". Even if all present uses of DDT were outlawed, however, the committee points out that because of the present levels of the pesticide and its persistence in the environment, a rapid decrease in the use of DDT will probably achieve the same result as suspension.

The committee bases those observations on the finding that in spite of the heat generated by the battle of words over DDT, there is little evidence that it is acutely toxic to man, no evidence that it is teratogenic and, on the basis of present intake of DDT and its metabolites, "the probability of tumorigenesis and carcinogenesis is low". The case against DDT therefore rests essentially on its effect on non-target species and on the ecosystem itself, and here the committee is able to cite a sheaf of undesirable consequences of widespread use.

By far the most damaging behaviour of DDT is that it can remain in the environment for several years in its original form or as the metabolites DDD and DDE. The result is that in spite of a rapid decline in the use of DDT in the United States during the 1960s (from about 70 million tons a year in 1962 to about 30 million in 1969), there has been no parallel decrease in the contamination of the environment. Levels of DDT in the soils of south-western, southern and

Table 1 Predicted Concentration of DDT and DDE in Human Adipose Tissue with Various Assumptions about DDT Usage

Year	Continued reduction of DDT usage at present rate	Zero future usage of DDT	DDT usage maintained at 5×10^6 lbs./year	DDT usage maintained at 1966 levels
1970	5.14	5.14	5.14	5.30
1974	4.18	4.13	4.20	5.08
1978	3.41	3.35	3.53	5.32
1982	2.78	2.73	3.02	5.60
1986	2.27	2.23	2.60	5.84
1990	1.86	1.82	2.25	6.03
1994	1.52	1.49	1.98	6.20
1998	1.24	1.21	1.75	6.32
2002	1.01	0.99	1.56	6.43
2006	0.82	0.81	1.41	6.52
2010	0.67	0.66	1.29	6.59
2014	0.55	0.54	1.18	6.65
2018	0.45	0.44	1.10	6.70
2022	0.37	0.36	1.03	6.73

eastern seaboard states still stand at between 0.10 and 0.56 parts per million, although in orchard soils they have been found to reach 52 ppm, and DDT is still found in rivers and lakes at concentrations approaching the limits of its solubility.

What seems to be happening is that run-off from agricultural soils has pumped DDT into the rivers to the extent that it has settled in bottom sediments. This creates a pool of DDT which is stirred up and released into the atmosphere by storms, and the rivers are continually being recharged by run-off from the soil. The upshot is that there is no prospect of marked decrease in water contamination until levels in soils and sediments are decreased—a process that will take years even if no more DDT is pumped into the ecosystem of the United States.

The chief cause of concern over the continuing contamination of the marine environment by DDT is that its high solubility in body fats causes it to accumulate in the tissues of animals in the higher levels of the food chain, sometimes with devastating consequences for animal populations. Evidence that the decline in populations of the peregrine falcon and bald eagle is linked to the build-up of DDT or its metabolites in their tissues is already well documented, and a committee of the National Academy of Sciences concluded earlier this year that marine fish are almost universally contaminated by chlorinated hydrocarbon residues. What happens is that phytoplankton accumulate DDT from water, and the pesticide then finds its way into the tissues of fish, and so on up the food chain. An example of how the levels of DDT become magnified in living tissue is the fact that half of the fish caught in Lake Michigan in 1966, for example, had at least five parts per million of DDT in their tissues, compared with 0.0012 parts per million in the water.

Although that sequence of contamination has been drummed into the public through the protestations of environmentalists for the best part of a decade, the committee nevertheless complains of a lack of hard evidence on which to base predictions of the body burden of DDT in future years. Present evidence indicates that a man consumes about 0.01 mg of DDT or its metabolites a day, and has about 6 ppm of DDT and DDE in his adipose tissue, but while DDT intake has been more than halved since 1966, tissue concentrations have declined by less than 25 per cent.

The committee believes that levels of DDT in food are now in equilibrium with levels in the environment, and since the environmental burden is unlikely to decline very rapidly, even if no more DDT is used in the United States, food levels will probably remain fairly constant over the next few years. Moreover, since average concentrations of DDT in human tissue have not yet reached equilibrium with the concentrations in food, they will continue to remain high for some time to come. These predictions are, however, necessarily hand waving extrapolations from incomplete data, and the committee decided to explore the possibility of devising a simple systems model to predict the level of DDT metabolites in man up to the end of the decade.

A study carried out by R. V. O'Neill and O. W. Burke of the Oak Ridge National Laboratory concluded that even if no more DDT is used in the United States, the adipose tissue of Americans would still contain 0.36 ppm by the year 2022. Moreover, tissue levels of DDT will decline at almost identical rates if DDT usage continues to decline at its present rate, or if the pesticide is removed completely from the US market. A small use of DDT will, however, have a marked effect on tissue concentrations at the end of the century (see Table 1).

Is the alarm engendered by the build up of DDT in human tissue matched by evidence of its chronic toxicity? The advisory committee believes not, and it bases its *sang froid* on the fact that there is more information on the toxicity of DDT than on any other pesticide, and yet there have been no well documented reports of fatal uncomplicated DDT poisoning and there is little evidence of carcinogenicity at the levels encountered by man—although the committee is quick to point out that firm conclusions cannot be drawn.

The committee cites studies carried out in 1956 which showed that rats fed DDT in doses of 15 ppm produced hypertrophy, inclusion bodies and cytoplasmic granulation in the liver, but that these changes were reversible after withdrawal of the diet. A later study by the Bionetics Research Institute, and studies carried out under the auspices of the International Agency for Research on Cancer, both showed a statistically significant increase in the incidence of hepatomas, and a study carried out in 1967 produced evidence of hepatic cell tumour in trout fed relatively low doses of DDT. These results have led the advisory committee to conclude that "the evidence to date clearly shows that DDT induces hepatomas and suggests it may be carcinogenic", but studies of workers in DDT factories, where average daily intake of the pesticide probably reaches about 18 mg, have produced "no clinical or laboratory effects attributable to exposure to DDT". Nevertheless, the committee suggests that long-term studies of occupational exposure to DDT are urgently needed, and that in spite of the evidence that there is little cause for alarm from health hazards, the possibility of carcinogenicity cannot be dismissed.

As for toxicity to animals and birds, however, the committee points out that data are incomplete and further research is needed to support definite conclusions. Nevertheless, there is sufficient circumstantial evidence to link build up of DDT levels in some species with their decline in numbers, and "there is sufficient toxicological information on DDT in aquatic species to indicate that reduction and prevention of contamination of water sources is a problem of major concern".

Materials Regrouped

by our Washington Correspondent

REPERCUSSIONS of the so-called Mansfield Amendment, directing the Department of Defense to keep its nose out of research not directly related to weapons development, are still being felt in the National Science Foundation. Apart from being given an extra $40 million in its budget to pick up projects dropped by the Defense Department, the NSF has inherited responsibility for so much materials science that it has decided to regroup its support programmes. A new division of materials science has been set up to look after the twelve interdisciplinary research laboratories acquired from the Advanced Research Projects Agency—a defence department agency designed to get advanced projects moving (it was at one time responsible for the Arecibo telescope)—and the National Magnets Laboratory that was once the responsibility of the Air Force. The new division will also take charge of the materials science activities that were funded by the other divisions of the NSF. The foundation last year distributed grants worth about $30 million for materials science, and its stake in the field is expected to double this year.

The director of the new division is Dr Harold W. Paxton, recruited to the NSF from the metallurgy department of Carnegie-Mellon University, and the deputy director is Dr Howard Etzel, formerly director of the NSF's Solid State and Low Temperature Physics Program. The chief problem facing the division at present is that although it is already formally constituted, it has run into staffing troubles because of restrictions imposed on government agencies by the wages and prices freeze.

These conclusions have led the committee to recommend that the use of DDT be phased out, but that it remains available for the control of disease bearing insects at least until satisfactory alternatives have been developed — a conclusion that has already been interpreted by the court of appeals as calling for suspension of the pesticide, and by some manufacturers as an acceptance of their thesis that DDT is the safest pesticide to use in most applications. Although the days for DDT in the United States are clearly numbered, there is no sign as yet that it will be allowed to pass peacefully.

MANPOWER

A Modest Plan

by our Washington Correspondent

THE Department of Labor has put up $3 million to help find work for highly qualified scientists and engineers who are at present swelling the ranks of the unemployed. The money will be used to establish internships in federally funded laboratories for some 420 young unemployed scientists and engineers who hold advanced degrees. A brainchild of the Office of Science and Technology and the Department of Labor, the scheme is being administered by the National Science Foundation, and it is expected to swing into action in the near future.

The idea was sketched out in a memorandum addressed to all directors of federally funded laboratories with more than 100 professional staff on their payroll, sent out last week by Raymond L. Bisplinghoff, acting director of the NSF. It explained that the foundation will provide $7,000 to pay the salary of each intern on a one year non-renewable basis, provided that the laboratory at least matches that sum to supplement the salary and to meet overhead costs. Laboratory directors have been asked to furnish the NSF with an estimate of the number of internships which can fruitfully be used to the mutual advantage of the laboratory and the intern, and the foundation will parcel out 420 internships on a first-come first-served basis. Interns will then be recruited by the laboratory with preference being given to veterans and those from areas of particularly high unemployment, which in general means areas in which defence and aerospace industries are concentrated.

Edward E. David, the President's science adviser, said last week that he hoped that the interns would be employed in positions "where they can best benefit the nation and themselves" —projects concerned with pollution, rubbish disposal, nuclear energy and the like. But the NSF memorandum made no mention of any constraints on the type of project except that care should be taken "in assigning interns to tasks which will improve their potential for later job placement".

The scheme is an offshoot of a $42 million programme launched by the Department of Labor in April to help find work for scientists, engineers and technicians thrown out of work by cutbacks in the defence and aerospace industries. The thrust of the programme is to provide retraining for about 10,000 people who have a strong possibility of being employed by specific employers, relocation grants for scientists and engineers who find employment out of their home area, and to set up a national registry to help match jobless engineers with job openings. These facilities are limited to applicants from fourteen areas particularly hard hit by unemployment, unlike the internships scheme, which is limited neither by the area in which the applicant is living, nor by his previous employment. One reason for the difference between the schemes may be that the NSF has been able to dictate the terms of the internship project.

The new initiative by the Administration in trying to find employment for some of the jobless scientists and engineers is probably a measure of the political embarrassment in having expensively produced graduates in the dole queues during election year. But the internship scheme is hardly likely to be a decisive influence on the problem, for according to a survey conducted by the NSF, some 4,000 scientists and engineers holding a master's degree or a doctorate were out of work in the spring of this year.

Short Notes

FAS on the Attack

THE Federation of American Scientists has launched a stinging attack on the F-14 carrier-based aircraft programme. A statement issued by the FAS describes the programme as "a purposeless, enormously expensive, gold-plated procurement scandal dependent on a missile that may not work; its only hope is to become a *fait accompli*". The idea of the programme is to provide about 300 aircraft to serve on carriers in "high threat areas", in an effort to protect them from enemy action, but the FAS—which has in the past been a consistent critic of federal arms policy—suggests that carrier-launched attacks are unlikely to be effective in Soviet wars, and that land-based aircraft are unquestionably superior in terms of both capability and cost.

The military appropriations request for 1972 is for $1,034 million for 48 aircraft—a figure which the FAS points out would result in a cost for 300 aircraft of $6,000 million, allowing for research and development on the first batch. "It is a self-evident distortion of priorities to give carriers marginally improved abilities to do a largely unnecessary and hopeless job," the FAS tartly states. The federation also calls the procurement of the F-14 a scandal because the House of Representatives has had no chance to debate the programme. It charges that the chairman of the Armed Services Committee held back the procurement request pending a review by Mr Packard, Deputy Secretary of Defense, of the number of aircraft to be bought, but long before the conference committee report is debated, the Administration will sign a contract for production of 48 aircraft.

Davis lashes OMB

JOHN W. DAVIS, chairman of the House Subcommittee on Research and Development, has lashed the Office of Management and Budget's decision to impound $30 million of the National Science Foundation's funds for support of science education. The OMB's action, which has already led to the abrupt resignation of Lloyd Humphries, an assistant director of the NSF, was cited by Davis in a letter to President Nixon as likely to endanger the "long run health of American science". Davis asked Mr Nixon to take immediate steps to remedy the OMB's action. The subcommittee on Research and Development specifically increased the NSF's budget authorization for science education, and it is naturally chary of having its work negated by a decision of the Office of Management and Budget, taken behind closed doors.

Aggressive Bees

A COMMITTEE of the National Research Council has been set up to plan methods to cope with the possible intrusion into Central and North America of a particularly aggressive strain of honey bee. The bee was accidentally introduced into South America 15 years ago during experiments designed to breed into the ordinary domestic bee the extraordinary work capacity of the African honey bee *Apis mellifera adansonii*. Unfortunately, however, the African bee, which has a painful sting and will sometimes attack when unprovoked, escaped and spread rapidly over South America. Beekeepers in North America fear that if the African bee spreads to North America, its viciousness might lead to demands for eradication of all bees near urban communities.

NEWS AND VIEWS

Cancer and Immunity

It would be hard to find a cancer researcher who would these days deny that the state of an animal's immune defence system crucially affects its response to carcinogens and transplanted cancer cells or that the growth of cancer cells into a tumour is correlated with at least a partial failure of the immune system. Indeed it has been seriously argued that the immune system first evolved as a defence mechanism against autochthonous tumour cells and only secondarily became adapted as a defence against infecting microorganisms and other foreign antigenic materials arriving from outside the individual. But if one of the chief functions of the immune system is to provide a surveillance mechanism which can recognize and destroy cancer cells because they carry tumour antigens on their surfaces which are not present on normal cells, how do tumours ever develop? In other words, by what mechanism is the immune system undermined to such an extent that tumours can grow and metastasize?

In an attempt to shed some new light on this crucially important question, Ambrose, Anderson and Coggin at the Oak Ridge National Laboratory have analysed the role of circulating antibodies during the development of tumours in hamsters injected with Simian Virus 40. And as they report on page 321 of this issue of *Nature*, they believe that cytostatic antibodies play an important part in tumorigenesis, during the early stages of which they seem to prevent the rapid proliferation of the initially arising tumour cells. Once the tumour, in the face of these antibodies, reaches some critical mass, however, tumour antigen becomes locally in excess, swamps the available antibody and cell mediated immunity and uncontrolled growth ensues.

In spite of its limitations, Ambrose and her colleagues chose to use as their model system Simian Virus 40 as a carcinogen for baby hamsters for three chief reasons; first, the virus reproducibly induces tumours; second, all SV40 induced tumours bear the same transplantation antigens; and third, and most importantly, it is possible to block the induction of tumours by immunization with either SV40 virus or SV40 tumour cells killed by irradiation.

The first problem encountered by Ambrose *et al.* was to devise ways of distinguishing the effects on tumorigenesis of humoral or antibody immunity responses from those of cellular immunity mediated by sensitized lymphocytes. That cellular immunity plays an important part in the defence against cancer is, of course, indisputable—non-immune animals, for example, can be protected against tumour cells by injections of lymphocytes from immune animals—but the role of antibody immunity is much more obscure and is something Ambrose *et al.* were intent on elucidating. To test whether antibodies as well as lymphocytes in animals immune to SV40 tumours can kill or at least prevent the proliferation of SV40 tumour cells, they placed such cells in plastic chambers permeable to antibodies in the peritoneal cavities of immune and non-immune hamsters. Circulating antibodies in the immune animals, but not those in the controls, retarded or prevented the proliferation of the cells.

The Oak Ridge group then exploited this technique to follow the course of appearance of these cytostatic, if not cytotoxic, antibodies during the latent period between the injection of SV40 virus into newborn hamsters and the appearance of tumours months later. During the first ten weeks of life the amount of circulating cytostatic antibody increases and in those animals which do not develop tumours, even after 500 days, antibody persists, but in those animals fated to develop tumours the amount of this antibody declines precipitously after about ten weeks. These findings suggest that during the first ten weeks after injection with SV40, transformed tumour cells are present but latent and indeed such cells can be detected by histopathology. Furthermore, by incubating SV40 tumour cells with sera from normal hamsters, immune hamsters and tumour bearing animals, Ambrose and her colleagues proved that sera of immune animals but not tumour bearing animals prevent the multiplication of tumour cells *in vitro*.

There can be no doubt that circulating antibody from immune animals is cytostatic, but sera from animals with tumours lack this material. A further set of experiments established three important facts about this antibody: first, it seems to be invariably produced before tumours appear; second, it retards tumour growth; and third, it is always present in immune animals. And if the transient appearance of the antibody precedes the appearance of tumours, what happens when tumours are removed by surgery; does the antibody reappear? As might be anticipated, it reappears in at least some animals.

What is the simplest interpretation of all these data? Ambrose and her colleagues, who firmly believe as a result of their own experiments as well as those of others, that the so-called tumour specific transplantation antigens are probably normal early embryonic antigens caused to be re-expressed by transformation, draw an analogy between the tolerance of a foetus and the survival of a tumour. They believe that immediately after exposure to a carcinogen, a small tumour mass is established and may for a few hours grow without restriction. But as cytostatic antibodies are produced the rate of proliferation of surviving tumour cells is greatly reduced and during the latent period the tumour mass increases only gradually. When, however, a critical mass is reached the cytostatic antibodies are locally mopped up by an excess of tumour antigen. The tumour cells can then grow rapidly producing more antigen and as this excess builds up circulating antibody becomes undetectable and amounts of antigen always outweigh amounts of antibody, unless of course the tumours are removed by surgery. And once antigen is in excess, antigen–antibody complexes may block cellular immunity and even cause immune enhancement.

This scheme clearly contains many elements of speculation but it is nonetheless attractive and suggests that assays for antitumour antibodies, be they cytostatic or cytotoxic, might provide an early warning system for human cancers still in their latent period and an indication of when treatment of established tumours is being successful.

NUCLEIC ACIDS

Genes Made Manifest

from our Molecular Biology Correspondent

ONE of the prettiest techniques to bubble up from the cauldron of molecular biology in recent years is Inman's denaturation mapping of DNA. The DNA is brought to a precisely defined temperature, or *p*H, at some point within its narrow melting range. Formaldehyde is introduced to prop open the melted parts of the chain, and a population of molecules so treated is examined in the electron microscope. The denatured regions are then indexed along the chain for a sufficient number of molecules on the grid, and correspond to tracts of sequence relatively lower in (G+C) than the rest. An interesting new application for this approach has now been found by Wensink and Brown (*J. Mol. Biol.*, **60**, 235; 1971), namely the identification of a gene, using its characteristic denaturation map as a fingerprint.

It is known that the DNA corresponding in eukaryotic cells to the ribosomal RNA is present in the form of many clustered copies, apparently interspersed by spacer segments, much richer in (G+C). Moreover this ribosomal DNA is separately amplified, and occurs as an extra-chromosomal component, differing apparently only in that none of its cytosine residues is methylated. Such a DNA, when subjected to the denaturation mapping technique, displays in the electron micrographs an immediately apparent periodicity, repeating up to fifteen times in one molecule. To ensure, however, that this effect is no trick of the eye or mind, Wensink and Brown have devised a means of testing for the presence of a periodicity and determining its precision and spacing. The measured distribution is matched against a Fourier function, the wavelength of which is varied until a correlation appears and is maximized. A sharp peak comes up at a periodicity of $5.4 \pm 0.4\mu$, whereas a denaturation map of T2 phage DNA shows only a flat background. From a calibration of the length measurement against T7 DNA, as a molecular weight standard, the repeating unit turns out to correspond to a molecular weight of some 8.7×10^6 which is the same as the molecular weight determined by Dawid and his colleagues of 9×10^6.

The repeating unit consists of a rather readily denaturable region, and another, somewhat shorter and much more resistant to melting, which may therefore be surmised to be richer in (G+C). This is exactly what would be expected from the size and composition assigned to the spacer region between successive copies of the ribosomal RNA gene. A comparison with Inman's results on λ phage DNA, which can be divided into two halves differing by 20 per cent in their (G+C) content, indicates that there is a similar difference between the ribosomal RNA tract and the spacer.

This is a very satisfactory result, but there is still more information in the denaturation maps, for the map of the low-melting segment contains a highly reproducible fine structure, which persists over a wide range of melting. Dividing the repeating unit into 100 elements, a histogram of the fraction of chains in which each element is melted shows a relatively broad region of melting, followed by a trough, corresponding to a much more resistant sequence, then another, narrower peak, followed in turn by a narrow and extremely resistant minimum, and then a mirror image of the first pair of separated peaks. The pattern is thus symmetrical about a short, highly (G+C)-rich segment on which the patterns are most readily indexed. This whole pattern corresponds to the 5×10^6 molecular weight of the 40S ribosomal RNA precursor, which contains the 28S and 18S chains of the large and the small subunit. In conversion of the precursor to these products a small portion of the chain is lost. This portion is believed to be rather rich in (G+C), and may be presumptively identified with one of the two shallower troughs in the denaturation map. This latter must therefore separate the 28S and 18S parts of the chain. The short very stable region can also be accounted for, because partial enzymatic degradation of 28S ribosomal RNA from other animal cells has led to the isolation of a sizable fragment (200,000 molecular weight) containing no less than 80 per cent (G+C). Wensink and Brown have compared finally the denaturation maps of the chromosomal and amplified ribosomal RNA, and found them to be identical.

Lord Kelvin's criterion that only that which can be measured and expressed in figures is science, can also be applied to another interesting essay in electron microscopy. Freifelder (*ibid.*, 401) has given experimental proof to the proposition that intercalative binding in DNA causes a change in the pitch of the double helix with a consequent increase in length. Using monodisperse phage DNA he has measured the length distribution of the molecules as a function of the concentration of added ethidium bromide. The standard deviation of measured lengths in each binding state is only 3 per cent, and the increase in length with ligand concentration reaches a sharp saturation level. At this point the chain has stretched by some 27 per cent. Moreover, the molecules look quite different: instead of a rather crinkly thread, broadly curved filaments are seen. Circular DNA–dye complexes have the appearance of smooth ellipses. It seems then that the hydrodynamic stiffness of the molecule must change on intercalation, so that direct inferences about the length from viscosity or sedimentation measurements are not in fact justified.

Locating a Quasar

OUTSIDE the circle of observational astronomy it sometimes comes as a surprise to learn that the exact positions of celestial objects are not always known, and in particular that there is considerable difficulty in relating positions measured by optical and radio techniques. A little thought, however, makes it seem more remarkable that identifications at optical and radio frequencies can be compared at all in some cases, at least to the accuracy required before theories can be built upon the observations. Even optical positions can only be measured relative to certain reference stars, and at radio frequencies sources can only be pinned down by a technique such as occultation, or, most commonly, by finding an optical counterpart to the source. The embarrassing aspect of the second technique is that it is less than adequate when the object of the exercise is to determine whether an optical source and a radio object are one and the same.

A classic example of the success of the occultation technique was provided by the identification of the source 3C 273, the first known quasar, by timing the eclipse of the radio source by the Moon. But it has proved impossible, until now, to state unequivocally that the small component 3C 273B really is coincident with the associated QSO, because of a difference of 0.7 arcsec between the best optical and radio positions published. Dr C. Hazard and his colleagues at the University of Cambridge and the Royal Greenwich Observatory have rectified this situation, and publish in next week's *Nature Physical Science* positions which confirm the association of the radio and optical objects to within 0.3 arcsec. Unlike the earlier recorded difference (0.7 arcsec) this figure is well within the limits of experimental error. Indeed, the best of the lunar occultation observations gives a radio source position exactly at the mean of the optical positions. Because of the differing reference systems, however, such good agreement is not to be taken at face value. There is no reason to prefer either the radio position or the optical position, so that the best position now available for 3C 273B should be taken as the average of the two positions determined by this work.

COSMIC RAYS

Hobart Conference

from a Correspondent

THE twelfth international conference on cosmic rays was held for the first time in the southern hemisphere at the University of Tasmania, Hobart, from August 16 to 25, 1971. In spite of the large distances involved for most participants delegates from twenty-two countries, not including Australia, attended.

In the high energy sessions the delegates heard of further experiments that had been carried out in the search for quarks and other particles. The contributions did not advance the position, however, and no conclusive new evidence for the existence of these particles was presented. The Sydney quark experiment has not been run significantly since the Budapest conference and no new events were reported. The experiment is currently being refurbished by the inclusion of five high pressure cloud chambers.

At the Calgary cosmic ray conference in 1967, the University of Utah group reported that their underground measurements on the variation of cosmic-ray muon intensity with zenith angle, θ, in the TeV range, showed no "sec θ" enhancement as predicted by theories involving pion parentage. It was suggested that this could be explained in terms of muon parents of very short lifetime, subsequently referred to as X-particles by the Utah group. The observations of the Utah group have continued and have been refined but the onset of the effect seems to have receded to somewhat higher energies and reaches a maximum, only to disappear again at even higher energies. Other experimenters, notably the group at the Tata Institute working in the Kolar goldfields, continue to find no evidence for a departure from the sec θ enhancement. It would seem that perhaps a third independent experiment at a depth of about 1,500 hg cm^{-2} should be carried out to try to resolve these apparently contradictory results.

Details of several large solid iron muon spectrographs being built or recently completed in order to study this effect directly were given at the conference. But the problems associated with the measurement of muon energies of about 3 to 5 TeV, coupled with the low flux of particles at these energies, mean that some time must elapse before these instruments will be able to contribute to an elucidation of this problem.

Although extensive air showers have been studied for several years, the origin and nature of the primary particles are not yet well understood. At the Jaipur cosmic ray conference in 1963 the results of the MIT (Volcano Ranch) group suggested that the slope of the integral primary energy spectrum changed from 1.6 (below 10^{16} eV) to 2.2 (between 10^{16} and 10^{18} eV) and back to 1.6 at energies greater than 10^{18} eV. These "ankles" were tentatively interpreted as reflecting a change in the mass composition of the primary cosmic-ray particles. The part of the spectrum beyond the second ankle was thought to be attributable to primary protons of extragalactic origin.

Perhaps the most significant change at the Tasmanian meeting was the report from the University of Leeds group working at Haverah Park in Yorkshire. These results showed no evidence for the existence of the second ankle. Furthermore, it was shown that by applying the same method of analysis to the MIT Volcano Ranch data, the evidence for the second ankle disappeared.

Preliminary data presented at the conference from the Sydney University Giant Air Shower Recorder (SUGAR) in the form of muon size spectra also showed no evidence for the second ankle at 10^{18} eV. Should these results be substantiated they will constitute an important observation which could lead to queries about the existence of extragalactic radiation. Measurements of the arrival directions of the most energetic showers yield no evidence of any anisotropy even when the galactic centre is overhead.

Several speakers described attempts to link the observed shower properties at sea level with the mass of the primary particles. Some progress in this field was reported by the Imperial College and University of Nottingham groups. It would seem that studies of the electron and muon component coupled with the observations of the radio emissions from showers might well be able to give more definitive answers.

Direct studies of the mass composition of the low energy part of the primary spectrum have continued. By using new techniques including superconducting magnets, knowledge of the light/medium element ratio (L/M) has been extended up to 10,000 MeV per nucleon. It has been found that the value is approximately 0.2, and that the composition at the higher energies is equivalent to that at the lower energies.

Studies of elements with $Z>26$ have shown that the abundance of uranium is greater than expected. The disagreement between the values of Z obtained from nuclear emulsion and plastic detectors has been resolved since the Budapest conference with the exception of one event. Studies of the light and heavy nuclei suggest that the age of the cosmic radiation is between 10^6 and 10^7 yr.

Arabinose Operon *in vitro*

IN *Nature New Biology* next week two groups, Zubay, Gielow and Englesberg and Greenblatt and Schlief, report the successful reconstruction *in vitro* of the regulatory system which controls the expression of the arabinose operon of *Escherichia coli*. Their experiments are notable, for this is the first time that a positive regulator protein which causes the expression of a specific operon has been made to function *in vitro*. Furthermore, these *in vitro* experiments confirm the picture of the regulation of the arabinose operon which has emerged from studies of intact *E. coli* and they provide a method for assaying for the elusive arabinose regulator protein.

Zubay and his colleagues used the cell free system developed by his group to support the regulated expression of the *lac* operon to define the elements required for the synthesis *in vitro* of L-ribulokinase when the system is programmed with phage *θ80dara* DNA which includes the arabinose operon. They find that in addition to cyclic AMP, the activator protein which binds cyclic AMP and ppGpp, cell extracts containing the protein specified by the *ara*C gene are required together with arabinose. Genetic analyses had indicated that the *ara*C gene protein can act both as a repressor and an activator of the arabinose operon and these *in vitro* experiments confirm the latter function of this protein.

Greenblatt and Schlief have, like Zubay and his colleagues, exploited mutants of the *ara*C gene to prove that the *ara*C protein is an activator *in vitro* of the arabinose operon. Moreover, they have shown that under certain conditions the *ara*C protein can act *in vitro* as a repressor of the arabinose operon. These findings fully confirm the idea that the *ara*C protein can exist in two functional states, repressor and activator, in equilibrium and that an inducer such as arabinose favours the activator form. Greenblatt and Schlief have also reached the interesting conclusion that the protein specified by constitutive mutants of the *ara*C gene can activate the arabinose operon *in vivo* in the absence of arabinose not because it is "frozen" in the activator state but because it can respond not only to arabinose but also to some as yet unidentified metabolite always present in growing cells.

Attempts to purify the *ara*C protein by virtue of its ability to bind to arabinose or arabinose operon DNA have all failed, but now that the cell free system for ribulokinase synthesis provides an assay for this protein, its purification can be anticipated and that will open the way to a detailed analysis of a regulatory molecule.

MINERAL RESOURCES

New Prospects

from a Correspondent

TYNAGH, Gortdrum and Silvermines are household words in metal mining today. All are mines in the Republic of Ireland which have been brought into production within the past decade and are likely to be followed by others in the near future. Great Britain can point to a major new tin development, the Wheal Jane mine in Cornwall, and hopes are high for potash, copper and nickel elsewhere in the country. Both Ireland and Britain are being explored for metalliferous minerals on a scale and in ways never seen before. Their geologists and mining engineers came together in Edinburgh on September 10 to describe the new findings and the methods of exploration at a symposium arranged by the Institution of Mining and Metallurgy as one of a group of earth science meetings held to celebrate the centenary of the University of Edinburgh Geology Department.

With so much ore already proved, the geologists working in Ireland inevitably had much to say. Dr R. W. Schultz (Northgate Exploration Ltd, Dublin) gave high marks to geochemical soil and drainage surveys in his analysis of exploration practice. Although reserving judgment on the origin of mineralization in the Lower Carboniferous of central Ireland, Dr C. J. Morrissey (Irish Base Metals Ltd, Dublin), Professor G. R. Davis (Imperial College, London) and Mr G. M. Steed (Imperial College, London) made a lucid comparison of the characteristics of these valuable lead, zinc and copper deposits. In England, the Carboniferous is receiving most attention for fluorite, and Dr T. D. Ford (University of Leicester) and Dr P. R. Ineson's (University of Sheffield) comprehensive account of the Derbyshire orefield will simplify the task of future exploration in that area. The Lower Palaeozoic rocks of Wales, eastern Ireland, the Lake District and southern Scotland together form a major exploration target and the recognition by Mr C. J. V. Wheatley (Imperial College) of an axial belt of copper deposits associated with acid volcanic rocks and bordered by lead–zinc mineralization provides a highly stimulating basis for considering the controls of metallization within them.

The rapid re-development of the Wheal Jane mine into a major tin producer has surprised many people. There is clearly more mineral wealth in Cornwall than is contained in narrow tin lodes and the account of the structural environment of the deposit by Mr B. D. Rayment (Consolidated Gold Fields Ltd, London), Professor G. R. Davis and Mr J. D. Willson (Consolidated Gold Fields Ltd) will help to stimulate further exploration in south-west England. In the Scottish Highlands, reconnaissance investigations by the Institute of Geological Sciences have revealed new evidence of uranium, lead and molybdenum in the Old Red Sandstone sediments and Caledonian granites.

ENTOMOLOGY

Insect/Plant Relations

from a Correspondent

IN contrast to other recent contributions to the subject of insect/plant relations, the symposium held in London on September 16 and 17 by the Royal Entomological Society covered the field in breadth in a way which made it possible to appreciate the overall relevance and interrelations of disciplines ranging from biochemistry to ecology.

In introducing the symposium, Professor T. R. E. Southwood (Imperial College, London) considered relationships in terms of shelter, food and transport. He mentioned in particular the evolutionary hurdle which is seemingly presented by seed plants as food, because in spite of the great abundance of these plants they have been exploited by relatively few insect taxa. Within these taxa, however, the insect/plant systems have co-evolved from predation by the insect on the plant through parasitism to symbiosis.

Biochemical relationships were well exemplified by Dr D. Osborne's (ARC Unit of Developmental Botany, Cambridge) contribution on mutual regulation of growth and development. Secondary substances in the plant may thus control development of the insect or even be needed to induce the female to emit its sex pheromone. Conversely, the insect may affect plant growth, not only by causing malformations but also by stimulating or delaying normal processes of leaf growth and senescence.

The Hon. Miriam Rothschild (Elsfield Manor, Oxford) discussed her work on warningly coloured insect species which sequester and store toxic substance from plants. This was a fascinating account of mechanisms which underlie forms of mimicry defined a century ago but, until now, inadequately examined biochemically. Miss Rothschild described how some tiger moths select only those host plants which retain certain alkaloids toxic to bird and mammal predators; the processes involved in such selectivity were examined by several other speakers. Dr L. M. Schoonhoven (Laboratorium voor Entomologie, Wageningen) described the chemoreceptors of a lepidopterous larva, which respond separately to a wide range of nutritional and secondary plant substances. He suggested that the basis for host plant specificity is more than mere recognition of particular plant substances and is dependent on the insect's ability to recognize the complex of many different substances associated with its own host plant and its nutritional requirements. Professor D. L. Wood (University of California, Berkeley) also described his research on

New Polynucleotide Structures?

BRAM has recently reported some unexpected findings on the dependence of DNA structure in solution on the base composition, and in next Wednesday's *Nature New Biology* he gives results of X-ray scattering studies on a set of two-stranded synthetic polynucleotides in solution. Leaving aside large differences in hydration or binding of counterions, differences in the low angle X-ray scattering envelopes from polynucleotides in solution should mean that they have differences in structure. The double-helical complex, poly dI.poly dC, shows a wide-angle scattering pattern which is different from that of A or B-form DNA. The axial radius of gyration, as derived from low-angle scattering, seems to be larger than that of B DNA and is interpreted to signify that the centre of gravity of the base pairs lies off the helix axis. The same is also found in poly dG.poly dC.

For the alternating double-helical polymer, poly d (I-C) the axial radius of gyration is similar to that of DNA and the alternating poly d (A-T). The corresponding helix cross-section agrees with that found in fibres. Bram finds, however, that the wide angle scattering patterns of both this polymer and of poly G.poly C are different from any others found in polynucleotides or natural nucleic acid.

The double-stranded RNA analogue, poly rI.poly rC, gives scattering patterns which are compatible with the A-DNA-like structure (A′-form) of this polymer, found in fibres. Bram regards this agreement as support for the validity of experiment and the theoretical analysis. The generalization with the data so far available is that in double-stranded polynucleotides with purines and pyrimidines on opposite strands, the radius of gyration is larger than in alternating polymers, and the base pairs lie off the helix axis. Altogether Bram now identifies six different structures for DNA-type molecules. He suggests that the unique configuration of the poly G.poly C raises the possibility that parts of a natural DNA rich in these nucleotides could have a different structure from the rest of the chain.

a bark beetle which kills its host tree following the attraction of massive numbers of beetles to particular volatile substances in frass and resin produced by the activity of perhaps no more than one initial beetle colonist.

The behavioural relationships of an insect to its host plant were emphasized in Professor J. S. Kennedy's and Mr I. H. M. Fosbrooke's (Imperial College, London) discussion on the plant in the life of an aphid. They suggested that the migratory aphid's flight behaviour continues to be influenced importantly by light reflected from plants irrespective of the height at which the insect is flying.

In discussing the plant in the population dynamics of insects, Dr H. F. van Emden (University of Reading) and Professor M. J. Way (Imperial College, London) pointed out that even "chemosensority susceptible" host plants often cause surprisingly large direct mortalities to populations of insects established on them. They also emphasized the role of the plant in providing the framework within which subtle density dependent effects of intraspecific competition operate.

The role of the host plant in the population dynamics of phytophagous insects is still very inadequately understood—and vice versa—as was shown by Dr P. Harris (Canada Department of Agriculture, Belleville), who used examples of successful biological control of weeds to show how introduced phytophagous insects have severely limited the distribution and abundance of a few introduced plant weeds. In general, however, the insect's effect on population dynamics of indigenous plant populations still seems to be largely a matter for speculation except in circumstances where the plant has become dependent for pollination on certain insects.

PACIFIC SCIENCE

Island Conservation

from a Correspondent

THE occasion of the twelfth Pacific Science Congress, held at the Australian National University from August 18 to 27, was taken to celebrate the fiftieth anniversary of the Pacific Science Association which held its first meeting at Honolulu in 1920, under the presidency of its founder, Professor H. E. Gregory.

The congress was addressed by its president, Sir Macfarlane Burnet, after which the Gregory Medal was presented to Dr F. Raymond Fosberg (Smithsonian Institution), the Shinkishi Hatai Medal to Dr Carl L. Hubbs (Scripps Institution for Oceanography) and honorary life memberships were conferred on Dr Sarwono Prawirohardjo (Indonesia) and Sir Maurice Yonge (Great Britain).

Much of the programme of the congress had relevance to the International Biological Programme with its emphasis on conservation. The resolutions submitted by the council at the final meeting reflected the general concern about the environment which, even in remote Pacific islands, is being increasingly degraded by the effects of pesticides, of mining, of the cutting down of primaeval forests and, by no means least, the effect of tourism with its impact on the dignity of native peoples.

Such problems had been the particular concern of a regional symposium on the conservation of reefs and lagoons held before the congress, at Noumea, New Caledonia, under the auspices of the South Pacific Commission in collaboration with the International Union for the Conservation of Nature and Natural Resources (IUCN). A resolution coming from this symposium included reference to the urgent need for appropriate environmental and eological surveys being conducted before any "developmental" project. It also urged intergovernmental action on the imaginative "islands for science" proposal whereby a representative number of islands, largely uninhabited, could be set aside as permanent reserves unaffected by environmental changes induced by man.

It was also suggested that periodic surveys might be carried out on coral reef areas to record long-term fluctuations in the comparison of reef ecosystems. The importance of such knowledge is emphasized by the present widespread population explosion of the coral destroying starfish, *Acanthaster planci*. In this connexion, also, the Pacific Science Council established a new Committee on the Scientific Study of Coral Reefs for the better coordination of work on reefs which, for a variety of uncertain reasons, are now widely endangered.

New Normal Geomagnetic Event

DETERMINATION of the detailed geomagnetic polarity-time scale from continental igneous rocks of the past four million years or so has proved a comparatively simple task, partly because the polarities of young fresh rocks unaffected by appreciable continental drift are determined easily and unambiguously, partly because radiometric dating of such rocks is less likely to be affected by such factors as mineral alteration, and partly because within this period the absolute errors of the potassium-argon dating process are small enough to enable polarity intervals of as short as a few tens of thousands of years to be resolved. For older rocks these advantages are lost; and so it seems unlikely that the detailed pattern of magnetic reversals will ever be delineated for tens or hundreds of millions of years, lest it be on the basis of ocean magnetic anomalies. The essential problem is that even if continental rocks ideal for radiometric dating and magnetic measurement are found, the inherent dating errors will always be larger than all but the longest geomagnetic polarity intervals.

But as Creer *et al.* point out in next Monday's *Nature Physical Science*, there is one geological period within which comparatively short magnetic intervals may be, if not resolved, at least located with a fair degree of precision. This is the period of about 60 million years within the upper Carboniferous and Permian during which the geomagnetic field polarity was apparently almost always reversed. Until recently no normal intervals at all were known within this Kiaman reversed period (about 235 to 290 million years). McElhinny (*Spec. Publs Geol. Soc. Austral.*, **2**, 61 ; 1969), however, has reported a normal event at about 280 million years, which he named the Oak Creek event, and which Burek (*Bull. Amer. Assoc. Petrol. Geol.*, **54**, 1120 ; 1970) later renamed the Graham event. Less well documented is a second normal event present in Italian mid-Permian sediments as reported by Guicherit (*Geologica Ultraiectina*, **14**, 1 ; 1964). But the point is that normal events within the Kiaman reversed interval seem to be so rare that a few which may remain to be discovered are likely to be easily distinguished from each other and from those already found.

And so it has proved in at least one case, for Creer and his colleagues have discovered a new normal event well separated in time from the Graham event. The rocks in question are basalts, andesites and rhyolites of the Porphyritic Series exposed in Mendoza Province, Argentina. All samples were magnetically cleaned ; and so there can be no doubt that normal polarities exist within this series. Moreover, the normal palaeomagnetic directions are consistent with the Permian field of South America as determined from the more common reversed rocks within the Kiaman interval. The stratigraphic age of the samples lies between about 270 and 210 million years ; but, more importantly, the potassium-argon ages of two of the normal samples are 262±6 and 264±6 million years, respectively. The best age for the new normal event within the Kiaman is thus 263±5 million years, which is distinguishable from the Oak Creek/Graham event.

PLANT ROOTS

Water Transport

from a Correspondent

A MOST useful exchange of information and ideas between plant scientists from both sides of the Iron Curtain took place from September 7 to 10 at Tatranská Lomnica, a mountain resort in the High Tatras National Park, during a symposium on the structure and function of primary root tissues. Unseasonably cool weather and showers lessened the lure of the mountains and the botanists were able to give their undivided attention to the matter in hand. The symposium was organized by the Institute of Botany, Slovak Academy of Sciences, and among the topics discussed were the organization and development of the root apex. Dr John Torrey (Harvard University) described some features of the quiescent centre—a group of non-dividing cells characteristically found in the middle of root apices—and speculated about its possible role in hormone biosynthesis.

Other sessions were devoted to consideration of the metabolic and enzyme basis of tissue differentiation and to the functioning of roots in the absorption and transport of water and mineral salts. One of the most stimulating and controversial contributions to the symposium programme concerned the absorption of water by root hairs. Dr Marcel Cailloux (University of Montreal) described an elegant technique which has enabled him to measure absorption of water by different parts of a single hair measuring less than 50 μm in diameter. Cailloux has observed that water is taken up much more readily by the growing tip of the hair than by the maturer regions and he associates this with an aggregation of cytoplasm at the tip. As growth of a root hair declines, so does its ability to absorb water and older hairs were found to excrete water rather than absorb it. These observations cast doubt on the commonly held view that root hairs serve to increase the area of absorbing surface in a root. They also raise the question of the mechanism of water absorption.

According to the classical view, the absorption of water by root hairs occurs by diffusion along a gradient of water potential between the soil solution and cell sap, which is maintained by accumulation of solutes. Cailloux disputes this because he finds that altering the relative humidity of the air surrounding the root hair from 99 per cent to 96 per cent, which is equivalent to an increase in the water potential gradient of about 44 bars, does not alter the absorption rate. Furthermore, metabolic inhibitors, such as malonate fluoride and cyanide, reduce absorption. It is concluded that water uptake by root hairs is controlled by some process other than diffusion which is closely linked with metabolism.

The idea that water is "pumped" metabolically into plant cells is not a new one, but no such convincing evidence has been presented before. A major objection to the concept of active water transport has been the deduction that the resistance of cell membranes to flow of water by diffusion in either direction is so low that a water pump would be grossly inefficient and make impossibly high demands on the energy supplies of the cell. It remains to be seen whether the cell membranes of root hairs, and perhaps other specialized water absorbing cells in plants, have unique properties which enable these cells to pump water efficiently.

STEREOLOGY

Analysis of Structure

from a Correspondent

BERNE proved an excellent choice of venue for this year's meeting of the International Society for Stereology. The president of the society, Dr E. Weibel (Berne University), chaired the congress organization committee and the whole meeting, which took place between August 26 and 31, was run with Swiss precision.

The word "stereology" was coined a little more than ten years ago to cover the discipline of obtaining three-dimensional information from two-dimensional sections or their projections on a surface. There is now a wide interest in stereology, particularly among microscopists, and members attending this meeting—the third international congress—were drawn from such diverse fields as anatomy, materials science and mathematics.

The basics of stereology are obviously the mathematical relationships between the object and the way it is imaged or sectioned. Professor G. Mathéron and his colleagues (Bureau de Recherches Géologiques et Minières, Paris) surveyed their work on the application of the theory of sets to this problem. A particularly interesting contribution from Dr R. Miles (Australian National University) derived one simple multi-dimensional formula from which all the standard formulae of stereology could be derived. Dr E. Underwood (Lockheed Georgia Research Laboratory, Atlanta), who is president-elect of the society, derived the formulae for the stereology of projected images and his approach was reinforced by Professor J. E. Hilliard (Northwestern University, Evanston) in a talk covering quantitative measurements on scanning electron micrographs.

Dr H. Elias (Chicago Medical School), the founder and first president of the society, illustrated the many pitfalls that could occur from a non-stereological interpretation of sections. Professor R. DeHoff (University of Florida) illustrated the use of serial sectioning in determining the topography of grains in metals and derived the basic equations of connectivity.

A major portion of the meeting was given over to the use of computers in image analysis with a survey from Dr G. A. Moore (National Bureau of Standards, Washington). It became apparent that the advent of cheaper computers of various types and interface software had already made stereology considerably easier for a much wider spectrum of scientists.

The generally held view was that this meeting was both excellently organized and scientifically worthwhile. It is quite clear that the International Society for Stereology will continue to grow rapidly and it is hoped that it will continue to maintain its interdisciplinary role.

Viscosity of the Earth's Core

IN next week's *Nature Physical Science*, Dr R. Hide of the Meteorological Office, Bracknell, argues that the kinematical viscosity of the Earth's core is not greater than 10^6 cm^2 s^{-1}. Previous estimates of this parameter have varied between 10^{-3} and 10^9 cm^2 s^{-1} and Hide's new upper limit is a clear step towards pinpointing the viscosity more accurately.

Hide bases his arguments on the discovery of a statistically significant correlation between gross features of the Earth's gravitational and magnetic fields (see Hide and Malin, *Nature*, **225**, 605; 1970), and on variations in the length of the day, both of which suggest that the core–mantle boundary is not smooth but is characterized by bumps which would seem to have horizontal dimensions of as much as a few thousand km and rather small heights of only a few km.

The height of a bump, Hide suggests, must be greater than the thickness of the viscous boundary layer at the core–mantle interface by at least a quantity determined by the horizontal dimensions of the bump, the Alfvén speed, the angular speed of the Earth's rotation and the radius of the core. Using a value of 1 km for the height of the bumps (as suggested by measurements of gravitational distortions) Hide deduces that the thickness of the viscous boundary layer must be $\lesssim 1$ km and, therefore, that the core viscosity is $\lesssim 10^6$ cm^2 s^{-1}.

CANCER CELLS

Chemical Vaccines

from our Cell Biology Correspondent

CANCER cells and cells transformed *in vitro* by chemicals or tumour viruses are about ten times more susceptible to agglutination by lectins such as concanavalin A or wheat germ agglutinin than are normal, untransformed cells. That much is generally agreed by those workers who have used lectins to investigate the surfaces of cancer cells. Why cancer cells are more agglutinable is of course still a matter of dispute; one camp argues that transformation leads to the exposure of previously cryptic lectin-binding sites whereas the other, which currently seems to have the upper hand, contends that it is the distribution of these sites rather than their number which differentiates the two classes of cells, the cancerous and the normal. But in any event there is a difference and it is common to all cancer cells, a fact which Shier has exploited in a remarkable set of experiments published in the current issue of the *Proceedings of the US National Academy of Sciences* (**68**, 2078; 1971).

Shier argues that because cancer cells are more readily agglutinable by wheat germ agglutinin than are normal cells (and he was assuming that this difference reflects a difference in the number of receptor sites exposed), it might be possible to immunize mice against tumours by raising an immune response against the wheat germ agglutinin receptor site. Exploiting Burger's discovery that this receptor is a soluble glycoprotein containing N-acetylglucosamine, he performed what seems to be an almost ridiculously simple and over-optimistic experiment, but the long shot has paid off handsomely.

Shier prepared a synthetic wheat germ agglutinin receptor site by condensing dimeric N-acetylglucosamine residues onto the sodium salt of polyaspartic acid and as a control he crossed linked polypeptide backbones without adding the N-acetylglucosamine residues. Having shown that wheat germ agglutinin has a much greater affinity for the synthetic receptor than for the control, the crosslinked polypeptide, Shier complexed the receptor and the control to methylated bovine serum albumin and used the two complexes (antigens A and B) to immunize mice in the presence of Freund's adjuvant. Two sets of mice, one immunized with the receptor-albumin complex and the other with the control antigen B, were then challenged with various numbers of cells of two BALB/c myeloma cell lines. Mice immunized with the synthetic receptor antigen rejected at least five-fold more tumour cells than those immunized with the control antigen B. Furthermore, the time taken for palpable tumours to develop after exposure to a large dose of the chemical carcinogen 3-methyl cholanthrene was significantly greater after immunization with the receptor antigen than after immunization with the control. Mice which had been immunized with the receptor antigen grew normally and their cellular and humoral immune responses were not impaired although wound healing, as judged by liver regeneration, was slightly impaired compared with that of mice immunized with the control antigen.

In short, Shier seems to have raised an immune response not only against transplanted tumour cells but also against the progression of cells transformed *in vivo* by a chemical carcinogen by immunizing against the wheat germ agglutinin receptor sites. No doubt hosts of laboratories will now be urgently mobilizing their chemists to prepare the antigens. Shier has used and numerous variations on his theme, in attempts to confirm and extend his fascinating observations, which, although they defy simple interpretation, provide a most novel and promising lead to the pipe-dream of immunotherapy for cancer. It can only be hoped they are not too good to be true.

Atlantic Islands and Continental Drift

EVIDENCE has been accumulating that the Eastern Canary Islands (Fuerteventura, Lanzarote and Concepcion Bank) may play an important part in the fit of Africa and North America before continental drift. The most recent of such fits is by Dietz and Sproll (*Nature*, **226**, 1043 ; 1970), who suggest that the most prominent gap (the Ioni Gap) is well matched by the East Canaries block. A small strike-slip translation of the East Canaries would essentially fill this gap. Deitz and Sproll's proposal that the East Canaries constitute a sialic continental fragment (a microcontinent) detached from the African margin is therefore attractive to geophysicists.

Before this idea is accepted, however, it is essential to take into account other evidence which might point to an origin for the Canary Islands (perhaps recent oceanic volcanism) fatal to the hypothesis. The bathymetry of this general region (from US Naval Oceanographic Charts) reveals that Fuerteventura, Lanzarote and Concepcion Bank together form a single elongate and largely submerged plateau lying subparallel to the African coast, with a submarine morphology not at all suggestive of a volcanic plateau. In contrast, the Western Canary Islands are revealed as rudely circular volcanic piles with much more steeply sloping sides than the East Canaries plateau. Seismic refraction and reflexion profiling, combined with gravity data (see, for example, Bosshard and Macfarlane, *J. Geophys. Res.*, **75**, 4901 ; 1970), suggests strongly that the four most westerly Canary Islands do not form part of the African continent but are independent volcanic edifices lying on essentially oceanic crust. The geophysical work shows Gran Canaria to lie in a transitional area between oceanic and continental crust, but is at present inadequate for defining the crustal structure around Fuerteventura and Lanzarote, although it suggests that it is essentially continental.

The purely geological evidence bearing on this question is the subject of much controversy. The occurrence of carbonatites on the Eastern Canaries (but not on the Western Canaries) might be thought to constitute further evidence in favour of their continental nature, because recent surveys of carbonatite occurrences (*Carbonatites*, edited by Tuttle and Gittins, Interscience, 1966) show that they are typically found in fracture or rift zones in old shield areas.

Carbonatites were in fact reported from Fuerteventura by Fuster *et al.* in 1968, and from the Cape Verde Islands (which also have a bearing on this question) in 1965 by Assuncao *et al.* But the distinction between hydrothermal carbonate rich rocks and carbonatites is sometimes difficult on petrological grounds alone. In next Monday's *Nature Physical Science*, Allegre *et al.* report the results of carbon, oxygen and strontium isotopic ratio studies of rocks from Fuerteventura and the Cape Verde Islands which show them unequivocally to be true carbonatites. Portuguese geologists (Assuncao *et al.* have already suggested that the occurrence of carbonatites in the Cape Verde Islands could be explained if these islands were situated in the Mesozoic Mid-Atlantic Rift Valley when the North American and African continents started to drift apart. This suggestion can now be applied also to the Canaries.

It is worth noting that further support for this idea can be derived from the pre-drift fit of Dietz and Sproll, which results in the Fuerteventura carbonatite occurrence being located in fairly close opposition to the Canadian occurrences in the provinces of Ontario and Quebec. Nevertheless, problems remain for the petrologist in that the host rock of the carbonatites in Fuerteventura is a mafic and ultramafic plutonic formation similar in most of its features to the basements occurring in the truly oceanic islands of La Palma and Gomera.

BOTANY

Endemism in Manchester

from a Correspondent

A CONFERENCE on the taxonomy and phytogeography of higher plants in relation to evolution, held at the University of Manchester from September 9 to 11, was organized for the Botanical Society of the British Isles, the Linnean Society and the International Organization of Plant Biosystematists by Professor D. H. Valentine (University of Manchester), who gave a short opening address.

Endemism was perhaps the most dominant theme which emerged, and several speakers related this phenomenon to past geological and climatic history. In the Aegean area, endemism is clearly a consequence of fragmentation of the land mass, and this was described in some detail by Dr W. Greuter (Jardin Botanique, Geneva) for Crete and Dr A. Strid (Lund University) for the Cyclades. In older islands such as the Canaries (Dr D. Bramwell, University of Reading) the proportion of endemics is higher and good examples are found at all taxonomic levels. Professor C. Favarger (University of Neuchâtel) provided an analysis which showed higher proportions of endemic species in the southern European mountain ranges than in the central mass of the Alps, as a result of the greater isolation in the former. Dr S. M. Walters (University of Cambridge) outlined the special case of the almost totally apomictic *Alchemilla*, many of whose agamospecies are narrow endemics yet show some ecotypic differentiation. Professor H. Lewis (University of California, Los Angeles) distinguished between recent endemics of California which have arisen as a result of hybridization and those which have resulted from other sorts of isolating barriers. In the West Indies (Dr B. Morley, National Botanic Gardens, Dublin) the pattern of endemism in *Columnea* varies between the Greater and Lesser Antilles because of differences in geological history and the distribution of bird pollinators between the two areas.

As might be expected, differences of opinion were expressed concerning the mechanisms which have given rise to disjunct distributions, although the diversity of ideas is no doubt to be partly explained by one of the examples chosen. These ranged from bipolar (Dr D. M. Moore, University of Reading) to amphi-Pacific (Professor H. Hara, Tokyo University) distributions. Professor J. K. Morton (University of Waterloo, Ontario) considered that the scattered distribution of montane species in West Africa can be explained by cool periods during which the montane species extended to lowland areas and migrated freely. Professor O. T. Solbrig (Harvard University) described semi-desert areas of great overall similarity in Mexico and Argentina, and outlined the aims and methods of an international team who are attempting to shed light on such situations by defining as precisely as possible the characteristics and relationships of the taxa and conditions involved. Dr F. Rose (King's College, London) presented evidence to show that the territory immediately north of the Somme Valley of northern France has been a greater barrier to the northern migration of species into Britain than has the English Channel, and that a number of continental species in southern England probably arrived from the former area direct and not by way of the Pas de Calais.

Hybridization is playing a major part in the modern rapid evolution of Hawaiian taxa. Dr G. W. Gillett (University of California, Riverside) pointed out that in many cases hybridization does not seem to be related to recent human activity, because it occurs in wind as well as in insect-pollinated genera (and is hence not related to human effects on pollinators) and the open communities favoured by hybrid progenies and segregates are provided by natural phenomena such as lava flows. Professor H. G. Baker (University of California, Berkeley) expounded his ideas on weed evolution with reference to California and described many different methods by which plants had become successful weeds there. Native species are most likely to become weeds in man-made situations which mimic natural ones, whereas alien weeds more often colonize new sorts of habitats.

The migration of taxa was the theme of several other contributions. Professor G. L. Stebbins (University of California, Davis) discussed the notion that angiosperms had originated in mesic conditions and subsequently migrated to areas showing extremes of temperature and water availability. Such a theory is based on the belief that the major characteristics of taxa and their evolution are similar now to when the angiosperms arose. Professor C. van Steenis (Rijksherbarium, Leiden) described the "hour-glass" type of world distribution in which there are wide temperate ranges linked by a narrow tract through Malaysia. Such situations are often accompanied by vicariousness at the family, genus or species level, for example, *Fagus* and *Nothofagus*. *Nothofagus* is now southern temperate, but probably arose further north and migrated to the south by way of Malaysia. A similar route was postulated for *Epilobium* by Professor P. H. Raven (Missouri Botanic Garden), because the genus is in many ways more stereotyped in Australasia than in the northern hemisphere even though there are more species compared with the area covered. Professor T. W. Böcher (University of Copenhagen), on the other hand, discussed east–west migrations in the Arctic region.

Inter-continental similarities and differences have often been investigated by anatomical means, and two contributions exemplified different facets of this sort of study. Dr D. F. Cutler (Royal Botanic Gardens, Kew) showed how a superficially similar stem anatomy in the Restionaceae is accomplished by quite different developments, and Dr A. W. Exell (British Museum (Natural History)) and Dr C. A. Stace (University of Manchester) described situations in the Combretaceae where certain apparently non-adaptive features were limited to one continent or another throughout a wide taxonomic spectrum.

MYCOLOGY

International Liaison

from a Correspondent

AT the First International Mycological Congress held at the University of Exeter from September 8 to 14, an International Mycological Association was established for the encouragement of mycology in all its branches, particularly international aspects, by promoting international mycological congresses and by liaison with other relevant international and national bodies. Membership of the association is open both to international and national societies or groups having mycological interests and to individual mycologists in countries lacking a mycological society.

According to the *International Mycological Directory* (published for the congress by the Commonwealth Mycological Institute, Kew, Surrey, and available at £0.50, post free), there are already a dozen series of international meetings devoted to special branches of mycology, and there are at least an equal number of recurring international congresses or meetings which include some mycology. An important task of the new association will therefore be to attempt to rationalize these events.

The first officers of the association are: president, Professor C. J. Alexopoulos (USA); treasurer, Dr J. A. von Arx (Netherlands); secretary, Dr C. Booth (Commonwealth Mycological Institute, Kew, Surrey, England).

Immunoglobulin E (Reagin) and Allergy

D. R. STANWORTH
Department of Experimental Pathology, University of Birmingham

A tissue-sensitizing factor found in the sera of allergic subjects has been identified as a unique immunoglobulin, IgE. Investigations of its mode of action could lead to the development of new forms of treatment.

FIFTY years ago Prausnitz showed that it was possible to sensitize sites on his forearms by the intradermal injection of serum from one of his allergic patients (Küstner) who was hypersensitive to fish[1]. The injection of fish extract into the same sites 24 h later evoked immediate weal and erythema reactions similar to those shown by the patient himself (and by other fish-sensitive individuals) in response to the direct intradermal injection of fish extract.

This observation was a historic "landmark" in a field which has not always been noted for objectivity. Besides demonstrating that human hypersensitivity of this immediate-type could be transferred to normal tissue, outside the influence of the allergic individual, it meant that a passively induced reaction could be restricted to a localized area of the skin with minimal discomfort to the non-allergic recipient. Of even greater significance, however, was the inference that immediate hypersensitivity (unlike that of the delayed type, of which tuberculin sensitivity is an example) was mediated by a humoral factor.

There soon followed similar demonstrations of the local transfer of human hypersensitivity to many common inhalents (such as grass pollens, animal danders and house dusts); the Prausnitz–Küstner (P–K) test, as it is known, being used as an alternative to direct skin testing in the diagnosis of hay fever and allergic asthma. Its principal application, however, has been in the experimental study of immediate-type hypersensitivity; where, until a few years ago, it offered the only satisfactory means of assay. Consequently attempts to characterize the skin sensitizing factor more fully have been seriously handicapped.

Early investigations showed this serum constituent to resemble antibodies which appear in the circulation of humans and animals in response to conventional immunization procedures. But it seemed to lack certain properties commonly associated with immune antibodies, such as the capacity to form a precipitate and to fix complement when combined with specific antigens *in vitro*. For these reasons, some investigators[2] preferred to reserve judgment on its antibody status by terming it "atopic reagin" ("atopy" denoting a form of human hypersensitivity in which there was evidence of a hereditary predisposition, the sensitizing substances being referred to as "atopen"). The factor demonstrable in the serum of individuals with immediate hypersensitivity of the asthma–hay fever–urticaria type, has since been termed "reagin" and it has been customary to refer to the provoking agents (in inhalents, foods and so on) as "allergens".

P–K testing revealed that reagins become firmly "fixed" in normal isologous human skin where they are detectable (by subsequent allergen challenge) several weeks after the transfer of the allergic serum. In contrast, antibodies produced by the immunization of rabbits with allergenic substances (such as pollen extracts and egg protein) failed to fix to human skin; although unlike reagins, they could passively sensitize the skin of heterologous guinea-pigs for relatively short times. Human antibodies (γG type) against diphtheria toxoid likewise disappear rapidly when injected into isologous human skin (with a half-life of 12 h)[3], whereas reagins transferred isologously have been estimated[4] to have a "half-life" of 15 days.

Quantitative P–K testing[5] based on the accurate measurement of the areas of weals produced on the backs of normal recipients showed that a maximal skin response was achieved with a time interval of about 50 h between transfer of allergic serum and challenge with specific allergen. Once this was effected, however, a weal and erythema reaction developed rapidly with the weal approximately doubling in area during 10–20 min after introduction of the allergen. The susceptibility of reagins to relatively mild heat treatment was also confirmed[5]. Similar conditions are used in the destruction of the complement activity of immune sera, but the addition of fresh normal human serum to heated allergic serum fails to restore P–K activity[6] and other evidence indicates that reagins do not depend on the complement system for their activity.

Reagins were also found to differ from immune (7S type) antibodies in their inability to cross the placenta. This situation is obviously fortunate for the offspring of allergic women, as is the apparent absence of reagins from human colostrum. It has been attributed by some investigators to the macroglobulin (19S) antibody nature of the tissue sensitizing factor, which was thought to be of sufficiently large molecular size to be retained by the human placenta's supposed sieving mechanism. But extensive studies by Brambell and his associates[7], and others, have indicated that the placental transmission of immunoglobulins is a highly selective process (controlled by sites located within their Fc regions).

The biological properties of reagins revealed by these early investigations, based principally on P–K testing, are summarized in Table 1. This was the position around 1940, when techniques of free-solution electrophoresis and ultracentrifugation were first applied to the fractionation of plasma proteins. Although such physico-chemical procedures offered better means of separating complex protein mixtures than had been previously possible, by salt or low temperature-ethanol precipitation, they were essentially analytical tools. Nevertheless, electrophoretic analyses of the sera of animals before and after immunization provided the first evidence of the γ globulin nature of precipitating antibodies[8]; while corresponding ultracentrifugal studies indicated a size heterogeneity (antibody activity being associated with both 7S and 19S components).

It was naturally hoped that a similar approach would provide more convincing evidence of the antibody nature of reagins; but this was thwarted by practical difficulties. It was established, however, that reagins were electrophoretically faster than immune γ globulins, moving in the β region (where

Table 1 Main Biological and Physico-chemical Properties of Reagins (γE-Antibodies)

(1) Bind firmly to isologous, and closely related heterologous, tissues
(2) Heat labile (destroyed by 56° C for 1 h)
(3) Not dependent on complement
(4) Fail to cross the placenta
(5) Move in the "fast γ" region on electrophoresis
(6) Sediment near to 8 S

19S type immune antibodies were also found). But this conclusion was very much an extrapolation, and the minute amount of skin sensitizing factor present in allergic sera could have been moving in the electric field in combination with a major constituent. More refined preparative fractionation procedures were required.

Physico-chemical Characteristics

As in the characterization of many other minor active protein constituents of biological fluids, it was the advent of zone-fractionation procedures which gave the first definitive indication of the physico-chemical characteristics of the skin sensitizing factor. Thus, zone electrophoresis of allergic sera in starch blocks[9] confirmed that reagins moved in the "fast γ" (slow β) region; whilst zone-centrifugation in buffered sucrose gradients[10] showed clearly that they sedimented in the 7S region (and were not macroglobulins, as had been suggested to explain their failure to cross the placenta). There were, of course, limitations to this type of correlative approach because each of the major serum electrophoretic fractions, including the γ fraction, comprised several components. It was at this stage, however, that the application of highly-specific and sensitive immunological techniques began to compensate for the shortcomings of the physico-chemical procedures. Studies on the monoclonal γ globulins, isolated in large quantities from the sera of patients with multiple myelomatosis and Waldenström macroglobulinaemia, led to the production of specific antisera which distinguished three major immunoglobulin classes[11]: γG or IgG (previously referred to as 7S γ globulin): γM or IgM (previously referred to as 19S macroglobulin) and γA or IgA (a newly discovered third class[12], which when isolated from normal human serum by a zinc precipitation procedure was found to comprise a major 7S component, with minor amounts of polymerized material, and which migrated in the fast γ region on electrophoresis). It was established that the three major immunoglobulin classes then known possessed common light polypeptide chains, but distinctive heavy chains (Fig. 1).

The problem then was to show that skin sensitizing activity was a property of one (or perhaps more) of these antigenically distinguishable immunoglobulins. Antigenic and physico-chemical analysis of fractions of allergic human serum separated by chromatography on DEAE-cellulose (which provided a high degree of resolution of the various classes of immunoglobulin) revealed maximal P–K activity in a fraction in which

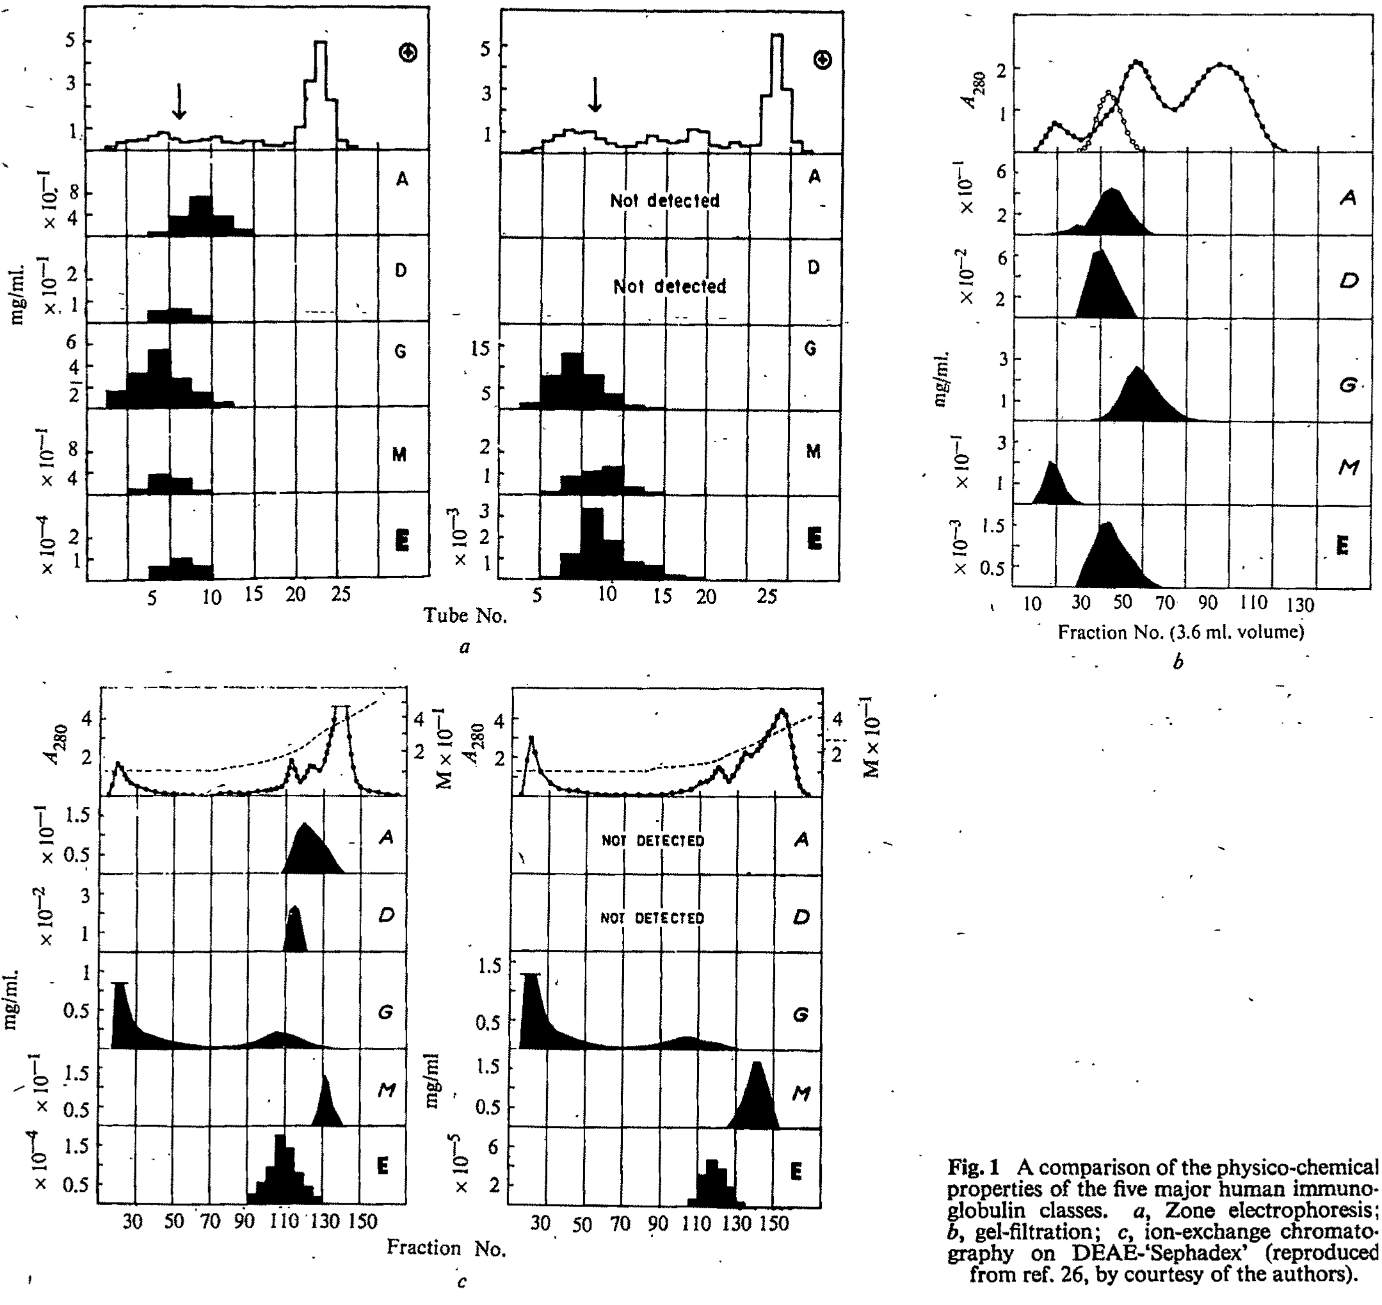

Fig. 1 A comparison of the physico-chemical properties of the five major human immunoglobulin classes. *a*, Zone electrophoresis; *b*, gel-filtration; *c*, ion-exchange chromatography on DEAE-'Sephadex' (reproduced from ref. 26, by courtesy of the authors).

only electrophoretically fast 7S γG globulin could be detected. As Fig. 2 shows, this was in an elution position well ahead of any detectable γM globulin; and even ahead of any γA globulin detectable by immunodiffusion analysis using specific antisera[13].

This latter observation was particularly significant, at a time when many claims were being made that reagins were γA globulins. These were based on such evidence as the recovery of P–K activity in highly purified γA globulin preparations[14], the removal of activity from allergic sera by absorption with specific sheep anti-human γA globulin antiserum[15] and the blockage of P–K reactions by normal human γA globulin or its isolated heavy chains[16]. They were of obvious teleological appeal as γA globulin had been found in high levels in nasal and other secretions, where it supposedly acted as a "front-line" defensive agent. But a lack of correlation was observed between reagin activity and γA globulin distribution in DEAE cellulose chromatographic fractions of allergic sera[13]; and other studies[17] suggested that P–K activity was associated with a minor component of the sera of hypersensitive individuals, which had appeared as a contaminant in the supposedly pure γA globulin fractions investigated previously.

Were reagins a unique type of immunoglobulin (a prospect on which I had speculated in 1963 (ref. 18))? The discovery of a new human immunoglobulin class (IgD or γD)[19], which resembled γA globulin electrophoretically, seemed a possibility; but several independent investigations suggested this immunoglobulin did not possess skin sensitizing activity.

Reagins were found, however, to have unusual physicochemical characteristics as well as distinctive biological properties (for antibodies). For example, the gel filtration of sera of people sensitive to ragweed (on 'Sephadex G200'[20]) led to the recovery of maximal P–K activity slightly ahead of the 7S peak containing the γG and γA globulins, but well behind the 19S peak containing the γM globulin. Furthermore, reagins in such sera were found by density gradient ultracentrifugation[21] to possess a sedimentation coefficient of 7.7S (7.4–7.9S range)—significantly greater than human γG and γA globulins. It also seemed significant that the reagin-like antibodies, occurring naturally in some animals (such as the dog) and induced artificially in others (for example, rats and rabbits), had sedimentation coefficients greater than 7S but much less than 19S (Table 2).

Table 2 Sedimentation Characteristics of Reagin-type Antibodies formed in Various Mammalian Species (as determined by Density Gradient Ultracentrifugation)

Species	Mode of antibody formation	Sed. coeff. (S°)
Human	Spontaneously	>7.4 S–7.9 S
Dog	Spontaneously	6.8 S–10.1 S
Rat	Experimentally	>7 S, ⩽19 S
Rabbit	Experimentally	>7 S, ⩽19 S

Further evidence that reagins were probably a unique class of immunoglobulins was obtained by Ishizaka and his associates[22], who isolated active preparations by application of a multi-step procedure to the fractionation of pools of sera from individuals showing marked hypersensitivity to ragweed pollen and who developed highly sensitive radioimmune-diffusion assays as *in vitro* alternatives to the P–K test for the measurement of the reagin in the isolated fractions. Reagin preparations thus obtained were used to produce anti-reagin antisera, which were rendered specific by absorption with the major classes of immunoglobulin and which were used in radioimmunoelectrophoresis to provide evidence that a radiolabelled ragweed allergen (E) preparation combined with the reagin isolated from ragweed-sensitive individuals' sera.

Ishizaka and associates[23] suggested that reagin activity was carried by a unique immunoglobulin which they tentatively termed "γE" (in view of its specific binding capacity for ragweed allergen E). Despite the evidence presented in support of this idea, however, some investigators felt that such claims were perhaps a little premature until chemical evidence was available to suggest the existence of a unique type of polypeptide chain.

Myeloma Protein

The final evidence that reagins were a unique class of immunoglobulins came with the isolation of an atypical myeloma protein (originally designated "IgND"), from the serum of a patient ("ND") with myelomatosis and Bence Jones proteinuria[24], which lacked the antigenic determinants characteristic of the heavy polypeptide chains of the then known immunoglobulin classes (γG, γM, γA and γD) while possessing similar light chain determinants (of sub-type L). Like myeloma γA and γD globulins, this atypical protein moved in the "fast γ" region on zone electrophoresis (Fig. 1); but it was eluted slightly ahead of these classes of immunoglobulin during chromatography on DEAE-'Sephadex'. Of greater significance, however, was its elution position during gel-filtration on 'Sephadex G100', where it emerged after the γA globulin but just ahead of the γG globulin. Furthermore, free solution ultracentrifugal analysis[25] showed the atypical myeloma protein (IgND) to possess a sedimentation coefficient (S°20, W) of 7.92S (and molecular weight 196,000 from Archibald analysis); a value very similar to that which had been assigned to the reagins in sera of ragweed-sensitive individuals on the basis of the observed rate of sedimentation of the P–K activity in buffered sucrose gradients.

This similarity in sedimentation coefficient between the new type of myeloma protein and reagin could have been fortuitous, but it seemed significant that the myeloma protein isolated from the serum of patient "ND" was the first known type of immunoglobulin to have similar size characteristics to the skin sensitizing factor. Other observations were beginning to suggest a relationship between the new class of immunoglobulin and reagin. For example, by means of a radio-immunosorbent technique based on the use of 'Sephadex'-coupled antibody directed specifically against the new myeloma protein[24], a significantly elevated concentration (5,900 ng/ml.) of an antigenically similar protein was detected in the serum of an individual with allergy to dog dander; in comparison with the much smaller amounts (100–700 ng/ml.) found in normal sera. Later comparative studies[26] of the antigenic characteristics of the new myeloma globulin and the reagin-rich fraction (designated γE) isolated from sera of ragweed-sensitive individuals were to provide evidence of a close structural relationship between the two proteins.

The most convincing evidence that the myeloma protein (IgND) was a pathological counterpart of reagin was obtained, however, from inhibition-P–K testing in a normal human recipient[27]. The intradermal injection of the myeloma protein mixed with, or 24 h before, the sensitizing serum (at a dosage of 5–50 times in excess of the level of reagin in the serum) completely inhibited a weal and erythema response on subsequent challenge with the specific allergen (isolated from horse dandruff). Thus not only was the myeloma protein (IgND) antigenically similar to reagin, it also seemed to have its striking affinity for isologous tissues. There was no evidence, however, that the myeloma protein could bind antigen (that is allergen). Thus it seemed to be a pathological counterpart of a new immunoglobulin class of which reagin was a normal representative, just as an over-production of monoclonal forms of the major immunoglobulin classes has often been seen in plasmocytic and lymphocytic neoplastic disorders.

Immunological and chemical studies[25] indicated that the myeloma protein IgND was a new class of immunoglobulin, with similar light chains to those in the other four classes, but distinctive heavy polypeptide chains somewhat larger (75,500 molecular weight) than those in the other immunoglobulins. Consequently at a meeting initiated by the World Health Organization in Lausanne in 1968 (ref. 28) it was decided that there was sufficient evidence to conclude that reagin was representative of this new class of immunoglobulin, which it was proposed should be designated "IgE" or "γE".

The availability of the myeloma protein offers a means of chemically characterizing reagins, and ultimately of explaining their unusual biological properties in structural terms. It has been calculated that the chance of finding a case of monoclonal production of γ globulin of the E type is about one in 50,000 that of finding a more common case of myelomatosis; so the protein isolated from the serum of the Swedish case has proved particularly valuable and highly sought after. Fortunately, however, a second case has been reported[29] in the United States, who has clinical manifestations similar to those seen in the case originally reported by Johansson and Bennich in Sweden.

Already the two γE myeloma proteins are providing important information about the role of the antibody (reagin) in immediate hypersensitivity reactions. For example, the myeloma IgE has been degraded into different types of polypeptide fragment by means of proteolytic and chemical cleavage procedures, and tested the ability of these to inhibit skin sensitization by the reagins (γE antibodies) in the sera of individuals sensitive to horse dandruff and grass pollen[30,31]. Of the various types of fragments tested (originating from the different parts of the IgE molecule as illustrated schematically in Fig. 2) only those incorporating the Fc region had the inhibitory activity of the parent molecule. Similar findings have resulted from inhibition studies in sub-human primates (for example, rhesus monkeys and baboons) which, like non-allergic humans, have proved receptive to sensitization by human γE antibodies but which (for obvious reasons) are now preferred as test recipients.

Other inhibition sensitization tests in baboons[32], have involved myeloma IgE preparations which have been reduced to various extents with 2-mercaptoethanol, to ascertain the importance of the relatively large number of disulphide bridges in maintaining the conformational integrity of that part of the IgE molecule involved in tissue binding.

Binding of IgE

Inhibition tests with proteolytic cleavage fragments of myeloma IgE have led to important conclusions about the binding of antibody IgE to isologous (or closely related heterologous) tissue. They suggest that, like the myeloma protein molecules, the antibody (reagin) molecules similarly bind to the tissue receptors through sites within their Fc regions (Fig. 3). Sites within the Fab region of the cell-bound antibody molecules are thus free to react subsequently with antigen (allergen) in the usual manner. In contrast, the myeloma IgE molecules (like most myeloma forms of the other immunoglobulin classes) cannot combine with antigen (Fig. 3). If, on the other hand, combination with the target cells had been found to occur through the Fab regions of the antibody IgE molecule, it would have been necessary to infer that immediate-type hypersensitivity is an auto-immune phenom-

Fig. 3 Diagrammatic comparison of the properties of antibody and myeloma γE molecules, showing mode of attachment to target cells (that is by means of sites in the Fc regions). *b*, Mode of interaction of γG type cytolytic antibody molecules with target cells, showing subsequent interaction of complement (c′) with sites located in the Fc regions.

enon involving the production of antibody against self-cell surface antigen (as occurs, for example, in autoimmune haemolytic anaemia.

Thus it is now possible to start explaining how the immunological reactions occurring at tissue mast cell surfaces bring about the pharmacological manifestations characteristic of hypersensitivity reactions of the immediate-type. Whether such reactions are mediated by γE-type antibodies in passively sensitized human tissues (as, for example, in the classical P–K test), or by non-reaginic γG-type antibodies in the heterologous tissues of guinea-pigs passively sensitized with the serum of experimentally immunized animals, the sequence of events is remarkably similar. The antibody plays a crucial role, not only in the initial sensitization process (which, of course, occurs spontaneously in the allergic individual or the actively sensitized guinea-pig), but also in the manner in which it subsequently interacts with specific antigen (allergen) to activate the enzyme system supposedly responsible for effecting the release of histamine, 5-hydroxytryptamine and other pharmacologically active substances. The elucidation of the structural basis of these different, but complementary, functions of tissue-sensitizing antibodies poses a problem of protein characterization. Moreover, it seems likely that studies along these lines on γE globulins will throw light on the mode of action of other classes of immunoglobulin fulfilling other roles on the surfaces of other types of cell (for example, receptor immunoglobulin or lymphocytes).

The emergence of *in vitro* alternatives to the P–K test in humans, and the PCA test in sub-human primates, is facilitating the delineation of the biochemical events set in train by the combination of cell-bound γE antibody and allergen. Such systems are based on passive sensitization by γE antibodies of chopped human lung[33], normal human leucocytes[34], chopped monkey skin[35] or other suitable primate tissue. The histamine released from the washed sensitized cells or tissues as a result of interaction with specific allergen can be measured accurately (down to levels of a few nanograms) by bioassay using isolated guinea-pig ileum, but a spectrofluorometric procedure involving coupling with ophthalaldehyde[36] has been adopted as a satisfactory chemical alternative. These indirect procedures have obvious advantages over the previous pharmacological approach to the study of immediate hypersensitivity reactions, which involved the direct assay *in situ* of the histamine liberated on presentation of the specific antigen to the actively sensitized tissue set up in an organ bath. Their application has provided convincing evidence[37,38] that the allergen-induced release of histamine and other mediations of immediate-type hypersensitivity reactions is accomplished by a multi-step, energy-requiring process to which the glycolytic pathway is essential. There are precise *p*H and temperature requirements, and a dependence on calcium and magnesium ions.

It is important, however, to distinguish this process from cytolytic reactions in which destruction of the cell membrane is effected through the combined agency of anti-cell antibody and complement. In contrast, γE-mediated histamine release has been shown (from K^+ efflux studies[38]) to be an active secretory process which is not intrinsically injurious to the target cell. Thus, there is a fundamental difference in the release mechanism initiated by sensitizing antibodies (for example of the γE type), in the absence of complement, and those more drastic processes induced by cytolytic antibodies (for example of the γG type) with the aid of the complement system. As I have already implied (Fig. 3), the type of process evoked depends on the manner in which the antibody is presented to the cell. Antibodies of the γE type seem particularly suited to binding to histamine-containing cells through sites on their Fc regions, and to possess within their own structures sites capable of direct action on the target cell membrane (or other cell constituents). On the other hand, cytolytic antibodies (whether directed against cell membrane antigen, or coating antigen) react initially through sites within their Fab regions, a subsequent intermolecular interaction between their free Fc regions[39] supposedly leading to the activation of the complement system responsible for the ensuing lysis.

Tertiary and Quaternary Structure

The problem now is to establish how the interaction of the cell-bound γE antibody (reagin) with allergen triggers off the events outlined, which seem (from microscopic studies of viable cell preparations) to be associated with characteristic morphological changes[40] in the target cells, involving the release of their histamine-containing granules. The amino-acid sequencing in progress on the two myeloma IgE preparations should provide important information as might the characterization of the relatively large carbohydrate (11.7%) prosthetic group. Furthermore, studies of the inhibitory capacity of proteolytic cleavage fragments of the myeloma IgE (mentioned earlier) are being extended to smaller and smaller fragments, with the hope of isolating a readily characterizable low molecular weight peptide retaining tissue-binding activity. It is becoming inincreasingly obvious, however, that the peculiar biological properties of γE antibodies (as well as those of the less efficient γG type sensitizing antibodies produced in experimental animals) will be explicable in terms of unusual tertiary and quaternary structural characteristics. It seems likely (as discussed fully elsewhere[41]) that the two structural features which will prove to distinguish sensitizing antibodies will be an ability to bind strongly to complementary tissue sites with no accompanying loss in the conformational integrity of their Fc region (which can soon occur as a result, for example, of relatively mild heat treatment); and the possession of sufficient flexibility within the "hinge regions" to permit the transmission of a critical allosteric change resulting from combination of allergen with sites in the Fab regions of adjacent cell-bound molecules.

There is evidence[42] that antigen-induced conformational changes can occur in free solution, in rabbit antibody directed against commonly used antigens such as bovine serum albumin and horse ferritin, and these lead to the exposure of new antigenic determinants within the Fc regions. It seems reasonable to conclude, therefore, that similar conformational changes could occur in γE-type antibody molecules in combination with specific allergen (as already proposed[43]). Moreover, if the γE antibody is already anchored to the target cell surfaces, through sites within its Fc region, newly exposed side chains could be brought into critical juxtaposition with points on the cell where activation of the appropriate enzyme system would occur (Fig. 4). Indeed there is evidence (from inhibition studies with aggregated IgE) that association of IgE molecules might lead to the formation of "tissue activation sites" which are distinct from the tissue binding sites in monomeric (antibody and myeloma) IgE molecules; and it is possible that activation sites are similarly formed in the Fc regions of adjacent cell-bound sensitizing antibody molecules as a result of the bridging by specific allergen, for which there is increasing evidence[45,46] and which presumably involves the cross-linking of sites within the antibody Fab regions (Fig. 4). The critical question then to be answered is whether groups exposed from the Fc regions of the cross-linked antibody molecules act cooperatively to form the activation site. In this event, the activation site could be linked to the active site of an enzyme, which of course is usually contained within a single polypeptide chain. Alternatively, the side-chains which are supposedly exposed in the Fc regions of the sensitizing antibody molecules might be proved to exert an independent effect on the target cell.

In attempting to decide between these alternatives it is worth considering the results of studies designed to short-circuit the histamine release process initiated by reagin-allergen combination. These involve the use of alternative, artificial, ways of cross-linking the γE molecules, and seem to lead to pharmacological responses similar to those of classical immediate sensitivity reactions. Apart from the pre-aggregation

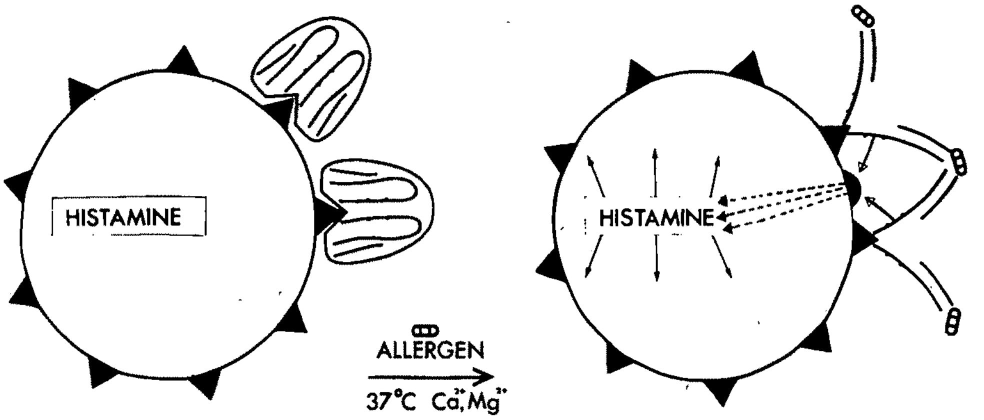

Fig. 4 Postulated mode of interaction between cell-bound γE antibodies and allergen leading to the triggering of release of vasoactive amines (modified from ref. 45).

of the γE molecule before presentation to the target cell (as already mentioned), it is possible to effect histamine release in human or monkey skin by bringing about the cross-linking of the cell-bound γE molecules with antibody directed specifically against determinants within their Fc regions. Thus, it can be demonstrated[46] that the intradermal injection of specific anti-human IgE antiserum induces an immediate oedematous and erythematous reaction similar to that observed in the P–K test.

Tissue Activation Sites

It is suggested that, as in the classical reagin-allergen mediated reaction, the exposure of tissue activation sites within the Fc region of the γE molecule triggers the release of the pharmacologically active mediators. But the cross-linking process which induces the required conformational change is less efficient than that effected by the cross-linking of the Fab regions of the γE antibody molecules by allergen. This might be expected by reference to the model shown in Fig. 5, which suggests that a force applied at position A (at maximum distance from the fulcrum) would be the most effective way of forming the activation site at position S; but application of a force at position B would accomplish the same effect in a less efficient manner. This analogy could offer an explanation of the skin reactions effected by the action of anti-IgE antibody, as well as that elicited by other agents such as protein A (an antigenic component of *Staphylococcus aureus*) which has an unusual capacity for combination with the Fc regions of immunoglobulins[47] and which presumably acts too by cross-linking cell-bound γE molecules[48].

Alternatively, it seems likely that the conformational changes necessary for the formation of tissue activation sites can also occur in non-specifically aggregated IgE (brought about, for example, by lyophilization of monomeric myeloma IgE). As already mentioned, IgE treated in this way is also capable of effecting an immediate release of histamine on injection into human or monkey skin[46]. Thus, perhaps surprisingly, in spite of the non-specific nature of the aggregation process, a conformational change seems to be induced within the Fc regions similar to that resulting from antigen-mediated association of the γE molecules. This is directly analogous, however, to the situation with regard to the association of human (and rabbit) γG molecules where biological activities (for example heterologous skin reactivity and complement fixability), and new antigenic determinants (similar to those formed on specific antigen–antibody combination) are induced by non-specific denaturation treatments. Moreover, recent studies[49] on the nature of the structural changes shown by γG globulins as a result of physical or chemical treatments suggest that here too association is initiated by preliminary (non-covalent) interaction between the Fab regions of the molecule but in this case, of course, without the agency of the antigen. This, it seems, leads to an unfolding of the Fc regions, similar to that occurring in antibody γG molecules on combination with antigen, thereby providing scope for intermolecular Fc interaction with formation of the sites of the various biological activities shown by aggregated γG globulins. Thus what might be expected to be a random aggregation process seems to be a highly ordered polymerization, directed presumably by the initial intermolecular reactions of the Fab regions of the monomer molecules.

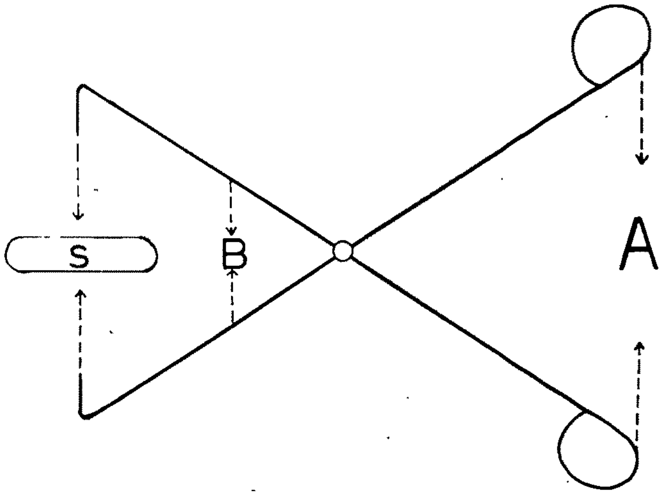

Fig. 5 Model illustrating various methods of inducing an allosteric transformation within cell-bound γE antibody molecules.

The complete characterization of these crucial tertiary and quarternary structural changes could have an important bearing on the explanation of other immunological phenomena. As far as immediate hypersensitivity is concerned, the need now is to characterize the "tissue activation sites" formed in γE globulin molecules on association, and to elucidate the nature of their "substrate" located on the target cells. Various possibilities are being considered. For example, could it be that reagin-allergen combination on the cell surface activates a phospholipase responsible for hydrolysis of membrane phospholipid[50]; or perhaps an esterase is activated, in a similar manner to that implicated in complement mediated cytolytic reactions[51]. Another possibility[52] is the stimulation of the adenyl-cyclase system, which is located on the inner surface of cell membranes (where it catalyses the conversion of ATP to cyclic AMP) and which has been shown to be involved in the action of certain hormones[53]. It could be more than fortuitous that certain polypeptide hormones (such as ACTH) which act in this manner are also potent histamine liberators[54]. It will, however, be important to exclude the simpler possibility that the primary triggering mechanism is a physical shearing of the cell membrane ("rigidification", as one investigator[44] has termed it), brought about by the association of surface-bound γE antibody molecules.

Future Tasks

Although the initiative is now passing to biochemists and biophysicists, many other aspects of the behaviour of γE antibodies require immunological investigation. For example, with the aid of specific antisera prepared against the myeloma proteins, it is possible to begin to identify the sites of binding of γE antibodies on their target cells; as well as their sites of synthesis in human lymphoid tissues. Immunofluorescence studies[55] have provided evidence that γE antibodies are formed locally in the respiratory and gastro-intestinal tract where they probably become involved in allergic states affecting these organs. In any studies of γE antibody synthesis it will be important to answer the fundamental question about the definition of the factors which govern the production of sensitizing rather than immunizing antibodies, Here the use of animal models[56] is particularly revealing, because it is becoming apparent that the reagin-like antibodies produced in species like the rat, the rabbit and the mouse closely resemble the human γE antibodies. The chemical nature of the allergen, and its form and mode of administration are proving important factors in deciding the nature of the resultant antibody response, as is the influence of other classes of antibody produced concomitantly. Through such investigations it is becoming possible to define the immunological basis of "desensitization" (that is hyposensitization), a prophylactic measure which has been practised by clinical allergists for several years and which is thought to encourage the production of γG-type antibodies which bind allergen preferentially (besides producing effects at the cellular level).

Other possible new forms of prophylaxis are suggested by studies[57] on the prevention of the passive sensitization of baboons with allergic human serum by the systemic administration of myeloma IgE, where a refractory state persisting for about a week has been induced by the intravenous injection of about 10 mg protein/kg body weight. The ultimate aim of this approach would be the isolation of a low molecular weight peptide fragment of the myeloma IgE, which retained tissue-binding activity and which could be made available in large amounts by application of modern methods of polypeptide synthesis.

Another advantage to the clinical allergist resulting from the discovery of the myeloma proteins has been the development of methods of measuring IgE concentration which do not rely on tissue or leucocyte sensitization. For example, radioimmunosorbent assay procedures involving the use of anti-IgE[24] or specific allergen[58] coupled chemically to dextran (or some other suitable insoluble carrier such as a cellulose carbonate derivative)[59] have been used to determine the total, or antibody, IgE levels in the sera of patients, and the use of radiolabelled antibody[59] has rendered the single radial diffusion test sufficiently sensitive to detect the relatively low levels of IgE in allergic sera by autoradiography.

It is important to recognize, however, that γE antibodies need not necessarily be deleterious, as suggested, for example, by studies[60] of the immune reactions occurring in the mucous membranes of the rat during the expulsion of an infecting nematode (*Nippostrongylus brasiliensis*). There is evidence of an association between a sharp rise in intestinal mast cells, an alteration of mucosal permeability (effected by vasoactive amines released from the mast cells) and the expulsion of the parasites. It is tempting to conclude, therefore, in this situation that γE antibodies are fulfilling a protective role (the so called "self-cure" mechanism[61]); and it may be significant that one of the few conditions (other than a hypersensitivity of the asthma–hay fever type, and atopic eczema) where very high serum IgE levels have been recorded is in human (as well as animal) parasitic infections.

Is this all you want when you buy NADH?

The extinction coefficient of the purest NADH is $6.22 \times 10^6 cm^2$/mole at 340 nm........... but this doesn't tell you how it performs in your **enzymatic reaction.**

That's why all Boehringer Mannheim nicotinamide coenzymes are assayed enzymatically as well as optically. When you use Boehringer Mannheim NAD$^+$, NADH, NADP$^+$ and NADPH you can therefore be sure that they are tested from a functional viewpoint.

Analytical specifications can be found in our catalogue. Please write for your personal copy.

ODUM: FUNDAMENTALS OF ECOLOGY

New Third Edition

574 pages. 227 figures with 63 tables. August 1971

£5.00

Here is a thoroughly up-dated review of the principles of ecology, world environments, and ecologic technology. Dr. Odum stresses man's environmental relationships and suggests solutions to his environmental problems.

The book's three parts: *Basic Ecological Principles*, *The Habitat Approach*, and *Applications and Technology* are abundantly cross-referenced so that each can be read, referred to, or taught separately.

This new revision is almost entirely rewritten to reflect today's great advances and increased interest in ecology. Completely new chapters include: Systems Ecology; Pollution and Environmental Health; and Space Travel. Dr. Odum emphasises such topics as crop ecology—world food production—the total energy environment—community development.

By Eugene P. Odum, *Professor of Zoology, University of Georgia.*

LENTZ: CELL FINE STRUCTURE:

An Atlas of Drawings of Whole-Cell Structure

437 pages. 184 illustrations. May 1971. **£4.80**

Information on biological ultrastructure has accumulated at a rapid rate and virtually all cell types have been examined with the electron microscope. Yet, due to the nature of the procedures necessary to view tissues with the electron microscope, it is difficult to obtain a complete picture of an entire cell in a single micrograph. Dr. Lentz has provided a solution to this problem through his new atlas. His collection of hand drawn and finely detailed diagrams permits all the information formerly available only through the study of numerous electron micrographs to be included in a single illustration.

A set of 35 mm black and white slides is available for use with or without the text.

SLIDES:

Cyclic Expression of Blood Group Determinants in Murine Cells and their Relationship to Growth Control

D. B. THOMAS
Department of Immunology, Middlesex Hospital Medical School, London W1

A model for antigenic variation is proposed on the basis of changes in the expression of blood group determinants during the cell cycle.

THERE is a correlation between the growth and surface properties of cells. The division of normal cells in culture is arrested at a critical density[1-3]. This "density-dependent inhibition"[4] of growth is less pronounced for tumours[5] and parallels their degree of malignancy[6,7]. Alteration of the surface membrane of neoplastic cells has been suggested as a mechanism for defective control of growth[1,8]. Consistent with such a proposal is the finding that virally transformed fibroblasts possess surface receptors for plant agglutinins[9,10] which normal fibroblasts express only during mitosis[11].

There are, however, several examples of change in the surface properties of tumours during cell division—an increase in electrophoretic mobility of human osteosarcoma cells[12], a decrease of surface immunoglobulin of human lymphomas[13], a decrease of H-2 alloantigens in the murine cell lines YCAB[14], JLS-V9[15], and the mastocytoma P815Y[16], and an increase of blood group H in HeLa cells during mitosis[17]. Such changes may reflect a common surface property of dividing cells.

The expression of blood group A on primary amnion cells in culture also varies with the growth conditions[17,18]. Franks and Dawson demonstrated that the number of A positive cells in cultures of the rabbit cell line, RK13, was higher during rapid division[19]. It was shown, by clonal selection, that antigen negative cells gave rise to both positive and negative progeny. I describe here the expression of blood group determinants B and H in synchronized cultures of the mouse mastocytoma P815Y and phytohaemagglutinin (PHA)-treated mouse lymphocytes, and propose a model for antigenic variation during cell division.

The mouse mastocytoma P815 strain Y was maintained in suspension culture in Fischer's medium supplemented with 10% horse serum. Cell synchrony was achieved by the double thymidine block procedure[20], as follows: an exponential culture (2×10^5 cells/ml.) was grown for 15 h with 2×10^{-3} M thymidine, 6.5 to 8 h in its absence and a further 8 h with 2×10^{-3} M thymidine. The cells were reincubated in fresh medium at a cell density of $2\text{–}3 \times 10^5$/ml. The degree of synchrony was monitored by serial cell counts and measurement of ^{3}H-thymidine incorporation into DNA. Cells had a mean generation time of 15 h.

Mouse mesenteric node lymphocytes were cultured with PHA (Wellcome Reagents Ltd, reagent grade, reconstituted to 5 ml. with distilled water) in Eagle's minimum essential medium (MEM) supplemented with 10% foetal calf serum. Control cultures were treated with PHA for 3 h before collection.

Cells were stained for blood groups B and H by indirect immunofluorescence. Cell suspensions (2×10^6; 200 µl.) were incubated with an equal volume of antiserum at the appropriate dilution (1/100 to 1/200) for 30 min at 3° C, washed three times with cold MEM, and incubated for 30 min at 3° C with 50 µl. of fluorescein-conjugated rabbit anti-human gamma-globulin (1/20 dilution, previously absorbed with an equal volume of mastocytoma cells). Cells were washed a further four times with cold MEM and examined with a Leitz Ortholux microscope under ultraviolet light. Controls for serological specificity were antisera absorbed with an equal volume of A-positive or B-positive human erythrocytes, or anti-A antiserum. Anti-B antiserum (Lot No. 70–52103) was a gift from Ortho Pharmaceuticals and anti-H antiserum ('Baxter' serum, activity for O and A human erythrocytes) was a gift from Dr K. L. G. Goldsmith, MRC Blood Group Reference Laboratory. For the determination of mitotic index, cells were lysed with 1% sodium citrate and the nuclei washed with cold methanol–acetic acid mixture (3 : 1 v/v). Air-dried smears were stained with May-Grünwald-Giemsa.

In P815Y cells, the expression of blood group determinants B and H was related to growth rate (Fig. 1). Resting cells (late log phase) were negative for B and positive for H. On transfer to fresh medium, an inverse change occurred in antigen expression during the exponential phase of growth. It was decided to study this event during the period of the cell cycle.

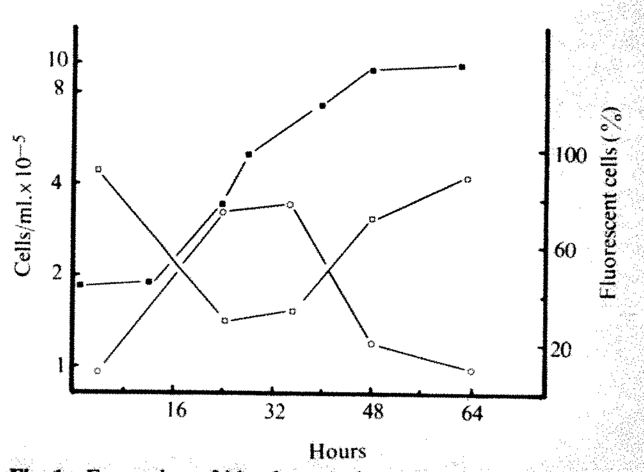

Fig. 1 Expression of blood group determinants B and H in an asynchronous culture of P815Y cells. ■, Cell number; ○, B positive cells; □, H positive cells.

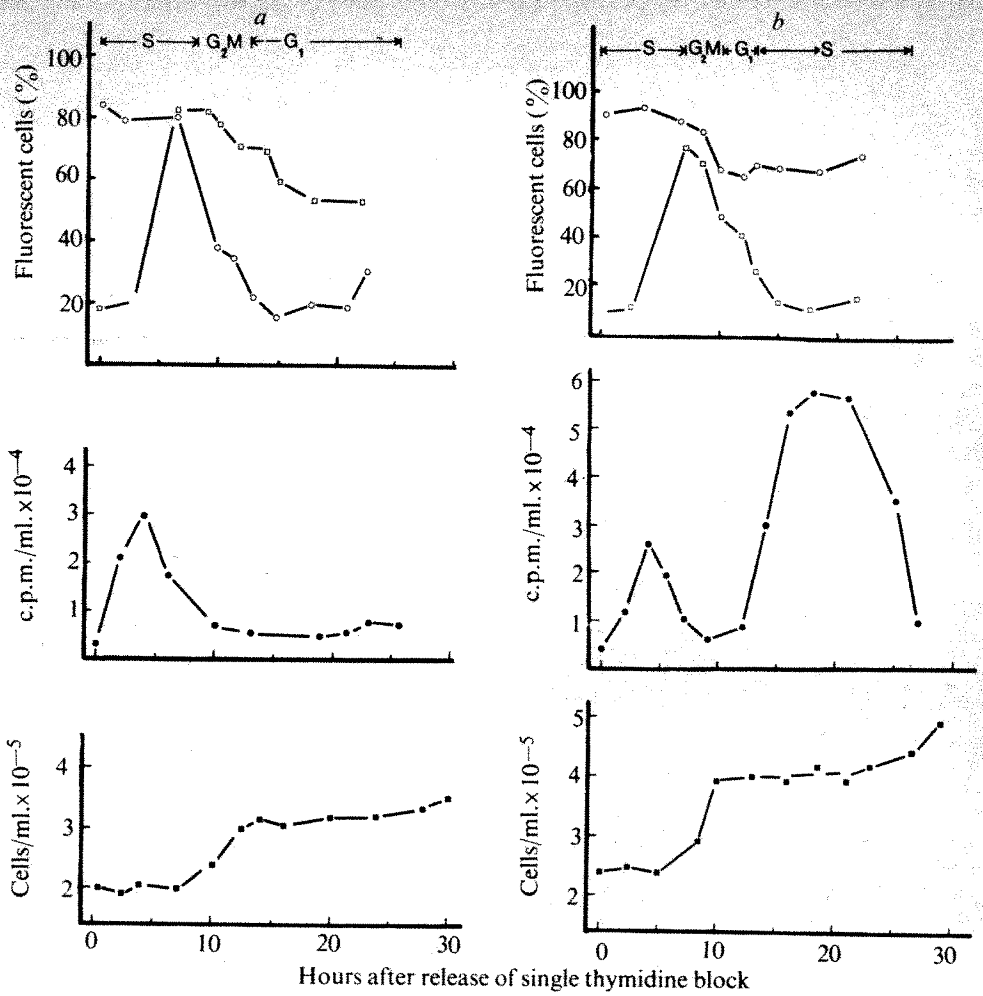

Fig. 2 Expression of blood group determinants B and H in synchronized P815Y cells. Conditions of cell culture were identical apart from the time of the second thymidine addition (7.75 h for *a*; 7 h for *b*). Cell samples (1 ml.) were removed at intervals and incubated with ^{3}H-thymidine (0.4 μCi/ml.) for 30 min. Cells were washed with MEM and the DNA was precipitated with 5% trichloroacetic acid. Precipitates were dispersed in 1% 'Triton X-100' and counted in a liquid scintillation spectrophotometer using a toluene phosphor. Samples of synchronized cells were analysed for cell number (■), ^{3}H-thymidine incorporation (●), blood group B (○), and blood group H (□).

In preliminary experiments, using the double thymidine block procedure, it was possible to obtain synchrony for two cell divisions occasionally (2 in 5). Failure to obtain more than one synchronous division is a common feature of different cell lines and synchrony procedures; the reasons remain obscure[21]. Appearance of a second peak of DNA synthesis was critically dependent on the release period between the first and second thymidine blocks. Also, the degree of synchrony was influenced by cell contact, spinner cultures being more successful than stationary cultures. This is illustrated in Fig. 2 where change in B and H expression was examined in cultures giving one (Fig. 2*a*) or two (Fig. 2*b*) synchronous cell divisions. Conditions of cell culture were identical apart from the time of the second thymidine addition; the sample in Fig. 2*a* was maintained as a stationary culture for the duration of the second thymidine block. In the absence of a second peak of DNA synthesis (Fig. 2*a*), G_1 cells were B^- and H^+. However, this is not always a feature of G_1 and the majority of cells in the second culture (Fig. 2*b*) were B^+ and H^- in this phase. Decay of synchrony and inability to express B was not a consequence of thymidine cytotoxicity. G_1 (B^- and H^+) cells were viable (>98% by dye exclusion tests) and exhibited asynchronous growth after a lag period of several hours. To decide whether the above changes occurred at mitosis or an early part of G_1, cells were released from a single thymidine block and cultured in the presence of the mitotic inhibitor, colcemid (Fig. 3). It is seen that H is maximal at mitosis. No quantitative difference was found for B expression in the interval between thymidine removal and complete mitotic arrest; different samples were equally positive for B at all dilutions of antiserum. Therefore expression of B and H at G_1 is related to the ability of cells to undergo further synchronous division. The difference in staining pattern for blood groups B and H in P815Y cells is illustrated in Fig. 4.

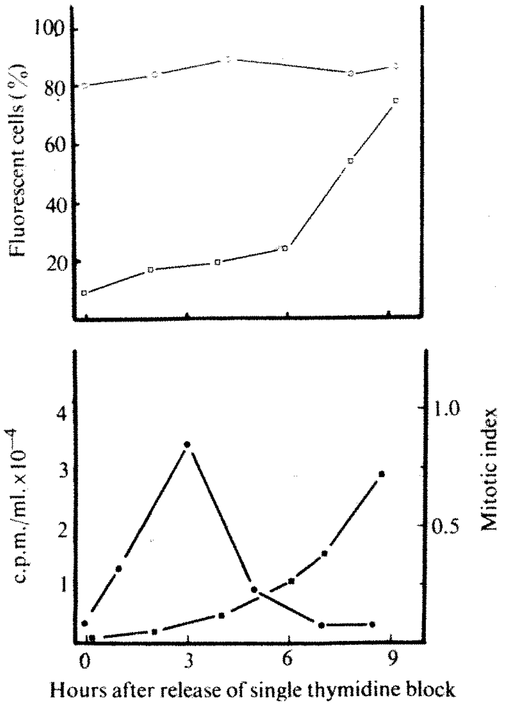

Fig. 3 Expression of blood groups B and H in P815Y cells after release of single thymidine block. An exponentially growing culture (2×10^5 cells/ml.) was exposed to 2×10^{-3} M thymidine for 15 h. Cells were washed and resuspended in fresh medium containing colcemid (0.04 μg/ml.). Samples were removed at intervals and examined for ^{3}H-thymidine incorporation (●), mitotic index (■), blood group B (○), and blood group H (□).

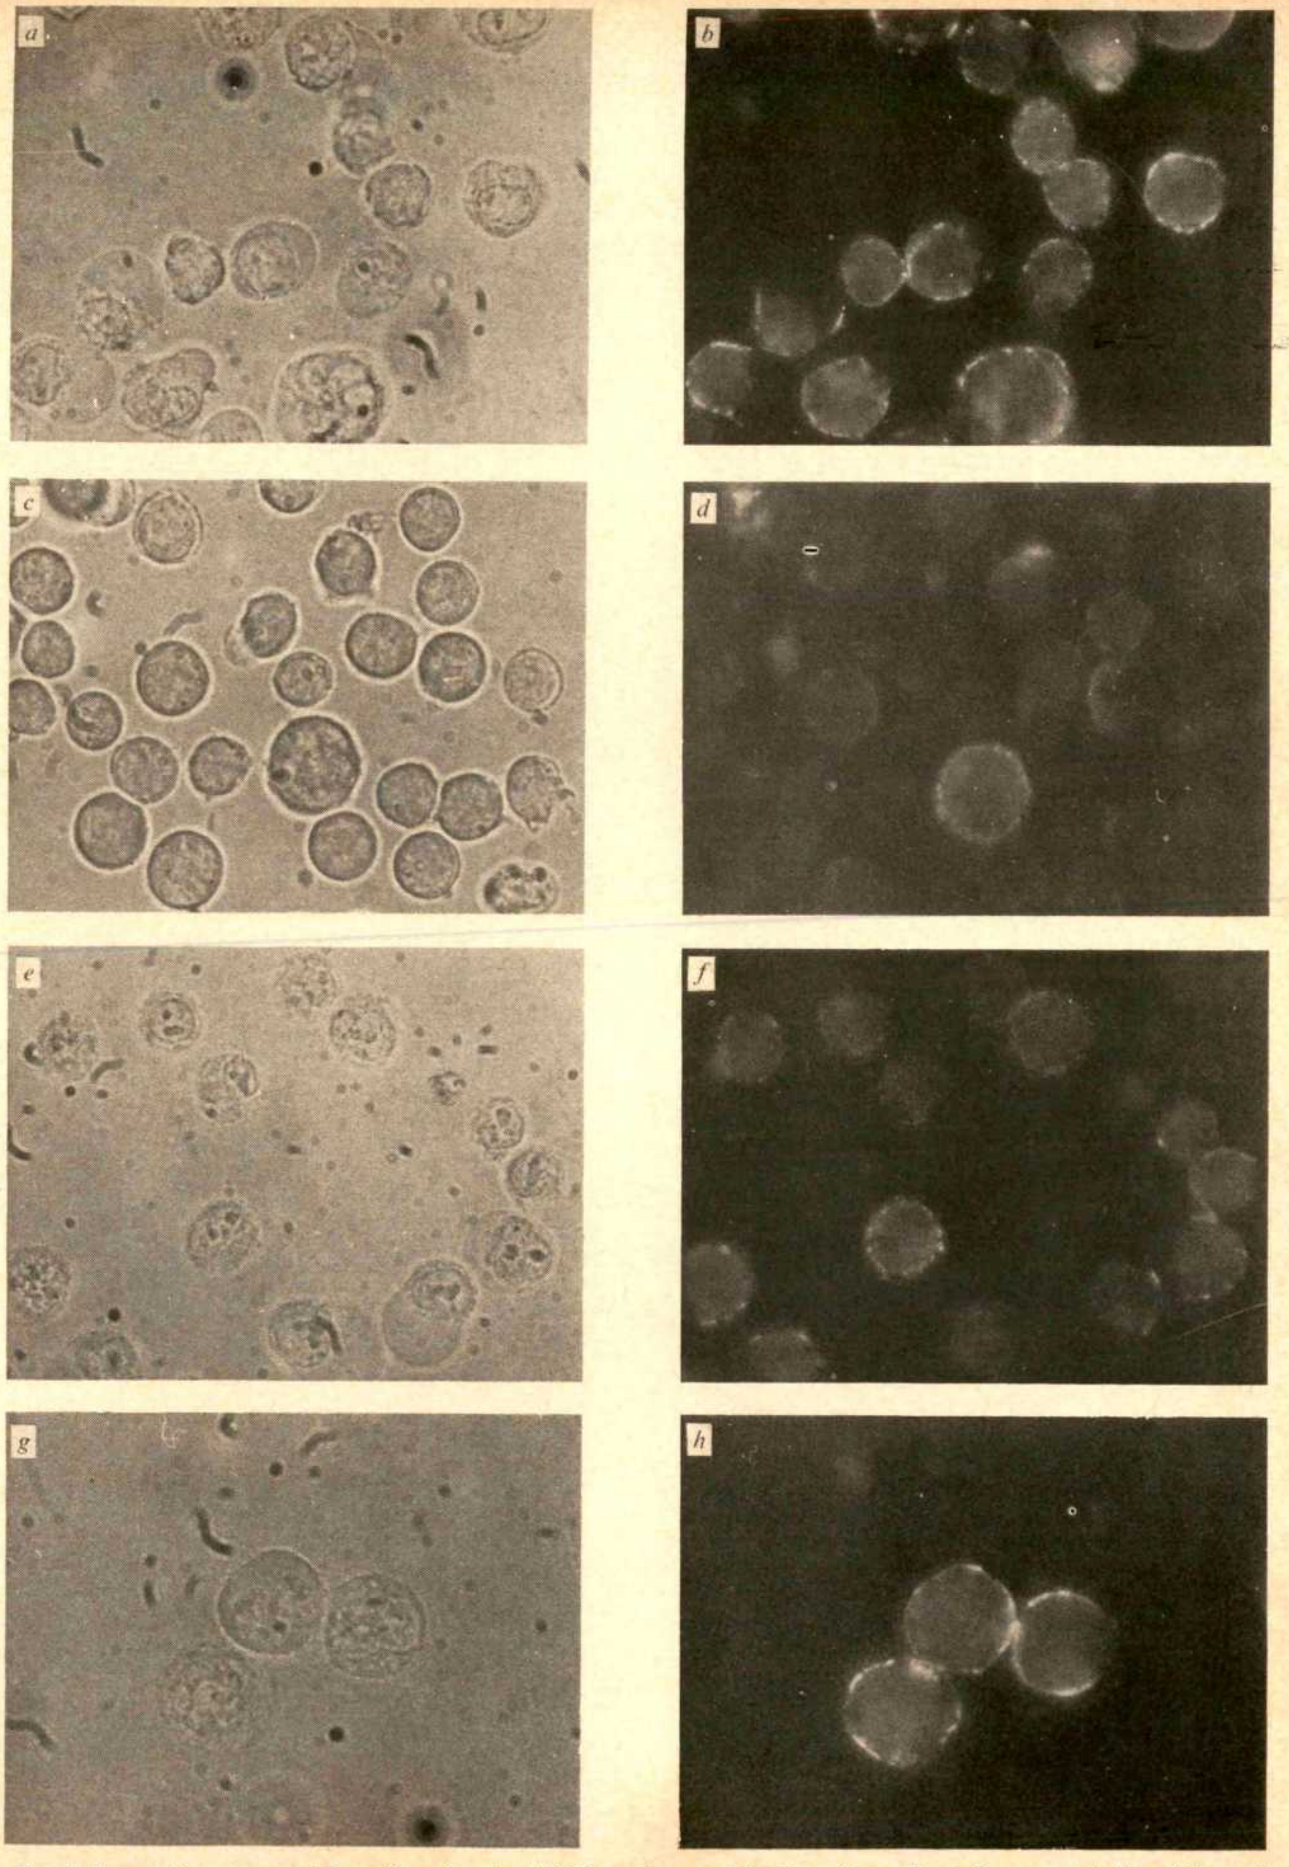

Fig. 4 Immunofluorescent staining of synchronized P815Y cells: *a* and *b*, H positive cells at G_1; *c* and *d*, B positive and negative cells at G_1; *e* and *f*, H positive and negative cells at S; *g* and *h*, B positive cells at S.

Preliminary experiments suggest that a similar change in B expression occurs in synchronized cultures of the murine leukaemia, L1210. Resting cells are B^-, thymidine blocked cells are B^+, and G_1 cells are B^- after one synchronous division. I have excluded the possibility that this restricted expression is only a feature of tumours by showing a similar occurrence for normal mouse by lymphocytes.

Lymphocytes represent a homogeneous population of resting, G_0, cells which divide only on contact with specific antigen or mitogenic agents such as the plant agglutinin, PHA. Also mouse lymphocytes are largely B^- (7–10% B^+ cells in mesenteric lymph nodes). Table 1 shows that B^+ cells were present in lymphocyte cultures after incubation with PHA. The number of positive cells was related to the PHA concentration, being maximal at or near the optimum mitogenic dose (Table 2). At earlier times (48 h, Table 1) the number of B^+ cells exceeded that of ^{3}H-thymidine-labelled cells. This finding suggests that expression of B is an early event of blast cell transformation. Appreciable agglutination of lymphocytes occurred after incubation with PHA and estimation of cell numbers was approximate. However, each cell with a typical lymphoblastoid appearance under phase contrast microscopy was also fluorescent. Appearance of B on PHA-treated lymphocytes is not strain specific; similar results were obtained with the strains Balb/C, CBA, C3H and DBA/2 all of which showed >20% B^+ cells at 48 h of culture. The occurrence of this surface change may prove useful as an additional index of lymphocyte transformation.

It was not possible to examine the spatial relationship of B to H-2 alloantigens on the cell surface by blocking procedures with specific antisera. The pretreatment of B^-, P815Y cells with anti-H-2^d (C3H anti-DBA/2) antiserum gave a positive result on subsequent immunofluorescent staining for blood group B. This may be due to cross-reaction of mouse immunoglobulin with the B determinant.

The chemical basis of serological specificity is established for the ABO system[22]; thus blood group antisera provide useful reagents for detecting the presence of specific sugar residues at the cell surface. The fortuitous cross-reaction of murine antigens with B and H determinants does not imply identity with the parent blood groups. It can be concluded only that a glycolipid or glycoprotein moiety with terminal α-galactosyl 1→3 galactose (B specificity) or α-fucosyl 1→2 galactose (H specificity) residues is present on the cell surface. It is a matter of conjecture whether appearance of B requires *de novo* synthesis or exposure of a pre-existing, cryptic antigen[10]. The restricted expression of B may not be a general feature of murine cells. Thus the thymus has a high mitotic rate, yet only 8–10% of thymocytes are B^+ by indirect immunofluorescence.

Table 1 Appearance of Blood Group B Positive Cells in Mouse Lymphocyte (Balb/c Strain) Cultures after Treatment with PHA (1/100 Dilution)

Time of culture (h)	Control cultures % B^+ cells	Control cultures % ^{3}H-thymidine-labelled cells*	PHA-treated cultures % B^+ cells	PHA-treated cultures % ^{3}H-thymidine-labelled cells*
0	7–10	0	7–10	0
24	3	<1	8–10	<1
48	<2	<1	20–25	7–10
72	<2	<1	20–25	24–28

* Determined by autoradiography after exposure of cells to ^{3}H-thymidine (1 μCi/ml.) for 3 h.

Table 2 Effect of PHA Concentration on the Mitogenic Response and Expression of Blood Group B in Lymphocyte (Balb/c Strain) Cultures at 72 h

PHA concentration	% B^+ cells	^{3}H-thymidine incorporation* (c.p.m./ml. × 10^{-3})
0	<1	0.65
1/500	5–10	6.0
1/200	20–25	19.7
1/100	20–25	35
1/50	<5	3

* Cells (2 × 10^6/ml.) were incubated with ^{3}H-thymidine (1 μCi/ml.) for 3 h and the trichloroacetic acid-insoluble radioactivity determined by scintillation counting.

In P815Y cells, there is an inverse relationship between expression of H-2 alloantigens and blood group H on the one hand, and blood group B on the other. H-2 has been shown to be minimal during the intermitotic period[16], in agreement with a reported variation of H-2 and viral antigens in other murine cell lines[14,15]. Variation in surface antigens during cell division has been accounted for by a limited period of gene transcription and/or decrease in rate of synthesis[14–16]. However, the appearance of a new determinant, B, suggests that decrease of H-2 and H might be due to a conformational change at the cell surface. A similar proposal has been made to account for change in surface charge and electrophoretic mobility during cell division[23].

The expression of H is maximal in synchronized HeLa cells at mitosis, but for surface antigens in other cell lines the peak occurs in G_1[14,15]. Cikes and Friberg have tried to reconcile this difference by suggesting that the appearance of H was an early G_1 event[15]. Yet the present studies show that, according to degree of synchrony (Fig. 2), cells can proceed directly at mitosis from an H^+ state to an H^-G_1 state. Thus the antigenic

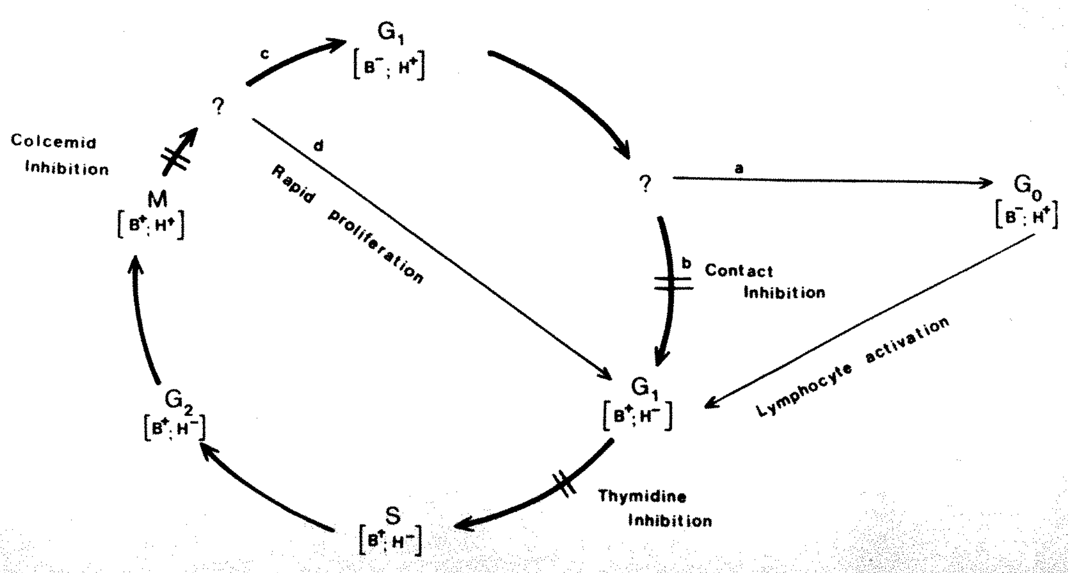

Fig. 5 Proposed model for antigenic variation during the cell cycle. B^+ is α-galactosyl 1→3 galactose; H^+ is α-fucosyl 1→2 galactose.

properties of G_1 cells may reflect a potential for further division.

Model for Antigenic Variation

I wish to propose a model for antigenic variation during the division of P815Y cells and the PHA-induced transformation of mouse lymphocytes (Fig. 5). The evidence in support of the scheme is as follows. (1) Resting cells (G_1 or G_0) are B^- and H^+ and give rise to B^+ and H^- cells during exponential growth (Fig. 1). (2) At mitosis, cells can proceed to a G_1 state which is B^- and H^+ (Fig. 2*a*) or B^+ and H^- (Fig. 2*b*). (3) G_1 cells (B^+ and H^-, Fig. 2*b*) undergo synchronous division while G_1 cells (B^- and H^+, Fig. 2*a*) are restricted to asynchronous growth. (4) Blood group B determinant is expressed on lymphocytes after treatment with PHA, and its appearance precedes DNA synthesis (Table 1).

Accordingly, the ability to express the α-galactosyl 1→3 galactose moiety (B determinant) is a prerequisite for cell division. It is not claimed that changes in B and H expression initiate cell division, but rather that they provide an index of a cell with commitment to mitosis. Two branch points exist in the cycle (a+b; c+d) which may serve as sites of growth control. Escape from growth inhibition is associated with the permanent expression of B at the cell surface (Fig. 2*b*). In limiting conditions of growth, there is an increase in the number of B^- cells (Fig. 1). It is suggested that cells, at mitosis, can be diverted from a path of rapid proliferation (d) to one of growth inhibition (c) with arrest in a G_1 (or G_0)B^- state.

It is known that variation in division time of cells, *in vivo* and *in vitro*, can be accounted for by differences in the G_1 period, the sum of $S+G_2+M$ being constant[24,25]. Also, G_1 is absent for some cells during rapid proliferation[26]. The possibility of two pathways, c and d, for cell division would provide a basis for this variation in the G_1 interval.

Furthermore, it is reasonable to expect that differences in surface properties of rapidly dividing (tumour, embryonic ?) cells and other cells would be most apparent in G_1 and would be minimal in limiting conditions of growth.

I thank Professor I. M. Roitt for advice and encouragement, A. V. T. for helpful discussion, and Mrs G. Stead for preparation of the manuscript. This work was supported by the Medical Research Council.

Cytostatic Antibody and SV40 Tumour Immunity in Hamsters

KATHLEEN R. AMBROSE, N. G. ANDERSON & J. H. COGGIN, jun.

Molecular Anatomy (MAN) Program, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830, and Department of Microbiology, University of Tennessee, Knoxville, Tennessee 37916

Ambrose *et al.* propose a likely scheme for the course of tumour development, as a failure of the host immune system.

THERE is growing support for the view that cancer involves a failure of the immune system of the host[1], and we have set out to investigate the mechanism of this failure in newborn hamsters injected with SV40 virus. For our purposes, this system has the advantage that autochthonous tumours occur reproducibly, that tumourigenesis can be prevented by immunization (which shows that the immune system of the host is functional before the occurrence of tumours) and that all tumours have the same transplantation antigens (TATAS).

Tumours occur reproducibly after a latent period of 90 to 300 days, during which the appearance of tumours can be prevented either by a second SV40 injection or immunization with irradiated SV40 tumour cells[2]. In previous studies, we attempted to delineate the roles of cell-mediated immunity and humoral immunity in this response. The occurrence of cell-mediated immunity is demonstrated by the way in which lymphocytes from immune animals will protect non-immune animals against challenge by tumour cells[3], but the role of humoral immunity is more obscure. Circulating cytotoxic antibodies have been reported in patients recovering from Burkitt's tumour[5], and there is some evidence that what are called blocking antibodies will enhance the growth of tumours, either by reacting with target cells[6] or with immune lymphocytes[7].

To distinguish between cell-mediated and humoral immunity *in vivo*, we have measured quantitatively the growth of tumour cells in small plastic chambers which are implanted in the peritoneal cavity and which are permeable to antibodies, not to cells[8,9]. After several days, the chambers are removed and the viable cells are counted. In non-immune animals, the number of cells increases, but in animals which are immune, growth is retarded or even prevented. So long as the humoral factors have not been isolated in pure form, we prefer to describe humoral factors defined by this method as cytostatic and not cytotoxic.

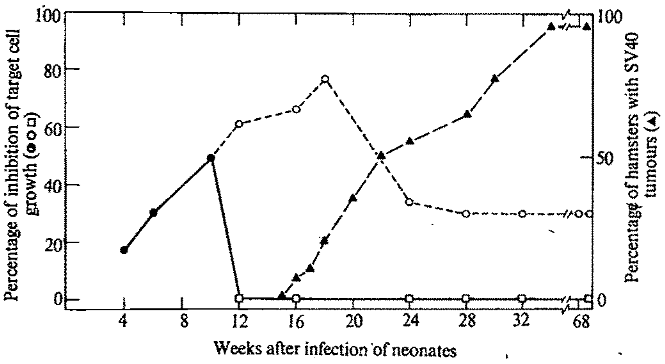

Fig. 1 Detection of cytostasis of SV40 tumour cells in diffusion chambers implanted in hamsters at intervals following neonatal infection with SV40 virus. ●, Cytostatic antibody in all animals; ○ tumour free animals; □, pre-tumour animals; ▲, palpable tumours.

In our experiments, we use animals of the LVG/LAK strain of Syrian golden hamsters. We produce autochthonous tumours by injecting newborn hamsters in the right subscapular space with 0.2 ml. doses of a suspension of SV40 virus (Fig. 1). Palpable tumours begin to appear at the site of injection after about 90 days, and 95% of the hamsters develop tumours after 200–300 days. To immunize adult hamsters so as to interrupt oncogenesis, three 0.2 ml. doses of the same virus suspension are injected at weekly intervals.

Antibody in Latent Period

One series of experiments was designed as a test for circulating antibody in the latent period before the appearance of tumours. After weaning at 21 days, we tested each week a group of ten animals (mixed sex groups) for circulating antibody, using as controls animals injected at birth with green monkey kidney passage control fluid medium containing no SV40 virus. Implanted chambers containing SV40 tumour cells were removed after 5 days and the animals were palpated for tumours at weekly intervals.

In the first 10 weeks of life, there is a surprising growth of circulating antibody in all ten infected animals in each infected group. Thereafter, there is a precipitous decline of circulating antibody in those animals which later develop tumours, with the loss of antibody always preceding the appearance of the tumour. Animals which remain free from tumours after 500 days still have measurable amounts of circulating antibody.

The transient occurrence of circulating antibody implies that the corresponding antigen is functional, which in turn implies that latency cannot be accounted for by dormancy of the virus. Instead, it seems as if transformed cells are produced and that they remain quiescent during latency, and we have been able to demonstrate that such cells do indeed exist.

To this end, we have been able to use the intracellular antigen called the T antigen which is produced when cells are transformed by SV40 virus and which may be detected with fluorescent antibodies[10,11]. The antigen is also produced during lytic infections[12] but is not always associated with oncogenicity, since cells transformed with SV40 virus but lacking T antigen have been found. Even so, the T antigen is a useful marker for cells which have been infected (but possibly not transformed) with SV40.

The inhibition relative to the control target cells is shown in Fig. 1.

Hamsters injected subcutaneously at birth with SV40 were killed in groups of ten, first at 8 h and then at 24 h intervals after injection. The tissue in the rejection area (5–8 mm in diameter) was sectioned and examined for T antigen using fluorescein conjugated antibody (Flow Laboratories). Within 8 h, approximately 10% of the cells examined showed strong diffuse immunofluorescence in the cytoplasm and a bright halo around the nuclear membrane. Cells from control hamsters injected with virus-free culture fluid were uniformly negative. In infected animals, more than 90% of the cells in the connective tissue region showed cytoplasmic fluorescence by 48 h but on the fourth day, few cells showed specific staining in either the nucleus or the cytoplasm, suggesting abortive infection. There was no evidence of cell degeneration. Intra-nuclear fluorescence was seen in a few pockets of six to eight cells after 7 days, but these numbered less than 5% of the cells in the injection area. During the next 17–20 days, cytoplasmic staining disappeared in the T antigen-positive cells and nuclear fluorescence weakened. A new type of large cell never seen in control sections was, however, observed to emerge among the positive cells. These cells, which formed foci and increased in number after 30 days are thought to give rise to tumours.

This work demonstrates that infected and presumably transformed cells persist in fairly large numbers during the latent period and produce the antigen or antigens giving rise to circulating antibody. As competence to produce humoral antibody appears before that for cellular immunity[14], circulating antibody may be produced initially and may inhibit a cellular response afferently or efferently.

To define the role of humoral factors more closely, we ask whether serum containing circulating antibody can inhibit SV40 tumour cell proliferation when administered passively in implantation chambers.

Table 1 Detection of Cytostatic Antibody against SV40 Target Cells following Passive Administration of Serum to Normal Hamsters

Serum donor	Average No. viable cells/chamber after 5 days' incubation *	% cytostasis compared with normal serum control
Normal control	618,000	
Hyperimmunized to SV40 tumour	327,000	47
SV40 tumour bearer	596,333	5

* Chambers seeded with 50,000 viable SV40 tumour cells.

SV40 target cells were incubated for 1 h *in vitro* in sera from normal immunized hamsters and from animals with tumours and then inoculated into diffusion chambers placed in weanling hamsters. Ten experimental and ten control animals were given 0.2 ml. of immune or control serum each day for 4 days. On the fifth day, the chambers were removed and the viable cells counted (Table 1). Normal serum gave a typical cell increase over 5 days, whereas animals receiving serum from SV40-tumour-immune hamsters showed cytostasis comparable with that observed in chambers implanted in immunized donors. In contrast, passive administration of serum from tumour bearers produced only slight inhibition of tumour cell growth. This confirms that a humoral factor plays a part in cytostasis but is absent or markedly decreased in tumour bearers. So far, the correlation between circulating antibody and the absence of a palpable tumour is complete, but the role of the circulating antibody remains obscure.

Course of Antibody Production

Does circulating antibody invariably follow immunization? To test this, the time course of appearance of circulating antibody was followed in adult hamsters after a single intraperitoneal injection of either 10^7 irradiated (5,000 r.) SV40 tumour cells or SV40 virus (Fig. 2). Circulating antibody was detected after five days, increasing to 65% inhibition and falling to a low level, followed by a slow rise in animals immunized with tumour cells. Baboon anti-hamster IgG serum labelled with fluorescein was used to show that cells recovered from chambers at 24 days were coated with IgG while those recovered at 8 days were not. Unfortunately, anti-hamster IgM serum was not available to determine whether the inhibition observed between 4 and 12 days was due to IgM, but it seems reasonable to make this assumption. The SV40 virus response apparently is due only to IgG. Animals immunized to both irradiated tumour cells* and virus were resistant to SV40 tumour cell challenge.

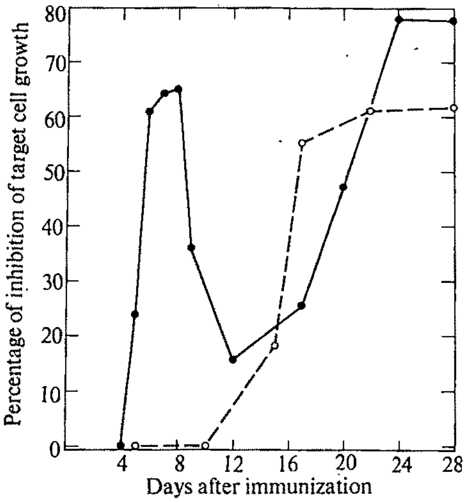

Fig. 2 Time course of appearance of cytostatic antibody against SV40 tumour cells in diffusion chambers in hamsters immunized with either irradiated SV40-transformed tumour cells grown in tissue culture or SV40 virus. ●, SV40 tumour cells (5,000 r.); ○, SV40.

The rapidity of the immune response observed with irradiated cell immunization raises the question of whether a transient circulating antibody response also occurs when nonimmunized animals are challenged with tumour-producing doses of SV40-transformed cells.

SV40 tumour cells (5×10^4 viable cells) were injected subcutaneously in the subscapular region of weanling hamsters. Before this and at 5 day intervals afterwards, diffusion chambers containing SV40 tumour cells were implanted into the peritoneal cavity; and 5 days later the number of tumour target cells was counted (Fig. 3). Circulating antibody was detected by 5 days after injection and persisted for approximately 10 days in all animals. No circulating antibody could be detected in any hamster by 15 days, at which time 25% of the challenged animals had very small palpable masses at the site of tumour cell injection. All animals developed tumours by 20 days.

In this system, therefore, circulating antibody invariably precedes tumour appearance, slows tumour cell growth, and is always present in animals immune to tumour challenge. Does it reappear when tumours are removed ?

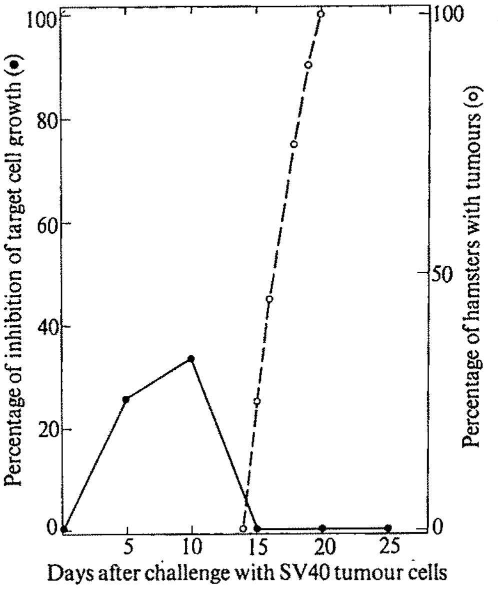

Fig. 3 Transient appearance of cytostatic antibody to SV40 tumour cells in diffusion chambers after implantation of live unirradiated SV40 tumour cells. ●, Cytostatic antibody; ○, palpable tumours.

Postsurgical Immune Response

Four weeks after injection of SV40 tumour cells into adult hamsters, a surgical cure was attempted. All animals had been monitored for circulating antibody, and none was found. Considerable attention to detail is required to achieve complete tumour removal. The cells used to produce tumours were injected subcutaneously in 0.1 ml. (5×10^4 cells) in a shaved area near the dorsal midline. Care was taken to minimize cell leakage or penetration of injected cells into adjacent tissues. When the fibrosarcomas reached 1–2 cm in diameter, the area was again shaved, the skin cleansed, and the tumour with considerable adjacent tissue lifted well away from the trunk and clamped off. The tumour and as much adjacent normal tissue as practical was cut away at the haemostat, and the wound was closed with clips, leaving the skin taut in the area of surgery. With these precautions and with care to avoid tumour cell dispersion *in situ* by vigorous palpation, a 50 to 60% cure rate could be achieved. Animals tumour free for 150 days after surgery were considered cured.

When circulating antibody levels were determined, about half the animals recovered after 10 days, which coincided with high levels of circulating antibody (Fig. 4). Results from all animals were pooled and plotted as a single result for each group, as the variation in cell counts was small for tumour-free animals (±5%).

Basis of Immune System Failure in Cancer

The conclusion that so called tumour-specific transplantation antigens, including those appearing after oncogenic virus infection, may be normal early embryonic antigens re-expressed in the tumour is reviewed in detail elsewhere[15–18]. The idea is based on four lines of evidence: (1) antisera to tumour surface antigens react with a variety of embryonic cells; (2) irradiated early embryonic cells immunize adult animals against a variety of tumours, including transplanted, autochthonous, spontaneous, and viral-induced tumours and elicit humoral and cellular responses against tumour detected *in vitro*; (3) during and after pregnancy circulating antitumour antibodies and lymphocytes are found; and (4) heterologous antisera to a wide variety of chemically induced tumours, after absorption with normal adult donor tissues, react with foetal cells. The para-

* We observed that splenectomy performed before multiple immunization of hamsters with irradiated SV40 tumour cells had no effect on circulating antibody formation, whereas splenectomy following immunization completely eliminated pre-existing levels of antibody. Both splenectomized animal groups resisted subsequent SV40 tumour challenge.

doxical problem inherent in the concept of immunologic surveillance is to reconcile why the foetal allograft, tolerated during normal pregnancy, is not rejected. Does a developing cancer survive by a similar mechanism, albeit outside the placental "barrier"?

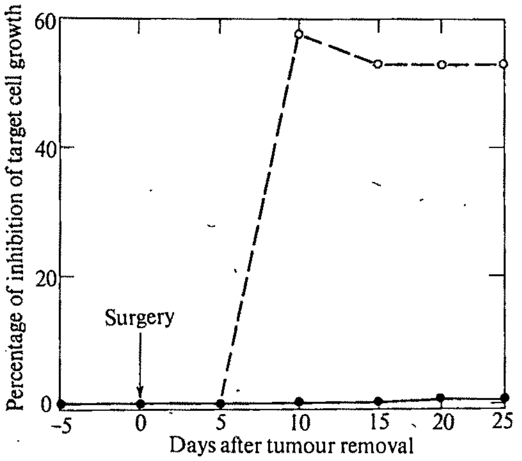

Fig. 4 Appearance of cytostatic antibodies after successful surgical removal of tumours (○) and continued absence of antibodies in surgical failures (●).

A solidly effective immune response to naturally occurring neoplasia may be difficult to achieve in practice, and may actually be effective only for very small groups of cells, as the data presented here suggest. We may divide the time course of tumour induction with SV40 virus into four phases: (1) Initial oncogenicity: a small tumour mass is established following virus infection which exhibits embryonic antigens. The cells may grow unrestricted for a short period (a few hours) before an immune response occurs. (2) Cytostatic immunity: some cells expressing tumour antigens may be destroyed during the initial antibody response; however, tumour cells are present for which the circulating antibodies are cytostatic and not cytotoxic. Numerous studies in our laboratory for many tumour systems in hamsters and mice revealed that *in vivo* humoral responses to tumour cells are cytostatic in nature[8,9,14,15]. It should be noted that the demonstration of cytotoxic antibodies usually requires a specially selected xenotypic complement to be effective[19,20] and that cytotoxicity is demonstrated experimentally *in vitro*. The result is a long latent period of very slow growth. During this period immunization with irradiated cells or virus is effective in preventing tumour formation. (3) Transition to local antigen excess: at some critical tumour mass, antigen production is thought to be sufficient to create a condition of local antigen excess, and rapid tumour growth ensues. As antigen excess becomes widespread, circulating antibody to the antigen becomes undetectable. (In preliminary experiments ^{131}I-labelled, tumour-eluted antibody injected into tumour bearers was rapidly localized in the kidneys as has been shown to occur with soluble antigen-excess complexes.) (4) Uncontrolled growth: once the circulating antibody is outstripped, the tumour mass increases rapidly. After successful surgery, however, the antibody rapidly reappears. Functional lymphocytes are present in tumour-bearing animals capable of destroying tumour cells *in vitro*[21,22], but these fail to eliminate the tumour. This failure most probably results from immunological "confusion" perpetuated by circulating antigen or antigen-antibody complexes at the lymphocyte surface. Circulating antibody may thus play a role as a masking factor preventing activation of both cell-mediated immunity and lymphocyte or macrophage function.

This is the simplest description consistent with the observations. Whether other tumours follow a similar time course remains to be determined. This description does not emphasize cell-mediated immunity, largely because it was not measured. However, both adoptive transfer of immunity with immune lymphocytes and colony inhibition studies have demonstrated a cellular defence mechanism against SV40 virus tumours[3,20,21].

Implications for Human Cancer

Many human cancers, including carcinoma of the cervix and prostate, have long latent periods during which cytostatic antibodies may appear. When rapid growth occurs, the antibody level should drop, to reappear again after successful treatment[22].

If the SV40 model studied here is a valid model for immunologic reactivity to autochthonous tumours in man, then the possibility of detecting cancer in the period of cytostatic antibody control exists.

We have not invoked here a multiplicity of different antibodies including enhancing or special blocking antibodies as distinct from cytotoxic ones. Rather, circulating antibody is thought to both depress tumour growth and prevent immune lymphocytes from being effective. In the latter role, these antibodies may produce enhancement. To evaluate the validity of this view, cytostatic antibodies and tumour surface antigens must be available in a high state of purity.

Decrease in Upper-atmosphere Rotation Rate at Heights above 350 km

THE average rate of rotation of the upper atmosphere can be evaluated from the small changes in inclinations of satellite orbits to the equator[1], and results obtained by analysing about thirty orbits have indicated[2] that the rotation rate increases from about 1.1 revolutions day^{-1} at a height of 200 km to about 1.4 revolutions day^{-1} at a height of 350 km. Various explanations of this "super-rotation" have been proposed[3–9], in terms of aerodynamic or electrodynamic theory, or both.

Recently, several values of upper-atmosphere rotation rate at heights above 370 km have been obtained[10,11], and these show that the increase with height does not continue beyond about 350 km. Instead the rotation rate seems to decrease to about 1.0 revolutions day^{-1} at 420 km and 0.7 revolution day^{-1} at 500 km. Fig. 1 shows results from thirty-two satellite orbits. The new values are those from the satellites Ariel 3 (1967–42A) at 390 and 500 km, from 1963–27A at 390 km and from 1968–86A at 410 km. Other previously unpublished results in Fig. 1 are from Cosmos 307 rocket[12] (1969–94B) at 240 km, and a preliminary value from Cosmos 316 (1969–108A) at 155 km.

If the upper atmosphere rotated at a constant angular rate, it would exert its greatest effect on a non-circular satellite orbit when the perigee was near the equator, and would have scarcely any effect when the perigee was at apex, that is, at maximum latitude. Consequently, as a first approximation, rotation rates obtained from orbital analysis can be regarded as averages over latitudes up to about half the satellite's orbital inclination. The four points on Fig. 1 at heights above 370 km are all obtained from near-polar orbits, whereas the two high values at heights near 360 km are from orbits with inclinations of 33° and 51°, which can be regarded as sampling the rotation up to latitudes of about 20° to 25° only. Thus if the equatorial rotation is particularly rapid, it would be appropriate for the line on the right in Fig. 1 to be faired in to the line on the left at a height of about 300 km, leaving the high values near 360 km out on a limb. If the rotation rate is independent of latitude, the join should be made at a greater height, near 350 km. Either method of joining gives a maximum rotation rate, that is maximum west-to-east winds, at a height between 300 and 350 km, which is near the height of maximum electron concentration in the F-layer of the ionosphere. A maximum rotation rate near this height might be expected if the rate is governed by electrodynamic forces, as suggested by Allan[3], Rishbeth[6] and Volland[9].

The decrease in the mean atmospheric rotation rate at heights between 400 and 500 km is not surprising. Pressure gradients and electrodynamic forces should be less important in the exosphere at heights of 500 to 1,000 km, where the neutral molecules, which are still numerically dominant, tend to pursue independent ballistic paths. Rapid rotation would imply that molecules in direct orbits travel considerably faster, on average, than those in retrograde orbits; but the faster molecules are more likely to escape, and this escape of the "high-velocity tail" should reduce the rotation rate in the exosphere, perhaps to much less than 1 revolution day^{-1}.

The wind pattern in the upper atmosphere at heights up to 500 km has an important influence on upper atmosphere heating, and analyses of orbits now being determined with

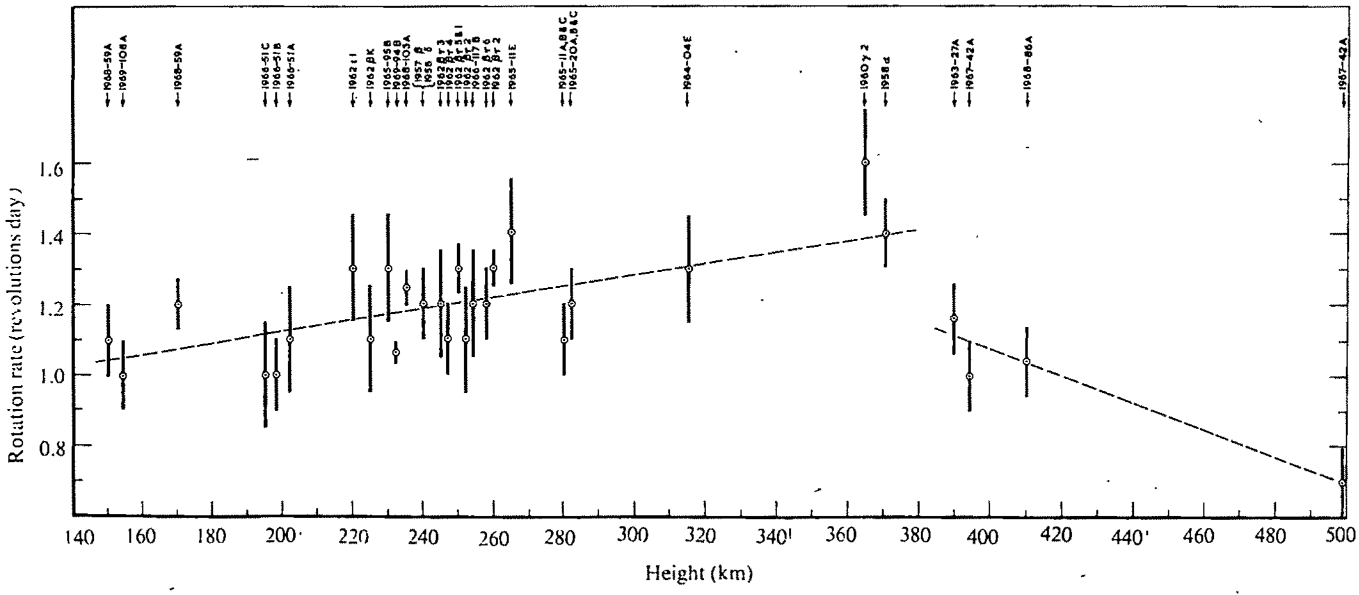

Fig. 1 Mean upper-atmosphere rotation rate derived from analyses of thirty-two satellite orbits.

the aid of the very accurate observations from the Hewitt cameras at Malvern and Edinburgh is yielding information on the variations of the zonal wind speed, which is likely to depend on local time as well as latitude. Results from Cosmos 307 rocket[12] and Cosmos 316 (unpublished data) suggest that the rotation rate sometimes departs greatly from its average value. This conclusion is in accord with recent measurements of very strong neutral winds, especially in auroral regions at times of geomagnetic disturbance when winds of more than 500 m s^{-1} have been recorded[13,14].

Use of Astronomical Telescopes to measure Aerosol Pollution

ASTRONOMICAL observatories are particularly suited for studies of the background aerosol content of the atmosphere for four reasons. (1) The observatories are usually in remote locations away from the lights and smoke of cities. (2) Most observatories have standard equipment designed to correct the measured light fluxes of stars for the loss of brightness in the passage through the atmosphere (in other words, to correct for atmospheric extinction). (3) There is good global coverage of observatories. (4) Observations of the extinction of starlight by the atmosphere have been made for nearly forty years and are available for re-analysis. The last point is particularly important because there are no other reliable records of the condition of the atmosphere in remote locations.

In this article we compare data from three astronomical observatories[1] with other measurements of the scattering of light by aerosols at clean air locations. The scattering coefficients obtained by the different methods support other evidence for the existence of a background level of aerosols in the atmosphere, and also establish the astronomical telescope as a potentially valuable tool for monitoring aerosol pollution.

Extinction measurements are made photoelectrically by observing the apparent brightness of standard stars at different zenith angles[2]. Charlson *et al.*[1] have examined data from seven observatories for atmospheric extinction, but data that is statistically meaningful has so far only been obtained for three observatories.

The three observatories are Rattlesnake Ridge (Washington), Kitt Peak National Observatory (Arizona), and Cerro Tololo Interamerican Observatory (Chile). Rattlesnake Ridge Observatory is about 30 km west of the nearest centre of population, Richland, which has almost no polluting industry, and is at an altitude of 1,080 m in a clean, nearly desert, climate. Kitt Peak is at 2,064 m in a desert climate about 75 km west of the nearest centre of population (Tucson), and Cerro Tololo, by far the least polluted site, is at an altitude of 2,195 m about 450 km north of the nearest centre of population, Santiago.

The third column of Table 1 shows the geometric mean of the ratio of the extinction coefficient due to scattering from the total column of air between the observatory and the star $(\bar{b}_{\text{scat}})$ to the Rayleigh scattering by air (b_{Rayleigh}). These values have been interpolated to a wavelength of 500 nm to standard temperature and pressure. Absorption was neglected because it is expected to be very small compared with scattering. Charlson *et al.*[1] reported extinction k in magnitudes at the zenith so the following conversion was used to obtain the scattering coefficient $\bar{b}_{\text{scat}}$

$$\bar{b}_{\text{scat}} = \frac{0.92\,k}{X}$$

where X is the optical depth for scattering above the observatory ($\simeq 8$ km for a sea level observatory). The extinction due to ozone absorption in the Choppuis band was removed from this data assuming an optical depth for ozone of 0.25 cm at Cerro Tololo and 0.35 cm at the other sites. The super and subscripts in Table 1 are the 90% confidence limits. Rattlesnake Ridge showed much more variation than Kitt Peak or Cerro Tololo. These ratios are consistent with nephelometer and sunphotometer measurements at similar locations giving ratios of 1.5 on Mt Olympus, Washington, and 1.95 at Point Barrow, Alaska[3].

Table 1 Light Extinction Properties of the Atmosphere over Three Observatories

Location (altitude)	Effective wavelengths	$\bar{b}_{\text{scat}}/b_{\text{Rayleigh}}$ at 500 nm (No. of nights measured)		α total			Aerosol only α (aerosol)	
			$\bar{\alpha}_{RV}$	$\bar{\alpha}_{VB}$	$\bar{\alpha}_{BU}$	$\bar{\alpha}_{RV}$	$\bar{\alpha}_{VB}$	$\bar{\alpha}_{BU}$
Rattlesnake Ridge, Washington (1,080 m)	$R\sim 693$ nm $V\sim 537$ nm $B\sim 440$ nm $U\sim 365$ nm	$2.0^{+0.1}_{-0.9}$ (20 nights)	$3.8^{+1.4}_{-1.8}$	$2.1^{+1.6}_{-0.8}$	$3.3^{+0.9}_{-0.7}$	$3.6^{+1.4}_{-3.0}$	$0.6^{+3.2}_{-1.9}$	$1.4^{+3.1}_{-1.6}$
Kitt Peak, Arizona (2,064 m)	$R\sim 693$ nm $V\sim 537$ nm $B\sim 440$ nm $U\sim 365$ nm	$1.7^{+0.5}_{-0.3}$ (24 nights)	$3.4^{+1.7}_{-1.5}$	$2.2^{+0.7}_{-0.5}$	$3.8^{+0.2}_{-1.4}$	$2.9^{+2.6}_{-1.9}$	$-0.4^{+0.8}_{-3.0}$	—
Cerro Tololo, Chile (2,195 m)	$V\sim 553$ nm $B\sim 440$ nm $U\sim 366$ nm	$1.3^{+0.4}_{-0.3}$ (17 nights)	—	$3.8^{+1.2}_{-1.9}$	$4.1^{+0.8}_{-0.7}$	—	$1.5^{+3.5}_{-3.0}$	$3.2^{+3.3}_{-1.3}$

The astronomical measurements were made at several different wavelengths (see Table 1) that were defined using broad band (100 nm) glass filters. The wavelength dependence of the atmospheric scattering coefficient due to both aerosol and Rayleigh scatter can be described by

$$\overline{b}_{\text{scat}} \propto \lambda^{-\alpha\text{total}}$$

where αtotal is an empirically determined exponent having a value 4 in pure air. Similarly, the contribution to extinction from aerosol scatter alone can be described by

$$\overline{b}_{\text{scat}}\,(\text{aerosol}) \propto \lambda^{-\alpha(\text{aerosol})}$$

where α(aerosol) has a typical value of 1.3 for urban air. Volz has related α(aerosol) to size distributions of the form

$$\frac{\mathrm{d}N}{\mathrm{d}\log r} = Cr^{-\beta}$$

where dN is the number of particles in the logarithmic radius increment d log r, C is a function of the total amount of aerosol and β is an exponent of about 3 for urban air.

Within a range of $2 < \beta < 6$ the following relationship applies

$$\beta = a(\text{aerosol}) + 2$$

Table 1 lists the geometric mean values of αtotal and α(aerosol) obtained from the total extinction coefficients at the indicated wavelengths. For example, α_{RV} is measured between the red (693 nm) and the visible (537 nm for Cerro Tololo), and similarly for the other αs with subscript R implying "red", B implying "blue", and U implying "ultraviolet". The effective wavelengths for each site are shown in Table 1.

These wavelengths, incidentally, correspond to those used in the multiwavelength nephelometer results of ref. 4, although of course the telescope determinations refer to the entire line of sight whereas the nephelometer gives a measurement at a point.

In the rest of Table 1 the aerosol contribution has been isolated using the aerosol scattering coefficient $\overline{b}_{\text{scat}}\,(\text{aerosol}) = \overline{b}_{\text{scat}} - b_{\text{Rayleigh}}$. In some cases negative values of α(aerosol) are obtained, when the extinction due to the aerosol component increases rather than decreases with increasing wavelength, and indeed more than half the nights at all three locations showed anomalous, that is, negative, values. This type of scattering behaviour has also been observed by Quenzel *et al.*[5] in clean oceanic air during the Meteor Expedition. This type of scattering must be due to an aerosol size distribution different from the simple power law with β between 2 and 6. On very rare occasions anomalous aerosol extinction may even dominate the strong Rayleigh scattering wavelength dependence (once in a blue Moon). Because of the wide variation in the α(aerosol) at all three locations, much more data will be required to characterize the wavelength dependence of background aerosol.

All the data reported[1] were reduced completely by computer from original raw intensity measurements. The probable error of a single reduced intensity measurement is typically less than 2% at 500 nm. This uncertainty increases slightly toward shorter wavelength. Because the extinction typical at an observatory of altitude 4,000 foot is only about 20% at this wavelength, it is possible for the extinction measurements to be uncertain by ±10%. As the actual measurement error is usually less than 1%, we can credit most of the uncertainty to the fact that the standard stars are measured at random times and random zenith angles throughout the night, and are reduced by assuming no time or spatial variation in extinction during the night. Both time and spatial variation often do occur, however, due to unobserved clouds. As a ±10% error in extinction is related to only a 2% error in the intensity of the star at that wavelength, this is sufficient for most routine astronomical photometry. Better extinction measurements (a 1% error in extinction) could be obtained in the future by using a local intensity standard (such as a radioactive light source) so that one measurement in space and time could be used to calculate the extinction of the light from a standard star. In calculating the wavelength dependence, the uncertainty in extinction exerts a strong influence on α, especially when $\Delta\log b_{\text{scat}}$ is very small. In the same way a slightly incorrect choice of effective wavelengths of the filters also exerts an influence on α. The determination of the effective wavelengh for the broad band filters is at present complicated by the fact that the standard stars observed usually have different spectral distributions, usually with significant slopes in the wavelength region being measured, and include many different patterns of absorption lines. Using the mean values of $\overline{b}_{\text{scat}}$ shown in Table 1 the error in $\overline{b}_{\text{scat}}$ and wavelength can combine to make as much as a 60% error in the measured αs.

We conclude that astronomically determined measurements of atmospheric extinction are consistent with other measurements in clean air locations. These data provide information that can be used to characterize the background aerosol in the atmosphere and changes due to world-wide air pollution. So far, not enough old data has been reduced to establish possible secular changes in global atmospheric extinction, although Hodge[6] has found a significant increase in atmospheric extinction over the Mt Wilson observatory in California in the past fifty years.

Exchange of SO_2 between the Atmosphere and Natural Waters

Little is known about the rate of exchange of gas between the atmosphere and natural waters (such as oceans, rivers, lakes and airborne water droplets), and most work so far has concentrated on the more common atmospheric constituents, N_2, O_2, CO_2 and water vapour. The transfer of trace components, such as oxides of sulphur and nitrogen, has received almost no attention. This article is an attempt to predict the principal factors controlling the exchange of SO_2 across air–water interfaces in the natural environment.

Gas exchange rates are often given either as an exchange constant (k = flux of gas/concentration difference), or its reciprocal, which measures the "resistance" of the interface to gas transfer. Danckwerts[1] has shown that the overall resistance of a gas–liquid interface may be interpreted as the sum of the resistances of the individual phases:

$$\frac{1}{K_1} = \frac{1}{k_1} + \frac{1}{H\,k_2} \qquad (1)$$

$1/K_l$ is the total resistance on a liquid phase basis, $1/k_l$ and $1/k_g$ are the individual resistances of the liquid and gas phases and H is the Henry's law constant, where

$$H = \frac{\text{equilibrium concentration in gas phase}}{\text{equilibrium concentration of unionized dissolved gas in liquid phase}}$$

For a sparingly soluble gas, the liquid phase resistance term in equation (1) is much larger[2,3] than that for the gas phase. This is partly a reflexion of the large value of H for such a gas, and partly due to the fact that the molecular diffusivity (and hence diffusive transport) of most gases is about two orders of magnitude less in water than it is in air. By contrast the exchange of water vapour, in common with evaporation–condensation of any pure liquid, is controlled by resistance in the gas phase. The behaviour of SO_2 is likely to fall between these two extremes. One reason for this is the moderate solubility of the gas in water, which makes the gas phase resistance term larger than for a less soluble gas. Another factor is that the value of k_l may be increased because of the chemical reactivity of the gas in solution. Provided that the liquid is not too acidic, SO_2 molecules entering the water will be rapidly hydrated and then ionized. Transport of SO_2 near the liquid side of the interface may then be enhanced because the normal dissolved gas concentration gradient will be supplemented by the gradient of ionic species. Such enhancement of the value of k_l for a chemically reactive gas has been observed by Hoover and Berkshire[4] in laboratory studies using CO_2. These authors have derived the following expressions for calculating the degree of enhancement to be expected.

$$\alpha\, k_{l\,(\text{inert})} = k_{l(\text{reactive})} \qquad (2)$$

where

$$\alpha = \frac{\tau}{(\tau-1) + \left\{\tanh\left[\left(\frac{k^*\tau}{D}\right)^{\frac{1}{2}} \frac{D}{k_{l(\text{inert})}}\right] \Big/ \left(\frac{k^*\tau}{D}\right)^{\frac{1}{2}} \frac{D}{k_{l(\text{inert})}}\right\}} \qquad (3)$$

α is the ratio of the k_l values for a reactive and an inert gas exchanging under identical conditions, τ is the ratio of total to ionic forms of the gas in solution, k^* is the hydration rate constant for the gas, and D is the molecular diffusivity of the dissolved gas molecules.

Although derived for CO_2 exchange, equations (2) and (3) should also be applicable to SO_2 transfer. As the hydration rate constant for SO_2 ($\sim 10^6$ s^{-1}) is much higher than that for CO_2 ($\sim 10^{-2}$ s^{-1}) the exchange enhancement for SO_2 should be considerably more pronounced than the enhancement found for CO_2.

If equations (1) to (3) are to be used to estimate exchange rates for SO_2 under environmental conditions, typical values must be found for $k_{g(SO_2)}$ and $k_{l(\text{inert})}$ The value for $k_{l(\text{inert})}$ must then be multiplied by the appropriate value of α to obtain $k_{l(SO_2)}$. The value of α depends critically on τ, which in turn is a function of the pH of the water. To cover most environmental situations, I shall calculate α for pH values 2 to 9.

Using the data given by Schooley[5], a mean value for $k_{g(H_2O)}$ over the oceans of about 3,000 cm h^{-1} may be derived. Values over smaller bodies of water (lakes, rivers and so on) will almost certainly be less than this, but a value of 3,000 cm h^{-1} will be assumed for the present. It will further be assumed that k_g for SO_2 and H_2O are approximately equal. A typical value for $k_{l(\text{inert})}$ seems to be more difficult to obtain. Downing[6] gives values between 0.4 and 7.5 cm h^{-1} for O_2 in various freshwater environments although, exceptionally, values as high as 300 cm h^{-1} have been recorded. Measurements at sea lie in the region 4 to 36 cm h^{-1} (my work to be published). A reasonable guess would seem to be about 10 cm h^{-1} for $k_{l(\text{inert})}$. It will be shown that the values chosen for $k_{g(SO_2)}$ and $k_{l(\text{inert})}$ are not very critical to the conclusions to be drawn from the calculations.

Table 1 shows the results of the calculations in which it is assumed that $H = 3.8 \times 10^{-2}$ (ref. 7), $D = 2 \times 10^{-5}$ cm^2 s^{-1}, $k^* = 3.4 \times 10^6$ s^{-1} (ref. 8).

Table 1 Calculation of the Ratio of the Gas to the Liquid Phase Resistance

pH	α	$k_{l(SO_2)}$ cm h^{-1}	$\frac{1}{k_{l(SO_2)}} = r_l$ h cm^{-1} × 10^5	$\frac{1}{H\,k_{g(SO_2)}} = r_g$ h cm^{-1} × 10^3	r_g/r_l
2	2.7	27	3,700	8.8	0.24
2.8	11.7	117	855	8.8	1.03
3	18.0	180	560	8.8	1.57
4	169	1,690	59	8.8	14.92
5	1,376	13,760	7.3	8.8	120.6
6	2,884	28,840	3.5	8.8	251.4
7	2,966	29,660	3.4	8.8	258.8
8	2,967	29,670	3.4	8.8	258.8
9	2,967	29,670	3.4	8.8	258.8

The final column in Table 1 gives the ratio of the gas to the liquid phase resistance. At a pH of 2.8 both resistances are approximately equal but when the pH is below this value the liquid phase resistance is more important than the resistance of the gas phase. Above a pH of 2.8 the gas phase resistance becomes increasingly dominant. The exchange of SO_2 is interesting because it changes from liquid to gas phase control as the pH is raised. By contrast, although the r_l value for CO_2 decreases with increasing pH (due to the ionic gradient effect) it is always greater than the value of r_g. Thus exchange of CO_2 is principally controlled by the resistance of the liquid phase.

For a number of years chemical engineers have been making measurements of SO_2 transfer rates in packed columns[9,10]. Their experimental results seem to support the ideas outlined above, in that both the gas and liquid phase resistances appear to exert an appreciable effect on the overall resistance.

The pH of most natural waters in surface environments is between 4 and 9. It can therefore be concluded from the calculations set out above that, for almost all environmental air–water interfaces, gas phase resistance should control the SO_2 exchange rate. This conclusion would not have been substantially affected by using rather different values for $k_{g(SO_2)}$ and $k_{l(\text{inert})}$. Under calm conditions in both air and water, $k_{g(SO_2)}$ and $k_{l(\text{inert})}$ might be 1,000 cm h^{-1} and 2 cm h^{-1} respectively; in this case r_g and r_l would have been equal at a pH of about 3.0. By contrast, under turbulent conditions in both phases ($k_{g(SO_2)} = 5{,}000$ cm h^{-1}, $k_{l(\text{inert})} = 30$ cm h^{-1}), r_g and r_l become equal when the pH is about 2.5. Thus for a wide range of mixing conditions, pH values greater than about 4 imply that gas rather than liquid phase resistance will control the exchange of SO_2. The behaviour of SO_2 in crossing a natural air–water interface will therefore tend to resemble that of water vapour rather than O_2 or CO_2.

Two tentative conclusions may be drawn from this result. First, the vertical gradients of SO_2 and water vapour (humidity deficit) close to the sea surface should be similar. Second, the mean residence time of an SO_2 molecule in the atmosphere should be of the same order as that for a water molecule (~ 10 days, ref. 11). This contrasts with the much larger residence time for a CO_2 molecule (~ 7 yr, ref. 12); in this case, exchange is controlled by resistance in the liquid phase. A residence time of about 10 days for SO_2 is in reasonable agreement with the mean value of 5 days given by Junge[11].

I thank Mr A. C. Chamberlain of AERE, Harwell, for helpful discussions and comments on the manuscript.

Determination of the Density of Seawater

KREMLING has recently described[1] a promising new method for the determination of the density of seawater. The agreement he demonstrates between his results and those based on the equation of state, determined by Knudsen as a function of salinity and temperature, is even better than he suggests. This arises from an error in Kremling's interpretation of the new definition of salinity.

Salinity, S, is now defined by the International Tables[2] in terms of conductivity. The best estimate of chlorinity[3] is obtained by using the relation $\mathrm{Cl} = S/1.80655$ and not the Knudsen equation. One thus arrives at a lower value for Cl than estimated by Kremling which is most marked for the lower values of Cl. When the densities are recalculated one finds that Kremling's estimates are reduced by 0.20 at $S = 5\%$ and by 0.009 at $S = 20\%$ with linear interpolation between. Application of this correction suggests complete agreement in the mean with Knudsen and exemplifies once again the great quality of standards measurements in the early years of the century.

Structure of Fibrous Carbon

THE existence of fibrous or whisker carbon has been reported in both synthetic studies of graphite[1,2] and in naturally occurring graphite[3]. The synthetic studies involved decomposition of hydrocarbons over metals[1] and decomposition of carbon monoxide over iron[2] and, particularly in the second of these studies, the occurrence of metal catalyst within the fibre was observed. Furthermore, it has been established[1] that the average orientation of the carbon crystallites is with their (0002) orientation parallel to the axis of the fibre. In this communication we describe the use of high resolution electron microscopy to establish the precise relationship between the orientation of the graphite planes and the catalyst particle within the fibre.

A nickel foil was heated to 700° C in 600 mm Hg of methane or propane for several hours and the ensuing film of graphite was stripped from the foil surface by immersion in concentrated HCl. The film of graphite was sufficiently thin to be studied by transmission electron microscopy and it contained outcrops of fibrous carbon as well as polycrystalline and high quality graphitic carbon. Fig. 1*A* shows the appearance of a typical carbon fibre formed in an atmosphere of methane, the very high width to length ratio of the fibres formed in methane being characteristic of this hydrocarbon. Fig. 1*B* is an enlargement of part of the previous figure so that the (0002) lattice planes can be seen. There are three principal regions of the fibre: in the centre is an irregular particle of what is believed to be metal (in this case it would be nickel) and surrounding this is a highly crystalline carbon with the (0002) lattice planes parallel to the surface of the metal particle; on the periphery of the fibre there is a narrow region of amorphous carbon. The first point of interest is the close parallelism of the graphite layer planes with the surface of the metal particle, because it has been reported

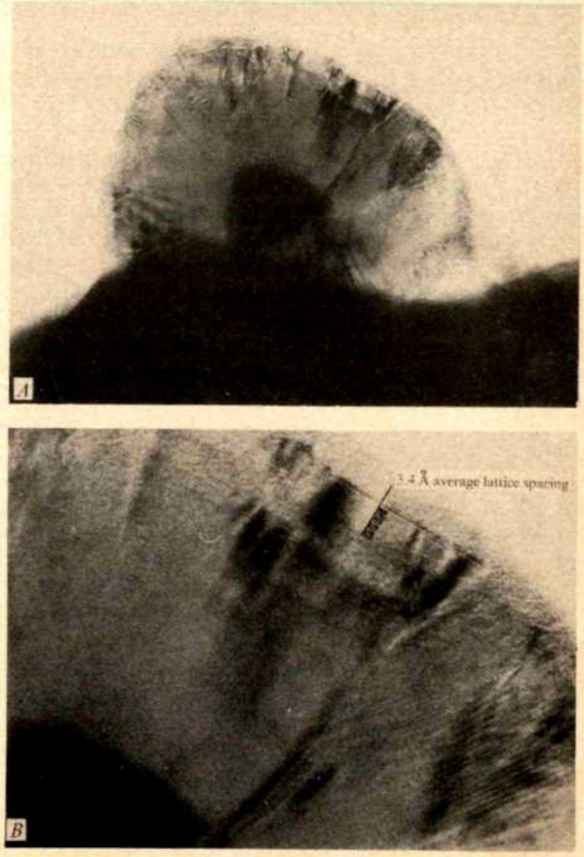

Fig. 1 *A*, Fibre produced by methane pyrolysis over nickel (× 312,000); *B*, Enlargement of a region of Fig. 1*A*, with (0002) lattice planes delineated for identification (× 1,000,000).

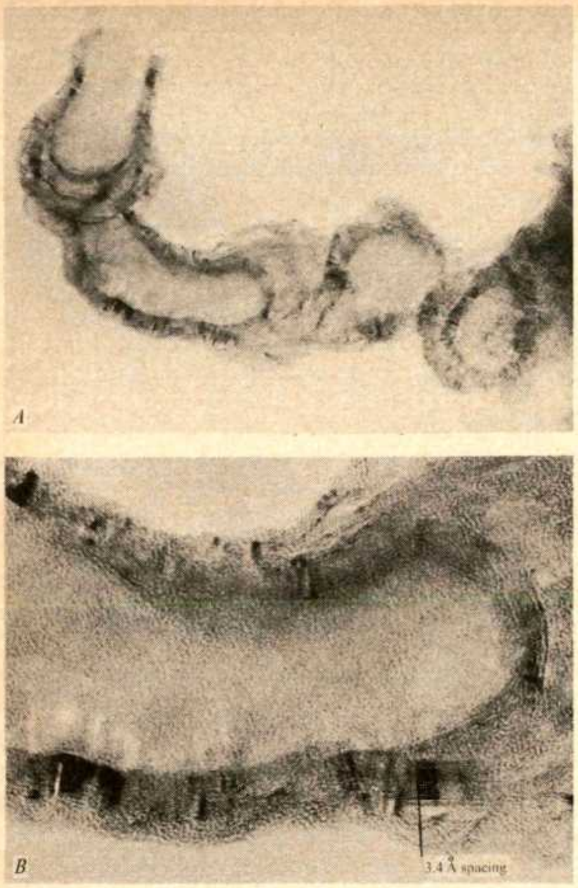

Fig. 2 *A*, Fibre produced by propane pyrolysis over nickel (× 312,000); *B*, Enlargement of a region of Fig. 2*A* with (0002) lattice planes delineated for identification (× 1,000,000).

that there is a preference for graphite growth on the (110) faces of nickel[4]. The irregular shape of the metal particle precludes the exposure of any single lattice plane all around its surface and yet there are no marked irregularities in the carbon fibre that would suggest a preferred direction of growth. From the intensity variations in the original micrograph, we also conclude that this fibre is approximately hemispherical in shape.

Fig. 2*A* is a carbon fibre formed by propane pyrolysis. No metal particle was observed in this fibre but the open nature of the end of the fibre and possibly along the centre indicates that the metal was removed by the preparative treatment in concentrated HCl. Fig. 2*B* is an enlargement of part of this fibre. Areas of resolved (0002) graphite lattice planes are again distinguishable throughout the fibre even at its root where it has grown from the main carbon deposit. The overall shape of this fibre, however, is markedly different from fibres produced by methane and the arcing that occurs periodically along the central region of the fibre suggests that the direction of growth bends in and out of the plane of the micrograph. The average direction of the (0002) lattice planes is, however, parallel to the axis of the fibre or, to be more precise, the direction is parallel to the areas where metal particles were believed to have been situated. The difference between these fibres and those produced from methane could be explained by the mobility of the metal particle in the case of the propane fibres; a much longer and more distorted fibre would then be produced as the metal moved away from the main carbon deposit.

The structure of these fibres—in particular, that produced by methane pyrolysis—raises several questions about the mechanism of their formation. It is difficult to imagine that the metal could exert catalytic influence up to 300 Å away from the metal surface and yet it is equally difficult to explain a mechanism that requires diffusion of active species perpendicular to the layer planes of graphite. Furthermore the micrograph in Fig. 1 shows that where there are faults in the layer plane structure which might provide an easy channel for diffusion, there is no marked production of carbon at the end of these channels as would be expected if a diffusion mechanism predominated. This argument is equally valid whether active species are considered to diffuse out or hydrocarbon molecules are considered to diffuse in, thus depositing the carbon layers adjacent to the metal surface and building up the fibre from the inside. We suggest that, as each carbon layer is laid down, atomically dispersed nickel is incorporated within this layer. In this form, catalytic deposition could take place on the outer layers of the growing fibre and would continue for some distance away from the metal although there would be a dilution of the metal atoms by the subsequent layers laid down. If this mechanism is applicable to general graphite formation, a dilution of nickel would be reached at some distance away from the metal surface where it is no longer possible for laminar graphite to be laid down; this has been observed by ourselves and by other workers[5]. At this stage the crystallite size of the carbon that is deposited is very small, and the crystallites are randomly oriented with respect to each other. This mechanism is further supported by oxidation studies on pyrolytic graphites that have been laid down by this technique. After removal of the graphite by oxidation there remain agglomerates of nickel that have been dispersed within the graphite[1], the agglomeration obviously being caused by the heating necessary for the oxidation reaction because agglomerates were not observed in the unreacted material.

BIOLOGICAL SCIENCES

Requirement of Thymus-dependent Lymphocytes for Potentiation by Adjuvants of Antibody Formation

THE mode of action of immunological adjuvants is of theoretical as well as practical importance. Adjuvants can not only increase immune responses; they can also bring about change from one type of immune response to another. For example, doses of bovine serum albumin (BSA) that in the absence of adjuvant induce tolerance, in the presence of adjuvants induce antibody formation[1,2]. To understand how adjuvants switch on antibody formation it may be necessary to determine which of the cells involved in the immune response are affected by adjuvants. Earlier experiments[3-5] led to the conclusion that the cells initially involved in the action of adjuvants are macrophages. This interpretation was based on observations that particulate adjuvants (such as bacteria) are ingested by macrophages but not by lymphocytes. Non-particulate or particulate adjuvants taken up by macrophages in culture and injected into syngeneic mice increased the antibody response of the recipients to two proteins (*Maia squinada* haemocyanin or bovine serum albumin (BSA)); in contrast, adjuvants taken up by lymphoid cells used to reconstitute immune responses in irradiated recipients had no demonstrable effect on antibody formation.

It is now clear that immune responses to many antigens require co-operation of thymus-dependent (T) and bone marrow derived (B) lymphocytes[6], the former possibly functioning as an antigen-concentrating system while the latter give rise to cells which can synthesize and release antibody[7,8]. If it is accepted that adjuvants act initially on macrophages, which are not themselves immunocompetent, two hypotheses can be considered. According to the first, adjuvants increase the probability of direct interaction of macrophages containing antigen and B lymphocytes capable of producing antibody, by-passing the T lymphocytes. According to the second, adjuvants increase the effectiveness of the interaction of macrophages and T lymphocytes, and this results in greater stimulation of the appropriate B lymphocytes to produce specific antibody. In an attempt to decide between these hypotheses we have compared the effects of adjuvants on antibody production against BSA in normal young adult CBA male mice and CBA mice deprived of T lymphocytes by neonatal thymectomy followed by two injections at 5 and 6 weeks of 0.2 ml. of rabbit anti-mouse lymphocyte serum (ALS) in some experiments, or thymectomy at 8 weeks followed by 850 r. whole-body irradiation and reconstitution with syngeneic bone marrow[9]. As an additional control, thymectomized (TX), irradiated and reconstituted mice receiving also a syngeneic thymus graft under the renal capsule[10] have been used.

The primary immunization was by intraperitoneal inoculation with 1 mg centrifuged BSA in 0.5 ml. saline; 20 days later the mice were bled for determination of primary antibody responses. The same day they were injected with 100 μg of BSA intraperitoneally, and blood samples were taken 10 days later for determination of secondary antibody responses. As adjuvants 2 μg of purified *E. coli* lipopolysaccharide (LPS) or 0.4 μg of *Bordetella pertussis* vaccine (Wellcome) were administered together with the antigen in saline. Freund's incomplete adjuvant (ICFA—mineral oil, Bayo F, containing mannoside—mono-oleate, Difco), or Freund's complete adjuvant (FCA–ICFA with 100 μg of *Myobacterium butyricum*/ml.) or 5 mg of 'Retinol' in ICFA were injected intraperitoneally 1 h after administration of antigen in saline. Antibody was assayed by the Farr test[1,4]. The antigen-binding capacity for each group of six mice (except for those marked with an asterisk, which contained 5) is presented as the geometric mean of the antigen-binding capacity (ABC) expressed as $\log_{10}$, together with the standard error (s.e.) calculated from the variance.

Representative results are shown in Table 1. In mice depleted of T cells by either procedure antibody responses to BSA are decreased, as previously described by Taylor[11], and the disparity between normal and T cell-deprived mice is greater when the primary immunization is made with adjuvant. In mice reconstituted with a thymus graft marked stimulation of antibody formation by adjuvants is again seen.

It therefore seems that T lymphocytes are required for potentiation of antibody formation against BSA by adjuvants. It has been suggested[3–5] that one of the effects of adjuvants may be to bring about the release from macrophages of a factor which stimulates proliferation of lymphocytes, and that when antigen is presented at this time there is an increased probability of antibody formation rather than tolerance induction. In keeping with this, it has been found[12] that vitamin A, which is an efficient adjuvant but is not in itself immunogenic, produces marked blast transformation and proliferation of cells in the thymus-dependent areas of draining lymph nodes, whereas substances, such as paraffin oil, without adjuvant activity have at most slight effects on the thymus-dependent areas of lymph nodes. These findings are consistent with the possibility that one of the effects of adjuvants is to increase the effectiveness of the interaction of macrophages and T lymphocytes. The macrophages concentrate antigen, which is presented to T lymphocytes in highly immunogenic form along with a stimulus for the latter to proliferate. This greatly increases the probability that T lymphocytes will mount an immune response, which in turn allows them to co-operate in antibody production by B lymphocytes. But whether or not the interaction of macrophages with T cells is augmented by adjuvants it seems that stimulation of T cells is an important aspect of the mechanism of action of at least some adjuvants. It is of interest to note that injections of allogeneic cells may also provide a general stimulus to T cell proliferation and overcome the requirement for co-operation by populations of T cells specifically stimulated by antigen in the potentiation of an immune response[13].

Variations of the Expression of HL-A Antigens on Human Diploid Fibroblasts *in vitro*

ALL kinds of human nucleated cells so far tested express on their surface the HL-A antigens which form the major histocompatibility system in man[1]. These antigens, which are easily detected on lymphocytes and on platelets of peripheral blood, have also been found on other human cells[2–9]. In long term human cell cultures, it has been possible to demonstrate the remarkable stability of the HL-A antigens. Analogous observations have been reported in mouse regarding the antigens controlled by H-2 histocompatibility system[10]. We report here results obtained from the study of ten varieties of human fibroblasts, which enabled us to analyse the behaviour of the antigens of the HL-A system in cell cultures of limited duration[11].

Taking advantage of skin graft experiments performed in our laboratory[12], we obtained fibroblasts through standard procedures, from skin biopsies of healthy volunteers belonging to families whose tissues had been extensively and repeatedly typed in lymphocytotoxicity and complement fixation on platelets (Table 1).

Fibroblasts were typed using Terasaki's lymphocytotoxicity technique, slightly modified[13]. The dose of immune sera was increased, the fibroblast suspension was adjusted to 1,000 cells per test, and the reading was made by dye exclusion.

The antisera used (Table 2) came from either multiparous women, immunized or multiple transfused individuals. Each specificity was defined by one to five reagents. All the results obtained with the reagents defining a same specificity were concordant.

Each specificity detected was tested directly against either the corresponding antiserum, or a cross-reacting antiserum[14]: for example, anti-HL-A1, which recognized HL-A3, and HL-A11 (refs. 15, 16), anti-HL-A5 which recognizes Da6, Da20, Da24, Te18 (ref. 17), anti-HL-A7 which recognizes BB (15). Except with fibroblast 109′ (Table 1), the fibroblast specificities detected were always the same as those determined in corresponding lymphocytes[8,9]. The HL-A antigens progressively disappeared (Table 3). The loss of expression of these antigens did not seem to be random, and occurred by locus, and not by haplotype. In nine cases out of ten, the antigens controlled at the second locus were the first to disappear.

Table 1 Comparison of the HL-A Antigens detected on the Lymphocytes and the Fibroblasts from a Same Donor

+, Passages when antigens were found. −, Disappearance either of specificity or of a cross-reaction demonstrating this specificity. a, b, c, d, e, f, g, see Table 1. h, Six fibroblasts were studied for the first time at a passage number not exactly determined (between fifteen and twenty-five—estimated at twenty in the table). i, Antigen HL-A3 recognized by an anti-HL-A1 anti-serum, because of the cross-reaction HL-A3, HL-A1 ;+ without i indicates the persistency of a positive reaction with anti-HL-A3 and the negativation of the reaction with anti-HL-A1.

In three cases—fibroblasts 46, 212, 35 (Table 3)—the HL-A3 antigen was recognized both by anti-HL-A3 immune serum, and by the anti-HL-A1 reagent, and we could observe that the serological negativation of the cross-reaction preceded that of the direct reaction.

The disappearance of histocompatibility antigens occurred together with the senescence of the cultures and preceded cell degeneration and death. The presence of all the HL-A antigens on the fibroblasts coincided with a phase of normal cellular multiplication with a generation time of about 24 h. In six cases out of ten, the partial disappearance of the antigens controlled by the second locus occurred after a number of passages which varied with the strains of the fibroblasts studied, and corresponded to a phase of an apparently normal cellular multiplication. There was, however, an increasing generation time from 24 h to 96 h and sometimes even more. On the contrary, in four cases out of ten, though the cells survived after the disappearance of all the HL-A antigens, the multiplication stopped rapidly, the morphological aspect of the culture was that of a complete degeneration of the strain, rapidly followed by death. Degeneration could be diagnosed by a decrease in the cell number and morphologically by the presence on the cells of aggregates of cytoplasmic origin, and by the loss of their initial spindle-shaped oblong form.

Concordance has already been observed on lymphocytes, and on fibroblasts regarding certain given groups. Our study confirms the presence of HL-A antigens on the surface of fibroblasts, in spite of their lesser sensitivity to immunological lysis, probably in relation with a lesser concentration of antigenic sites. It implies the concept of a large distribution of antigens on human tissues, and underlines the importance of their role in transplantation. Our results differ from those of other authors[8] on the stability of the HL-A antigens on human fibroblasts in culture: more specificities of the second locus have been observed and for a longer time.

As we have explained, the serological behaviour of the products, which are controlled by the first and the second loci, is different when these products are studied in the course of time on cultured human diploid fibroblasts. By loss of specificity we mean the disappearance at a given moment of a specificity which could previously be detected in a reproducible manner. Our experimental conditions do not allow us to determine whether it is a question of qualitative or quantitative loss of antigens, but absorption experiments are in progress. It is possible that antigens are still present, but can no longer be detected by immune sera. In nine out of ten fibroblast strains, however, the products controlled by the second locus were the first to become serologically undetectable. It is unlikely that the antisera used to determine the antigens at the first locus are more sensitive than those applied to the antigens of the second locus, for comparison of the titres of the immune sera shows that the mean activity is the same in the two cases. It thus seems that the stability of the antigens controlled by the first and second HL-A loci is different, and that the products of the former are more stable in our experimental conditions. It is still possible that at a certain stage of cell degeneration following multiple passages, some of these antigens may become more susceptible to trypsin action, because of a general change in the cell membranes. The asymmetry observed between the products controlled by the first and second HL-A loci can be compared with that observed between the D and K regions of mouse H-2 locus, shown *in vitro* by the mixed lymphocyte test[18], and *in vivo* by graft versus host reaction[19]. Furthermore, cross-reactions are a general phenomenon observed in the serology of the HL-A system[14]; this experiment, which shows that the loss of cross-reactivity is independent of that of direct reactivity, suggests that the antigenic determinants responsible for the direct specificity and those responsible for cross-reactions are distinct.

Finally, our results lead us to discuss the possible biological role of the HL-A system: in four cases out of ten, either degeneration or cell death (fibroblasts 32, 33, 44, 35) rapidly followed once the point was reached at which specificity in the HL-A system was no longer detectable. On the other hand, in the other six cases (fibroblasts GUI, 46, 212, 154, 109′, and 115), where at least one of the specificities controlled by the two loci of the HL-A system was still detected, no sign of cellular senescence was observed except an increased generation time. Indeed, from the results obtained, it is not possible to confirm that there is a relationship between loss of HL-A antigens and cell degeneration. But if these results are compared with those obtained for the mouse H-2 locus in which all the strains have at least one set of antigens of the H-2 locus[20-23], it becomes tempting to speculate that HL-A antigens behave in the same fashion. The practical interest of the detection of HL-A antigens is first their role as genetic markers, yet with a certain limitation regarding their stability of expression during the cell senescence period; and second, the fact that it makes it possible to define the identity of strains and to determine their age.

We thank Dr J. Colombani for helpful criticism, and Mrs Roche for her help with the English manuscript.

Fluorescent *Y* Screening of Hospitalized Newborns

QUINACRINE dihydrochloride and quinacrine mustard have been used to identify chromosomes at metaphase[1,2] and the *Y* chromosome in interphase[3-6]. We now report a preliminary survey of blood smears for *Y* chromosome fluorescence from all

Table 1 Characteristics of the Infants Studied

Case	Gestation (weeks)	Birth weight (g)	Admission diagnosis	*Y* chromosome	Congenital defects	Final outcome
1	35	1,680	Umbilical omphalocoele Respiratory distress	*XYY*	Mongoloid facies Umbilical omphalocoele Cong. bilat. hydronephrosis VSD PDA	Died age 2 days

3	31	1,340	Prematurity (twin of case 4)	Small	Nil	Alive
4	31	1,845	Prematurity (twin of case 3)	Small	Nil	Alive
5	40	2,400	Cleft lip and palate	Small	Bilat. cleft lip and palate Undescended testis	Alive
6	41	2,780	Ambiguous genitalia	Normal	Hypospadias Imperforate anus	Alive Colostomy
7	36	1,770	Prematurity Ambiguous genitalia	Normal	Marked hypospadias	Alive

newborn males transferred to this hospital from February to April 1971.

Blood smears were air-dried, fixed for 5 min in 100% methanol, dried, stained in 0.5% quinacrine dihydrochloride ('Atebrine', Gurr) for 5 min, rinsed in running tap water, dried, mounted in phosphate buffer (*p*H 4.5) and examined under a Zeiss photomicroscope with an HBO 200 lamp, excitor filter BG 12 and barrier filter 53/44.

Blood smears were taken from 140 male and five female infants. Ten lymphocytes and usually ten neutrophils were examined from each smear without prior knowledge of the sex or clinical status of the infant. *Y* chromosome abnormalities or normal variants, confirmed by karyotypes, were detected in five infants by this fluorescence study (Table 1 and Fig. 1). A further two infants, admitted specifically for definitive sex determination because of ambiguous genitalia, had normal male fluorescence patterns and karyotypes (Table 1 and Fig. 1).

In the *XYY* smear (case 1), three cells with two fluorescent spots (F-spots) were seen in the initial twenty leucocytes. On further screening, approximately 30% of 100 cells examined had two F-spots, and none with a single large F-spot. F-spots were noticed to be very large in almost all leucocytes from case 2 (large *Y* chromosomes).

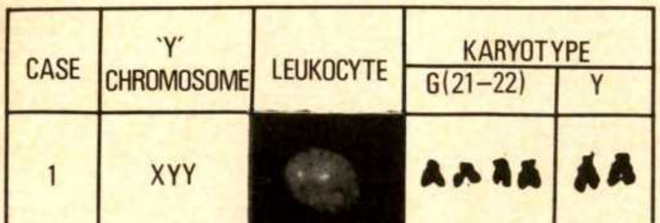

Fig. 1 Comparison of leucocyte *Y* fluorescence pattern with karyotype. The fluorescent spot in leucocytes from cases 3–5 was present but difficult to illustrate because of its small size.

Smears from cases 3, 4 and 5 had definite F-spots but these were so small and difficult to see that they might have been classified as negative (female). Smears from the five females had no F-spots and were easily identified.

Two cells in each of two other smears contained two F-spots and were shown to be false positives by karyotypes. In the remaining smears, 83% of lymphocytes (and 65% of neutrophils) contained an F-spot of normal size(Fig. 1, cases 6, 7). Karyotypes were not made on any of these males.

This study shows that *Y* chromosome abnormalities and variants can be rapidly detected by this fluorescence technique and then confirmed by karyotype. Parallel chromosome studies were not done and the number of false negatives is unknown. This study might suggest that the number of false negatives is small because a large proportion of cases with interesting *Y* chromosomes were found. This was, however, a selected population, hospitalized because of neonatal problems. Whether the large proportion of interesting *Y* chromosome cases was related to selection of this type of patient or was a chance finding will have to be determined by further studies.

Identification of male nuclear sex by the fluorescent technique is a valuable addition to the sex chromatin test in cases of ambiguous genitalia.

We thank Dr Paul Swyer for his cooperation. This work was supported by the Ontario Cancer Treatment and Research Foundation.

Scrapie in Immunologically Deficient Mice

ALTHOUGH the agent responsible for scrapie is classified as a slow virus, many features distinguish it from a typical virus[1-3], one of which is its apparent failure to elicit an immune response. Attempts to demonstrate antibody by neutralization[4,5], complement fixation[4], precipitation[4] and immunofluorescence[4,6] have been unsuccessful, but the role of cell-mediated immunity in scrapie has been less well studied.

Neonatal thymectomy did not alter the incubation period or pathology in one small series of mice inoculated intracerebrally with scrapie[2]. We have studied the course of scrapie produced by intraperitoneal inoculation in thymectomized mice, lethally irradiated and reconstituted with foetal liver cells. Although they were markedly depleted of thymus-derived (T) lymphocytes and were incapable of rejecting allogeneic skin grafts, their response to the scrapie agent was not different from that of normal mice.

CBA/He mice of both sexes were used: group I was thymectomized at 4 weeks old, irradiated with 900 r. and reconstituted with syngeneic foetal liver cells; group II received 900 r. and was reconstituted with foetal liver cells; group III was untreated. Four weeks later they all received skin grafts from A strain donors and after 9 days half the animals in each group were inoculated intraperitoneally with 0.25 ml. of 10^{-1} dilution of normal BSVS mouse brain; the rest received 0.25 ml. of 10^{-1} dilution of brain from BSVS mice with scrapie; these materials were supplied by Dr R. L. Chandler.

Cell-mediated immune function was followed by assessment of skin allograft survival. In addition the percentage of cells bearing the θ allo-antigen (a marker for T lymphocytes[7]) and the microscopic appearance of the lymphoid organs were studied in two animals from each group, 7 months after inoculation (Table 1). Animals in group I retained skin allografts throughout the experiment, had very few θ-bearing cells in their blood and were markedly depleted of lymphocytes in the thymus-dependent areas of spleen and lymph nodes[8]. In contrast, mice in groups II and III rejected their skin grafts after 13.6 and 10.3 days respectively, had normal numbers of θ-bearing blood lymphocytes and normal lymphoid organs.

Mice were observed five or six times a week for the appearance of scrapie following the criteria of Dickenson *et al.*[9]. No mice inoculated with normal brain developed signs of scrapie, but those injected with scrapie-affected brain developed scrapie and either were killed in extremis or died within 230 days of inoculation. Many of the immunologically deficient mice in group I died before developing signs of scrapie. None of these mice had neuropathological lesions consistent with scrapie during the clinical phase of the disease.

Table 2 shows that scrapie began between 163 and 170 days in all three groups. There was no significant difference between mean times of death of 190 and 205 days seen in groups I and III respectively; they were even closer than appears because four of the mice in group I were killed when judged to be preterminal in order to obtain satisfactorily histology and peripheral blood for determination of θ-bearing lymphocytes. Although the extent and magnitude of the nervous system lesions were not compared in detail, the neuropathological changes revealed by haematoxin and eosin or Cajal were consistent with scrapie in all three groups. Thus we could demonstrate no appreciable difference in the clinical and pathological aspects of scrapie in immunologically deficient mice depleted of T lymphocytes when compared with normal mice. This suggests that cell-mediated immunity neither contributes to the pathogenesis of scrapie nor plays a significant role in the host's defence against the agent.

Table 1 Cellular Immune Status

Group	Treatment	Skin allograft survival in days (mean)	% θ-bearing cells in blood*	Lymphoid* organs
I	Thymectomy 900 r. Reconstituted with foetal liver	Greater than 200	4, 17	Lymphocyte depletion in in thymus-dependent areas
II	900 r. Reconstituted with foetal liver	9–19 (13.6)	77, 68	Normal
III	None	9–14 (10.3)	74, 73	Normal

* Evaluated after 7 months.

Table 2 Time Course of Scrapie

Group	No. of mice	Onset of disease (days)	Time from inoculation to death (days) Range	Mean
I	7	163–170	174–200	190
II	16	163–170	200–223	215
III	24	163–170	173–228	205

Extraction of Prostaglandins from Human Blood

EXISTING methods for extracting prostaglandins from tissues or seminal plasma with 70–90% ethanol[1] or acetone[2] give poor and inconsistent recoveries from blood. Equilibrium dialysis and recovery experiments with labelled and unlabelled prostaglandins show that this is due to binding with precipitated serum albumen (unpublished results of W. G. U.). Plasma globulins and intact blood cells do not seem to interact with the prostaglandins. When precipitation of protein is avoided by using 40–50% ethanol acidified with formic acid, the prostaglandins can be extracted quantitatively into chloroform. The method is as follows: (1) centrifuge heparinized or citrated blood; (2) mix 1 volume each of plasma and saline with 2 volumes of ethanol (analytical grade); (3) extract twice with petrol (boiling point 40°–60° C, 2 × 2 volumes) to remove neutral fats including carotene; (4) adjust to *p*H 3–3.5 with formic acid (1–3% v/v); (5) extract twice with amounts of chloroform each equal to the total volume in stage 4; (6) evaporate chloroform in a thin film evaporator at 30° C; (7) redissolve residue in 10 ml. chloroform and evaporate to aid the removal of formic acid; (8) blow oxygen-free nitrogen through vessel until odour of formic acid is gone; (9) dissolve in Krebs solution for bioassay or in appropriate solvent for chromatography.

The plasma should be either fresh or frozen (−10° C in the present experiments). Plasma stored in glass and freeze-dried whole plasma were found to contain acidic biologically active material which was not a prostaglandin. Formic acid is used in stage (4) to achieve the desired *p*H because its *pKa* is near *p*H 3 and because its volatility allows easy removal; the amount of acid needed varies with different samples of plasma. Chloroform is used to extract the alcoholic solution (stage 5) since only a small amount of alcohol or water enters the chloroform phase; diethyl ether and ethyl acetate used in other procedures are miscible with 50% ethanol.

The resulting extract in stage (9) is still crude, and contains bilirubin, phospholipids and traces of neutral fats in addition to the prostaglandins. Substantial amounts of haematin will also be present if haemolysis has occurred. These impurities do not affect the biological assays but they can affect the rate at which prostaglandins run on thin-layer chromatography. Phospholipid material can be removed by precipitation in cold acetone[3,4], but this is undesirable because a biologically active unidentified material is formed probably from the phospholipid fraction. This might account for the high blood levels of prostaglandin reported by Hickler[4]. The extracts can, however, be purified suitably for thin-layer chromatography by evaporating the chloroform, dissolving the residue in 10 ml. of 70% ethanol and shaking briefly with 250–500 mg Fuller's earth. After diluting the supernatant to 50% with water and acidifying with formic acid, the prostaglandins re-extract quantitatively into chloroform. This procedure removes haematin and phospholipids, but not bilirubin.

Assays of PGE$_1$, E$_2$, F$_{1\alpha}$ and F$_{2\alpha}$ on the rat fundus[5] and of PGA$_1$ and A$_2$ in anaesthetized cats and rats[6,7] gave recoveries of 102% (range 72–140%, 52 experiments) from human blood containing 0.01–1 μg/ml. added prostaglandin. The levels of prostaglandin activity in peripheral venous blood from fifteen normal males was found to be 1.6 ± 0.9 ng/ml. (assayed as prostaglandin E$_2$ ± s.d.).

We thank Dr J. E. Pike, Upjohn Ltd, Kalamazoo, for prostaglandins, Professor D. A. van Dorp, Unilever, Vlaardingen, for ^{3}H-PGE$_1$, and the Wellcome Trust and King's College Hospital Research Trust for support (W. G. U. and I. F. S.).

New Porous Biomaterials by Replication of Echinoderm Skeletal Microstructures

AN important aspect of materials science is the development of new porous solids for prosthetic applications, especially for synthetic teeth and bone replacement. To be acceptable, such biomaterials must meet some rather demanding specifications, among which are high strength and compatibility with body fluids or tissues. The structure of the porous medium is important as the pores must be both interconnected and have the proper size, shape and uniformity to permit ingrowth and attachment of body tissue. The problem lies in attaining the optimum combination of these properties to yield a high strength to weight ratio material, with a microstructure which best facilitates firm attachment of tissue. Ideally these materials should be easily machined or fashioned into particular shapes for different individual implants, and should be relatively inexpensive.

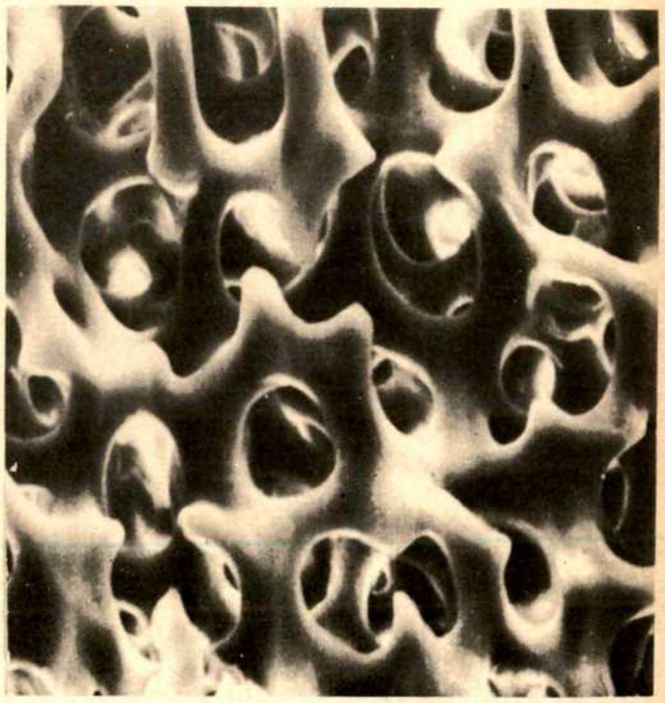

Fig. 1 Three dimensional fenestrate structure of skeletal high-magnesium calcite secreted by echinoderms. Photomicrograph by scanning electron microscopy. The diameter of the pores is approximately 10–15 μm

Ceramics show considerable promise in that strength and inertness requirements are likely to be met. Such materials have high compressive strength, do not corrode and have a specific gravity similar to that of bone[1,2]. But because of the difficulties of creating the ideal pore structure artificially, we propose a new technique of replicating the microstructure found in the CaCO$_3$ skeletal elements of echinoderms. Using these methods it seems possible to select a natural microstructure with the most desirable geometry or morphology for a particular application, and then reproduce this structure by replacing the original skeletal material with one possessing adequate physical, chemical and mechanical properties.

The mineral phase of echinoderm ossicles is high-magnesium calcite[3] which is secreted in optical continuity. Each spine of a sea urchin or echinoid, for example, is indistinguishable from a single crystal by X-ray diffraction or optical methods. The skeletal calcite, however, is permeated by interconnecting channels forming a fenestrate microstructure in spite of the single crystal nature of the inorganic phase (Fig. 1). In life, these passageways are filled with various organic cells and body fluids[4]. Donnay and Pawson[5] have described this structure as a "periodic minimal surface" which divides space into two interpenetrating regions, each of which is a single yet multiple connected domain. The two regions, however, have no connexion with each other and the surface is the interface

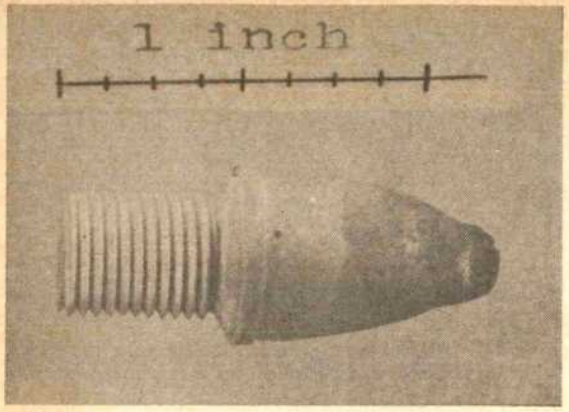

Fig. 2 Screw thread machined from a spine of the echinoid *Heterocentrotus trigonarius*.

between the skeletal calcite phase and the soft-tissue organic phase. Maximum contact for crystal growth is provided by this structure, which according to Donnay and Pawson[5] has not been found in nature other than in echinoderm skeletons.

Although the fenestrate microstructure is found in almost all echinoderm skeletal ossicles[5-7], few of these are large enough for practical applications. Spines of the echinoid *Heterocentrotus* are of sufficient size and ready availability to constitute a suitable source of material for replication. The genus *Heterocentrotus*, commonly referred to as the "slate-pencil urchin", is widely distributed and common in the Indo-Pacific area. The external morphology of the spines ranges from rather slender, pencil-like bodies with a tricarinate tip, to very thick, cylindrical or club-like forms. The length and width of the larger primary spines may exceed 160 and 13 mm respectively.

Although echinoderm skeletons are characterized by a unique and potentially useful microstructure, the calcium carbonate of which they consist is highly unsuitable for prosthetic applications. Calcite is considerably softer (H=3, Mohs scale) than the hydroxyapatite (H=5) found in bones and teeth. Other undesirable properties of calcite include high solubility, perfect rhombohedral cleavage, and decomposition in the presence of acids. In spite of its high degree of cleavage, however, the high-magnesium calcite of echinoderm ossicles is easily machined without damage, as illustrated by the threaded echinoid spine in Fig. 2. The very properties that preclude the use of this mineral in human implants, however, facilitate reproduction of the microstructure in other materials.

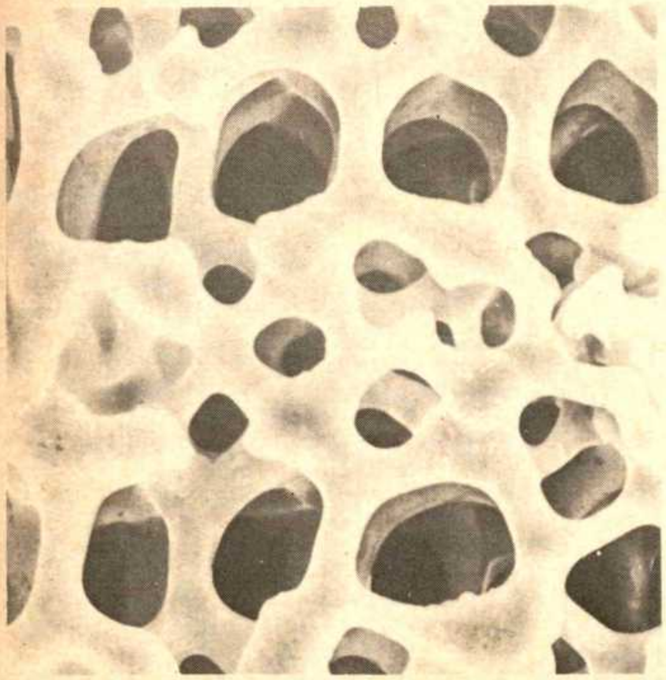

Fig. 3 Scanning electron photomicrograph of an epoxy resin negative replica of the microstructure from a spine of *Heterocentrotus trigonarius*.

Three dimensional negative replicas, made successfully from both epoxy resin and sodium silicate, reproduce the exact morphology of the void phase. Before vacuum impregnation, spines of *Heterocentrotus* are immersed in 5% sodium hypochlorite to remove organic matter, rinsed with distilled water and dried at 100° C. General Electric No. 3255 'Permafil', catalysed with 0.8% tertiary butyl perbenzoate, is used to prepare the epoxy resin replica. Air is removed from the pore volume in vacuum and replaced by the resin which effectively fills all pores. After curing the impregnated samples for 24 h at room temperature, the original calcite of the skeletal structure is removed by dilute (1 : 10) HCl. The same procedure is used to prepare the sodium silicate negative replicas except that the curing time is extended to 4 days. Epoxy and sodium silicate replicas are illustrated in Figs. 3 and 4.

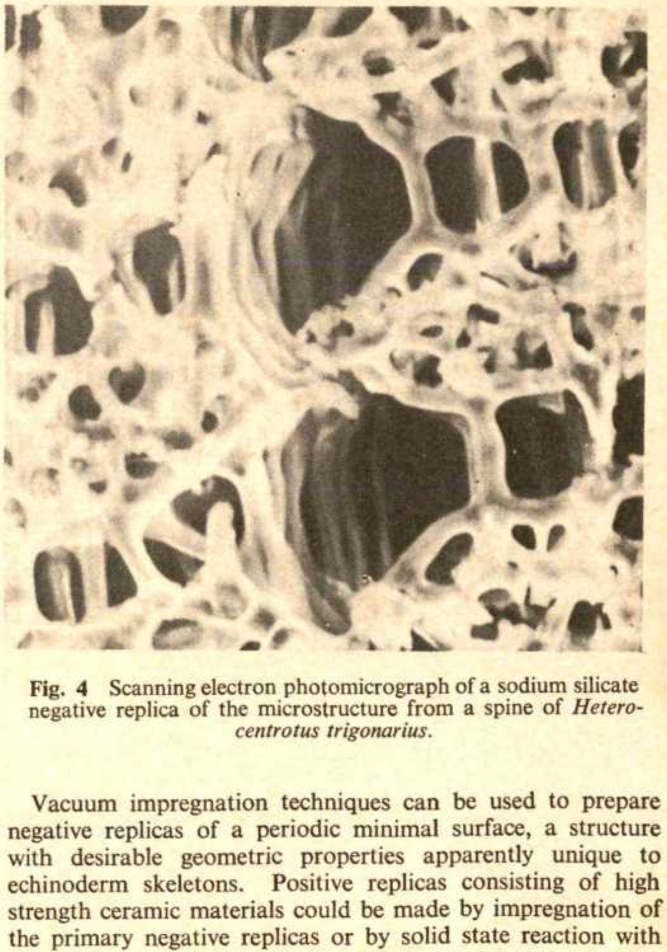

Fig. 4 Scanning electron photomicrograph of a sodium silicate negative replica of the microstructure from a spine of *Heterocentrotus trigonarius*.

Vacuum impregnation techniques can be used to prepare negative replicas of a periodic minimal surface, a structure with desirable geometric properties apparently unique to echinoderm skeletons. Positive replicas consisting of high strength ceramic materials could be made by impregnation of the primary negative replicas or by solid state reaction with the high-magnesium calcite. Phosphate-bonded alumina ceramic, for example, is particularly suitable in that it is well tolerated by tissues, does not elicit an immunologic response, and allows the attachment of fibrous connective tissue[8]. The concept of replicating natural microstructures for special applications offers considerable potential for the development of new porous biomaterials with an optimum combination of strength, density and infiltrability.

Spontaneous Rhythms in Physiological Control Systems

MEAN arterial blood pressure in man undergoes spontaneous and broadly repetitive fluctuations with a typical period of about 10 s. We present an explanation for these fluctuations which we believe may also be applicable to the vasomotor activity associated with thermoregulation and therefore widely relevant.

Fig. 1*a* illustrates the two broadly periodic fluctuations in the arterial blood pressure of a seated adult breathing voluntarily. One of these is related to respiration; the other occurs spontaneously, probably originates in vasomotor action, and is loosely described as a Traube wave which can also occur during periods of apnoea[1]. We believe that this spontaneous oscillation is intrinsic in the sino-aortic reflexes for regulating blood pressure, as a consequence of system nonlinearity, and that it is subject to entrainment[2] by the respiratory rhythm. The two oscillations can exist simultaneously provided that the respiratory period exceeds that of the spontaneous oscillation. But if the subject breathes at a higher frequency than that of the spontaneous oscillation, only the respiratory component remains, unless the respiration is too shallow to produce the effect (Fig. 1*b*). Detailed spectral analysis of the blood pressure confirms this observation.

The magnitude of the external signal, here respiration, required to entrain the spontaneous oscillation depends on the relative frequency of external signal and spontaneous oscillation and is much greater for signal frequencies appreciably below that of the spontaneous component than for frequencies in the region of, or even appreciably greater than, that of the spontaneous component. It has been possible to accommodate the physiological facts and observations in a model[3] (Fig. 2*a*). Disturbances such as postural changes, or respiratory movements, can affect the system; respiratory disturbances are thought to contribute additively because the arteries in which the baroreceptors are located pass through the intrathoracic cavity. Because the arterial walls are elastic, variations in intrathoracic pressure produce redistributions in arterial blood volume, hence a change in distension of the blood vessels which in turn determine baroreceptor activity. Even in the absence of any disturbance, however, the model will continue to oscillate spontaneously.

With systems structured in this way, entrainment is known to be possible with adequate magnitudes of disturbance (Fig. 2*a* and *b*). The gain K_{NL} of the non-linear element to a sinusoidal signal input is inversely proportional to the signal amplitude, as far as the output component at the same frequency is concerned, because the output magnitude is fixed by the limits between which it switches. The overall gain round the feedback loop is $K_{NL}\,KG(j\omega)$; to meet the Nyquist criterion for stability the Nyquist plot of this loop gain must pass within the point $(-1,0)$ at ω_0, the frequency of spontaneous oscillation. Fig. 2*b* shows the frequency response of the linear part $KG(j\omega)$ of this loop gain at various frequencies. Thus the

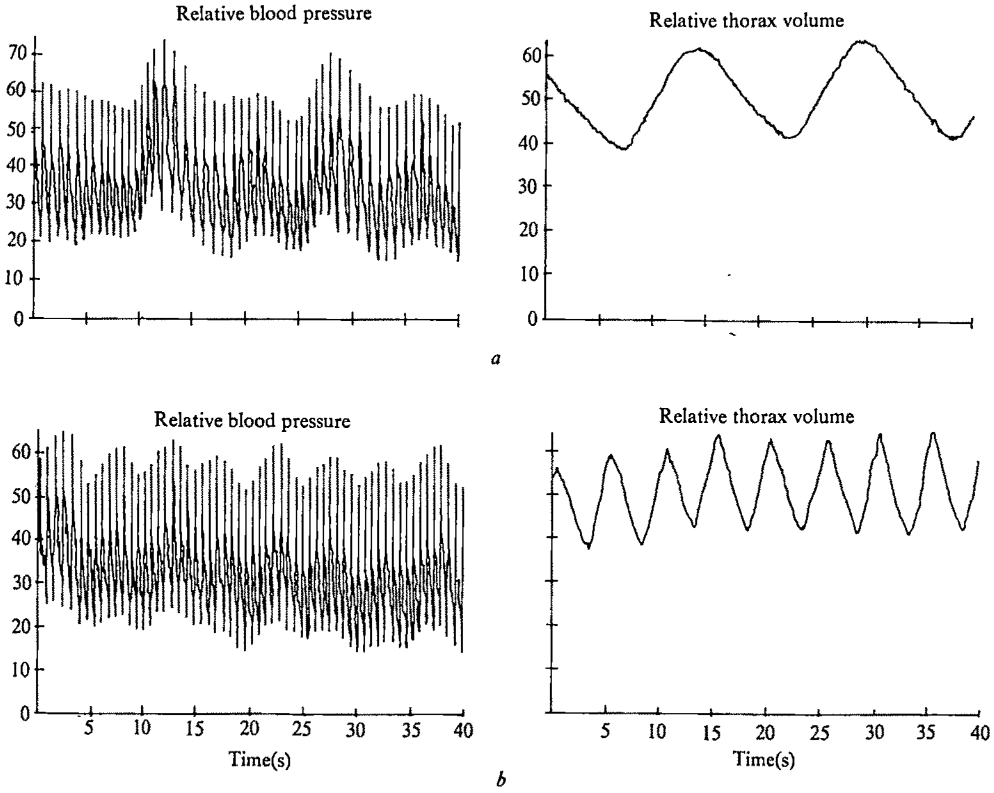

Fig. 1 *a*, A typical record of arterial blood pressure of a seated resting adult. The respiratory period is 15 s and there are two dominant low frequency components in the arterial pressure waveform, one of which has the same period as the respiration. *b*, The respiratory period is 5 s and a component of the same period only is evident in the arterial pressure waveform.

critical point of instability is reached when the value of $KG(j\omega_0)$, shown by X_0, is equal to $-1/K_{NL}$; but the latter is under the control of an externally applied signal. Consequently if the magnitude $-1/K_{NL}$ is made greater than $KG(j\omega_0)$ by applying a sufficiently large external periodic disturbance (with frequency, ω_1 say) (Fig. 2*a*) spontaneous oscillation will cease and the system responds only to the disturbance. The magnitude of disturbance needed to produce this condition, entrainment, is proportional to the magnitude A_1 determined according to the graphical method of Johnson[5], which evaluates the vector difference $[X_1-X_0]$ or $K[G(j\omega_1)-G(j\omega_0)]$. If the frequency response KG of the linear elements circles in towards the origin at higher frequencies as shown (this is broadly true for vascular smooth muscle and other biological effectors), the magnitude of the disturbance required to produce entrainment is much larger for disturbance frequencies (ω_1, say) appreciably below the frequency of spontaneous oscillation than for frequencies (ω_2, say) near, or even appreciably above, that of the spontaneous oscillation (compare A_1 with A_2).

We consider that this property of "selective entrainment" will account for our experimental observations. As another consequence of its nonlinear nature, the model can simulate the high degree of control accuracy of the blood pressure control system. For example, in the normal adult, a positive Valsalva manoeuvre leading to a 60% reduction in cardiac output (which in the absence of nervous regulation would produce a corresponding decrease in mean arterial blood pressure) may often produce only about 5% decrease in mean blood pressure[6]. Similarly, the output of the model will deviate by only 3% from the reference when the corresponding effect is simulated (this is done by decreasing the parameter K by 60%). It would not be possible to achieve this degree of accuracy if the nonlinear element were replaced by a linear block because of the stability restrictions defined by the Nyquist criterion[7].

This raises the possibility that a similar mechanism applies in other biological control systems—especially those with a high degree of control accuracy and periodic oscillations in the controlled variable. This can be tested by looking for "selective entrainment" of the spontaneous component by a periodic disturbance introduced as close as possible to the sensors of the system. We have applied this technique in an investigation of the human thermoregulatory system. Burton[8] has ascribed the slow fluctuations (period of 15 s or greater and above) seen in human digital plethysmograms to the action of the thermoregulatory system. We have studied such a digital plethysmogram signal obtained from the small finger of a normal resting adult seated in a room maintained at 19° C. Apart from the faster components of period less than 15 s, which are probably due to the action of the blood pressure control system described above, the signal comprises only slow fluctuations thought to represent activity of the thermoregulatory system.

If the subject places one hand alternately in containers of hot (40° C) and cold (18° C) water for fixed intervals (say, 10 s, giving a 20 s period), the waveform of the digital blood flow signal is found to be quite different from the spontaneous signal. It comprises only a substantial component having the same period as the stimulus; "selective entrainment" seems to occur because in this case entrainment is possible while a similar magnitude stimulus of longer period, say, 2 min, is found to be ineffective.

We suggest that the spontaneous fluctuations in peripheral blood flow are due to adjustments in the cutaneous circulation by the thermoregulatory system. With the body core temperature at 37° C, thermal variations in the extremities are handled

by the peripheral system. Selective entrainment occurs when a periodic thermal stimulus is applied, implying that the thermoregulatory system operates on a similar nonlinear basis to the blood pressure control system.

Decreased Feeding after Injections of Amino-acids into the Hypothalamus

BUT for two exceptions[1,2], attempts to inhibit feeding behaviour by direct intrahypothalamic administration of glucose have been unsuccessful[3-6]. The effects of other nutrients have yet to be assessed. We have found that microinjections of balanced amino-acid solutions into dorsolateral perifornical hypothalamic tissue, where consummatory behaviours are obtained with electrical stimulation, inhibit feeding in rats.

Nine male albino rats with unilateral electrode-cannulae aimed for perifornical hypothalamic tissue were used. Each animal also had a bipolar electrode aimed at the corresponding area in the contralateral side of the hypothalamus for another study. They were caged individually and allowed free access to powdered lab chow and water except during short deprivation periods before feeding tests, and the cages received light for 12 h each day.

Initially the behaviour of each animal was observed during electrical stimulation (50 Hz, sine wave, 8–46 μA) of the brain underlying the tip of the electrode-cannulae and for chemically induced feeding after cannulae-directed injections of 65 mM L-noradrenaline bitartrate dissolved in 90 mM NaCl in volumes of 1 μl. Then the effects of intrahypothalamic injections of amino-acids were determined on three separate occasions. In the first two runs, the effects were compared with those of urea; in the third, they were compared with those of NaCl and D-glucose. Amino-acids and glucose were injected as 10% w/v solutions; urea and NaCl were injected as 4.2% w/v and 2.0% w/v solutions (approximately equiosmotic to the amino-acid solution). Each 10 g of the amino-acid mixture contained 0.33 g histidine HCl, 0.79 g lysine HCl, 0.29 g tryptophan, 0.72 g methionine, 0.72 g phenylalanine, 0.91 g leucine, 1.14 g isoleucine, 0.82 g valine, 0.72 g threonine, 2.60 g sodium glutamate, 0.31 g glutamine and 0.65 g glycine. L-Isomers were used. During all tests intrahypothalamic injections (1 μl. each) were given 1 h 30 min and 5 min before the rats were given access to food. For the first run, food was removed 30 min before the start of the dark period and returned 1 h later; for the second and third runs, food was removed 1 h after the start of the light period and returned 6 h later.

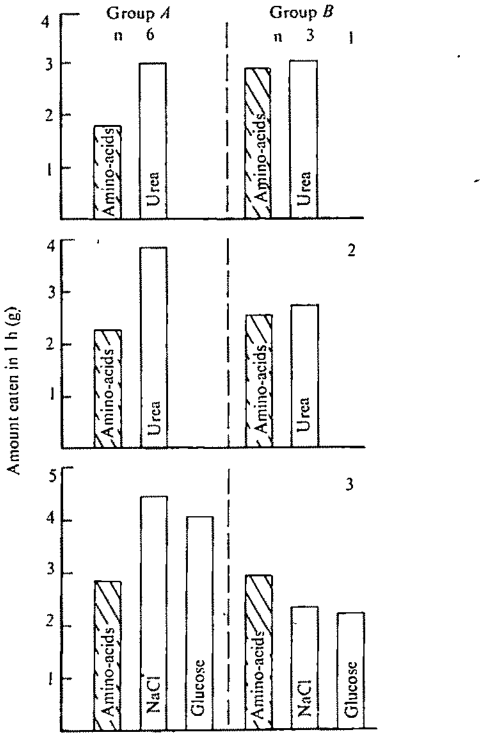

Fig. 1 Mean 1 h food intakes during three runs (see text).

Mean 1 h food intakes for the three runs are presented in Fig. 1. In six subjects, amino-acids depressed feeding more than control injections during every test (group *A*) ($Ns=6$, $Ps<0.2$; randomization test for mixed pairs); in three they did not (group *B*). In no case did the injections produce visually distinguishable abnormalities in behavour. The two groups also exhibited differential responses to injections of noradrenaline bitartrate and to electrical stimulation of tissue surrounding the tips of the cannulae. After noradrenaline injections, rats in group *A* ate 1.1 g (mean value) more than after saline injections; rats in group *B* ate only 0.4 g more ($n_1=6$, $n_2=3$, $V=1$, $P<0.5$; Mann Whitney test). Five rats in group *A* showed consummatory behaviour[7] during electrical stimulation through the electrode-cannulae and also learned to self-stimulate for the current; the remaining subject in group *A* only self-stimulated. Animals in group *B* exhibited flight during electrical stimulation and none exhibited appetitive behaviour or self-stimulation. Histological studies indicated that cannulae tips of rats in group *A* were located in dorsolateral perifornical hypothalamus, where consummatory behaviour has been obtained with electrical stimulation, while those of group *B* were in the far lateral hypothalamus or in mid-lateral hypothalamus near the ventral surface of the brain.

These data complement recent reports that high systemic levels of amino-acids depress feeding more than comparable levels of the other major nutrients[8,9] and suggest that circulating amino-acids depress feeding by a relatively direct action on hypothalamic neurones which are active during feeding behaviour. But the data do not necessarily imply the existence of a discrete sensory system which is responsive to blood amino-acids. Some amino-acids which are absorbed into the brain from the bloodstream[10] slow neural firing rates nonspecifically[11-13]. After the consumption of protein-rich meals, all neural activity, as well as that necessary for the facilitation of feeding, may be so affected. In any case, it is not yet known whether the observed effect reflects the operation of a physiological control mechanism.

Teratogenicity Studies of Methadone HCl in Rats and Rabbits

METHADONE maintenance was reported as a treatment for heroin addiction in 1965[1], and more than 10,000 patients are now maintained on the drug at more than 100 centres throughout the United States (unpublished Lilly Survey, 1970). Wallach *et al.*[2] observed that although women experienced abnormal menses during heroin addiction, regular menstruation and ovulation resumed with daily methadone treatment. In these studies several pregnancies were followed in which methadone maintenance was initiated before or during pregnancy with no apparent effect.

Guidelines for the clinical investigational use of methadone in maintenance programmes in the United States have been established only recently[3]. Because methadone was introduced as a narcotic analgesic several years before pre-clinical teratological studies were done, data about the effect of methadone in the pregnant animal are limited. In view of the lack of animal reproduction studies involving the drug, and the limited documented clinical experience with methadone in pregnant patients, the recommended treatment for the pregnant addict is hospitalization and narcotic withdrawal.

Foetal anomalies and decreased litter size were observed in hamsters after females had received large subcutaneous doses of methadone on the eighth day of gestation[4]. We now present data for species more commonly used in teratological studies. Rats and rabbits were given doses ten to fifty times the average daily human maintenance dose.

Methadone HCl (*dl*-6-dimethylamino-4,4-diphenyl-3-heptanone hydrochloride) was administered to pregnant Harlan albino rats and Dutch belted rabbits as previously described[5]. The beginning of gestation (day 0) was determined in the rabbits by artificial insemination. The rats were mated, and the time of conception was noted by the presence of a copulatory plug. The rats and rabbits, in groups of twenty-five and fifteen respectively, were given daily oral doses of distilled water, or 20 or 40 mg/kg of methadone by gavage during organogenesis and early foetal development (gestation days 6–15 in the rat, 6–18 in the rabbit). Doses of 60 mg/kg, given in preliminary studies, induced unacceptable levels of toxicity (maternal death and/or foetal resorption). Foetuses were recovered before term by Caesarean section, and examined for external abnormalities and visceral or skeletal defects.

In rats, methadone produced distinct maternal toxicity similar to that of morphine[6,7]. Hypertonia of skeletal muscle, which persisted up to 4 h after dosing, was often accompanied at the larger dose by catalepsy and respiratory depression; eight of the rats given methadone (three at the smaller dose) died of respiratory insufficiency. In rabbits, 40 mg/kg doses of methadone induced mild sedation during the early phases of the study. Two does on this regimen did not complete the test—one died on the twelfth day of gestation with signs of anorexia, weight loss and snuffles; the other aborted on the twenty-fifth day of gestation. The reproductive status of the animals that died was normal (necropsy evaluation); pregnancy was confirmed in seven of the eight rats and both rabbits.

In general, the treated rats ate and gained less than the control rats; in the rabbits, food intake was reduced in both the control and treated animals during the dosing period. These effects were not marked and were considered to be inconsequential in view of the negative teratological findings.

Pregnancy rates (Table 1) were depressed among animals on the 40 mg/kg regimen, but there was no sign of any impairment of reproduction. Normal litter sizes and numbers of corpora lutea indicated that the reduction in pregnancies was an isolated finding, unrelated to methadone treatment. Moreover, the fertility findings were not significantly variant from our cumulative control data (fertility in rats: range 70–100%, mean 90%; rabbits: range 40–100%, mean 80%). In treated rats resorption was slightly more frequent than in the controls; this was attributed to maternal toxicity.

* 1/3 of each litter was designated for visceral examination, 2/3 for skeletal examination. † Littermates. ‡ Same foetus.

Defects observed in the foetuses (Table 2) were representative of our control rat and rabbit populations. In the rats rudimentary tail, hydrocephalus and twelve ribs occurred as single, isolated defects; hydronephrosis was seen in foetuses of each treatment group, but most frequently in the control progeny. In the rabbits there was a low incidence of varus forepaws, hydrocephalus and hydronephrosis. Thirteen ribs, a common anatomical variation of our rabbits, and a few minor skeletal defects were observed as frequently in the control foetuses as in those of the methadone regimens.

Doses of 20 or 40 mg/kg of methadone administered orally to rats caused hypertonia of skeletal muscle and respiratory depression; some of the treated rats died of respiratory insufficiency. In rabbits, oral doses of 40 mg/kg induced mild sedation. Reproduction was not impaired in the rats or rabbits regardless of maternal condition. No drug-related defects were observed in the foetuses, and we concluded that methadone HCl in the doses which we used was not teratogenic in the rat or rabbit.

Impairment of Recent Memory by Marihuana and THC in Rhesus Monkeys

Several studies with humans have indicated that marihuana and its active ingredient, delta-9-tetrahydro cannabinol (THC), have disruptive effects on short term memory[1-3]. Of the few animal studies on THC, only that of Scheckel *et al.*[4] addressed the question of memory impairment. The results of that study were attributed to lack of motivation. The study described here was designed to elucidate the effects of marihuana on short term memory in rhesus monkeys using an automated delayed matching-to-sample task. In our laboratory, monkeys have been trained to puff cigarettes for a water reward, and thus we are able to study the effects of marihuana smoke while avoiding the set problems associated with human subjects. Another group of monkeys, trained on a similar memory task, was administered oral THC. Significant memory impairment was established with both modes of administration.

In the first experiment, two adult male rhesus monkeys, trained to smoke cigarettes[5], were placed on a two-task procedure for water reward. A smoking apparatus was attached to a 'Plexiglas' panel covering a 14 inch square opening on one side of each monkey's 36 inch cubic home cage. The smoking procedure has been described[6]; the only modification here was the absence of a dummy air tube, so that the monkeys were forced to puff smoke rather than having a choice of smoke versus air. A matching test was also attached to a 'Plexiglas' panel covering a 14 inch square opening on an adjacent side of each monkey's cage. The matching test has also been described elsewhere[7]. The combined smoking–matching procedure operated as follows: first, the monkey was required to make thirty puffs on the smoking machine (a fixed ratio 30 contingency was used throughout); this behaviour extinguished a light next to the puffing tube and signalled the start of the matching test. The monkey was then presented with a green or red sample light for 3 s on the matching panel. Touching a centre tube under the sample light turned off the light and, after a predetermined delay, two side

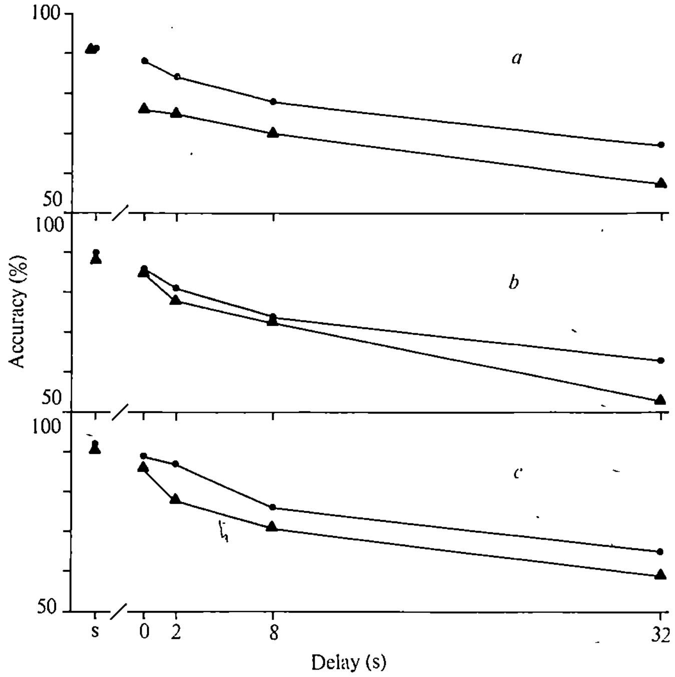

Fig. 1 Effect of THC on delayed oddity performance (s = simultaneous). ●, Control; ▲: *a*, 2.0 mg/kg THC; *b*, 1.0 mg/kg THC; *c*, 0.5 mg/kg THC.

lights appeared, one green and one red. Touching the solenoid of the light which matched in colour the previous sample light resulted in a 2 ml. water reward. If an error was made, or if no response was made after 8 s, the side lights were turned off and the light of the smoking machine appeared, signalling the start of the smoking test again. The monkeys were tested on a total of three delays in the matching test: 0 s, 5 s and 30 s; however, only two delays were used during the same session (either 0 and 30 s, 5 and 30 s, or 0 and 5 s). The delays were programmed randomly and the delay combinations were presented in a balanced order to control for possible sequence effects. Testing was programmed automatically by Digibit logic circuits as well as by punched tape devices, all of which were located in a separate control room.

The monkeys were tested in the two-task procedure 7 days a week and received all their water during a daily 4 h testing session (starting at 1030 h). On all days the monkeys were given access to thirty cigarettes. On control days the subjects received tobacco cigarettes (Raleigh plains). On drug days (Tuesdays and Fridays) thirty marihuana cigarettes, rolled in the laboratory, were used, with tobacco plugs at either end. Each cigarette contained approximately 0.5 g of marihuana, obtained from *Cannabis sativa*, Mexican female, 1969, which was supplied by DHEW, Public Health Service, NIMH (analysis: THC, 1.5%; cannabidiol, 0.12%). The effect of marihuana on each monkey's performance on each delay was tested an average of six times. The total number of smoking puffs per session, the total number of matching trials taken, as well as the accuracy on each delay, were recorded and analysed. Drug days and control days were compared, the day immediately preceding the drug day being considered as the control day. Chi-square tests were used to compare statistically the differences.

The results (data for two monkeys combined) are presented in Table 1. Accuracy was lowered but not significantly impaired by marihuana at 0 s ($P > 0.2$) and 5 s (just missed significance with $P = 0.06$). On the 30 s delay, however, accuracy was significantly impaired ($P < 0.01$) by marihuana. The rate of puffing smoke as well as the rate of responding on the matching test were both significantly decreased ($P < 0.05$ in both cases). (There were no significant differences between the two monkeys on any performance measure in any drug or control condition.)

Table 1 Effect of Marihuana Smoking on Delayed Matching Performance

Accuracy %	Marihuana	Control
0 s	99	100
5 s	89	94
30 s	68	74
Total puffs	4,614	5,795
Total matching trials	150	198

In the second experiment, four adult rhesus monkeys (different monkeys from those used in the first experiment) were used, all with extensive previous experience on the memory task. The task was similar to the matching test used in the first experiment, except that instead of matching the colour of one of the side lights to the sample light, the monkey had to choose the odd colour[8]. The oddity test was attached to a 'Plexiglas' panel covering a 14 inch square opening on one side of each monkey's 36 inch cubic home cage. On each trial one of five delay conditions was used: simultaneous, 0, 2, 8 and 32 s. They were presented in randomized order such that each animal received 960 trials (192 for each delay) during an 8 h session (starting at 1000 h). For the simultaneous presentation a red or a green light (the sample stimulus) was presented on the central display unit at which time the animal was required to touch a centre tube (under the sample light) within 3 s. A response to the sample stimulus immediately resulted in presentation of one red light and one green light (the comparison stimuli) on each of the two side units, respectively, for up to 8 s; the sample stimulus remained on with the comparison stimuli. The monkey then had to non-match (oddity) one of the side comparison stimuli with the colour of the sample stimulus by touching the correct tube in order to receive a water reward (1 ml.). The procedure for the real delay conditions was the same, except that the sample stimulus appeared alone and terminated some time before the comparison stimuli appeared. The monkeys were tested 7 days a week and received all their water in the test conditions.

The THC (supplied by NIMH) was diluted in 10 ml. of apple juice and administered orally. On control days 10 ml. of apple juice alone was administered. The monkeys drank the juice from a small plastic bottle through the front of their cages. The juice or juice–drug mixture was administered 15 min before testing. Drug days were Tuesdays and Fridays; six drug administrations were given, one at 0.5 mg/kg, three at 1 mg/kg and two at 2 mg/kg. The accuracy (% correct) and rate (% responses made out of possible total) data recorded on punched tapes were sorted and summed for drug and control days according to delay conditions. Again, the day before the drug day was considered the matched control day. Chi-square tests were used for data analysis.

The accuracy results (data for four monkeys combined) are presented in Fig. 1. Accuracy was significantly impaired by 0.5 mg/kg of THC on the 2 s and 32 s delays ($P < 0.05$ in both cases); by 1.0 mg/kg on the 32 s delay ($P < 0.05$); and by 2.0 mg/kg on the 0, 2, 8 and 32 s delays ($P < 0.05$, 0.05, 0.05 and 0.01, respectively). Accuracy was never impaired when sample and comparison stimuli were simultaneous. The rate of responding was significantly decreased by all doses of the drug in all testing conditions ($P < 0.01$ in all cases). The percentage of responses, taken out of the total offered, was approximately 60% on control days, 48% for 0.5 mg/kg THC, 39% for 1.0 mg/kg THC and 27% for 2.0 mg/kg THC.

In both the marihuana and THC studies, both the rate of responding and the accuracy were affected. The rate effects possibly confirm the conclusion[4] that THC induces a "loss of ability or motivations to perform complex tasks". But our results also strongly suggest that marihuana and THC have a definite effect on short term retention processes *per se*. In the smoking–matching test, marihuana lowered accuracy only when a 30 s delay was used. In the oddity test, THC impaired accuracy only in delay conditions and never in the simultaneous condition. This type of impairment is different from that shown with amphetamine, scopolamine, chlorpromazine, pentobarbital, LSD[7,9–11] or mescaline (unpublished data) on a similar task. By comparison with these other drugs, the specificity of THC is indeed remarkable.

Unlike Scheckel *et al.*[4] we obtained no evidence of long term effects. Performance on days immediately following drug administrations was always similar to that on days preceding them. Scheckel *et al.*[4] used squirrel monkeys and we used rhesus monkeys; this species difference may explain the variant results. We also failed to find objective criteria which would warrant the assumption of hallucinations[4] in our monkeys; their behaviour may have changed quantitatively, but not qualitatively. Scheckel *et al.*[4] also reported a biphasic effect of THC on response rate, with depression occurring at low doses and stimulation at high doses (16, 32 and 64 mg/kg). As more than half of their monkeys died after being administered these high doses, we were unwilling to attempt a confirmation of possible excitation effects.

Oddity and Specific Searching Image more Important than Conspicuousness in Prey Selection

IN an earlier report[1] I presented results from a pilot experiment which suggested that conspicuousness of prey was the most important determinant in prey selection. I now have results from 1,600 laboratory experiments performed with two species of hawks in rigorous experimental conditions, which suggest that oddity and the specific searching image are more important. Many observations and experimental results fit well into the generalization that predators have a tendency to select odd prey, animals that differ in some way from most prey[2,3], although unequivocal evidence is lacking. Predators also show a tendency to continue to select a given type of prey, even though other types may be as readily, or even more easily available, a phenomenon that L. Tinbergen[4] has termed the "specific searching image". My experiments are a simultaneous test of three factors which influence prey selection: conspicuousness, oddity, and the specific searching image.

Six tamed American kestrels (*Falco sparverius*) and two broad-winged hawks (*Buteo platypterus*) were allowed to prey on white laboratory mice, some of which had been coloured grey with food dye. In each experiment, nine mice of one colour and one of the other were presented on a substrate which was painted to match one or the other colours of mice. Each of the two colour combinations of mice was replicated fifty times on each of the two colours of substrate, giving a total of 200 experiments for each bird (Table 1). The sequence in which given mouse and substrate combinations (*A*, *B*, *C*, *D*) were presented to the hawk was randomized. The hawk was allowed to select only one mouse per experiment; the expected number of captures of each colour of mouse, assuming no (or random) selection is given in Table 1. The mice were presented individually on pedestals about 10 cm square and 15 cm high which were arranged about 10 cm apart on an arc of a circle of approximately 2 m radius. The hawk was placed on a perch at the centre of the circle. Laboratory mice rarely leave such a pedestal and the distribution of mice can thus be controlled. The position of the odd mouse in each experiment was randomized.

All eight hawks showed a statistically significant preference for odd mice, but only of one colour; four for white, odd mice and four for grey, odd mice (Table 2). In two cases the preference for white was sufficiently strong that no grey (and odd) mice were taken from a grey substrate. Three birds took significantly more odd mice of the preferred colour when these differed in colour from the substrate than when the mice matched the substrate. Thus mice of a particular colour were preferred, but only when they were odd, and the conspicuousness of the mouse had relatively little influence on the results.

My results thus suggest that the specific searching image may be the major determinant in prey selection in hawks although oddity is very nearly as important. I am conducting

Table 1 Experimental Design

CO_2-dependent Oxygen Evolution by Envelope-free Chloroplasts

THE chloroplasts isolated by Hill[1] in the 1930s were capable of rapid rates of oxygen evolution when provided with an artificial electron acceptor (oxidant) but did not retain the ability to assimilate CO_2 at rates detectable by the methods then available. Nearly 20 yr later the ability of isolated chloroplasts to fix CO_2 was demonstrated by Arnon, Allen and Whatley[2] but even then the rates were only 3–6% of those supported by the intact plant. By 1966, when the rates of fixation by chloroplasts isolated in sugar media first matched those of intact leaves[3,4], it had been established[5,6] that high rates of carbon assimilation were only achieved by chloroplasts with intact envelopes. It is unlikely that all the earlier difficulties were caused by the unintentional isolation of damaged chloroplasts but, except for some early work by Arnon[7] (in which chloroplasts were supplemented with cytoplasmic malic enzyme), it has certainly not been possible to show CO_2-dependent oxygen evolution by envelope-free chloroplasts[8] and rapid rates (comparable with the Hill reaction) have not been previously reported. Such high rates have now been observed in a reconstituted system containing ATP, ferredoxin, NADP (nicotinamide adenine dinucleotide phosphate), R5P (ribose-5-phosphate), CE (soluble components released from osmotically shocked chloroplasts) and envelope-free chloroplasts.

Fig. 1 shows that oxygen was evolved immediately after illumination of a mixture from which PGA (3-phosphoglycerate) and R5P were initially omitted. This evolution is attributable to the reduction of NADP and it ceased (or slowed, depending on the activity and content of the chloroplast extract) according to the stoichiometry of equation (1).

$$H_2O + NADP \rightarrow NADPH_2 + \tfrac{1}{2}O_2 \qquad (1)$$

At this point evolution can be restarted by the addition of PGA[9,10] or by the addition of R5P (if CO_2/bicarbonate is present), and it can be assumed that both of these compounds lead (by the appropriate reactions of the Benson–Calvin cycle) to the formation of DPGA (1,3-diphosphoglycerate) which then regenerates NADP in the oxidized form according to equation (2).

$$NADPH_2 + DPGA \rightarrow \text{glyceraldehyde-3-phosphate} + NADP + \text{orthophosphate} \qquad (2)$$

The response to the addition of PGA is very rapid (Fig. 1*A*) and the maximum rate is attained within seconds. The response to R5P depends to some extent on the activity of the preparation but it is always detectably slower (Fig. 1*B*) than the response to PGA and in some experiments the rate was not maximal for 2–3 min.

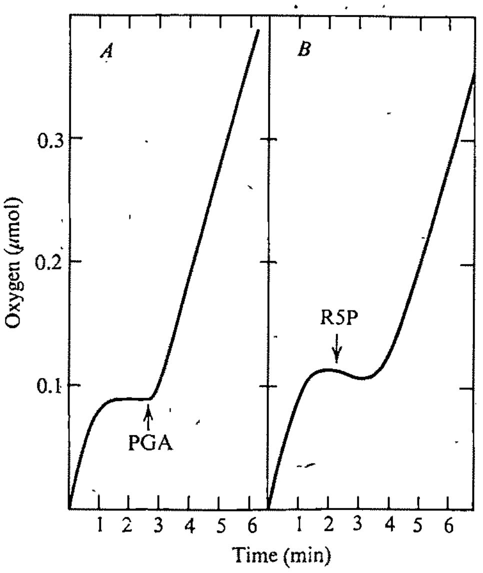

Fig. 1 Oxygen evolution by envelope-free chloroplasts initiated (*A*) by adding PGA or (*B*) by adding R5P. Only reaction mixture *B* contained added CO_2/bicarbonate. Intact chloroplasts were prepared in sorbitol medium[6] from 80 g pre-illuminated spinach leaf and freed of their envelopes by resuspending in 10 ml. assay medium (AM) at 1/25 full strength. NaCl was then added to a final concentration of 0.1 M. After a second centrifugation the envelope-free chloroplasts[6] were resuspended in AM and the supernatant retained and designated CE[9,10]. The chloroplasts from which the fraction CE was derived contained a total of 4 mg chlorophyll. The protein content of CE was 12 mg/ml. Each 2 ml. reaction mixture contained CE (0.9 ml.) envelope-free chloroplasts (100 µg chlorophyll) double strength AM (1 ml.) ferredoxin (3 nmol) and NADP (0.25 µmol). AM contained HEPES[17] (50 mM at *p*H 7.6), sorbitol (0.33 M), EDTA (2.0 mM) $MgCl_2$ (1.0 mM), $MnCl_2$ (1.0 mM). In *A*, the reaction mixture also contained 0.4 µmol of ATP and 3 µmol of PGA were added as indicated. In *B*, 4 µmol of ATP and 200 µmol of $NaHCO_3$ were added at the outset and 3 µmol of R5P as indicated. Oxygen evolution was measured in twin oxygen electrodes at 20° C in saturating red light[9].

Oxygen evolution could be initiated by PGA in the absence of added CO_2 (Fig. 1*A*) whereas with R5P (Fig. 1*B*) CO_2/bicarbonate was also needed. This requirement for bicarbonate is illustrated in Fig. 2. In this experiment, as in Fig. 1, the $MgCl_2$ content of the reaction mixtures was the same as that used in earlier experiments with intact chloroplasts (for example, ref. 6). At this concentration of $MgCl_2$, however, it is necessary to add CO_2/bicarbonate in ten-fold excess of that needed to saturate intact chloroplasts. The addition (Fig. 2) of the necessarily large volume (0.2 ml.) of bicarbonate solution produces a dip in the oxygen electrode trace (owing to the problem of matching the oxygen concentration of the reaction mixture with that of the added bicarbonate solution). This causes some difficulty in interpreting the kinetics of response but many experiments of this sort have led us to the conclusion that there is again a finite lag between the addition of bicarbonate and the subsequent attainment of the maximum rate (compare the addition of R5P in Fig. 1). If the concentration of $MgCl_2$ is raised by 4 mM there may be measurable oxygen evolution in the absence of added bicarbonate and saturation is reached at bicarbonate concentration closer to 10 mM (compare refs 11–14).

The CO_2-dependent oxygen evolution was observed only in the presence of added ATP. The response to added ATP was immediate (unlike that to R5P or CO_2/bicarbonate) but the immediacy of this reaction may be partly related to the further conversion of small quantities of PGA (newly formed at the expense of endogenous ATP) rather than to an excep-

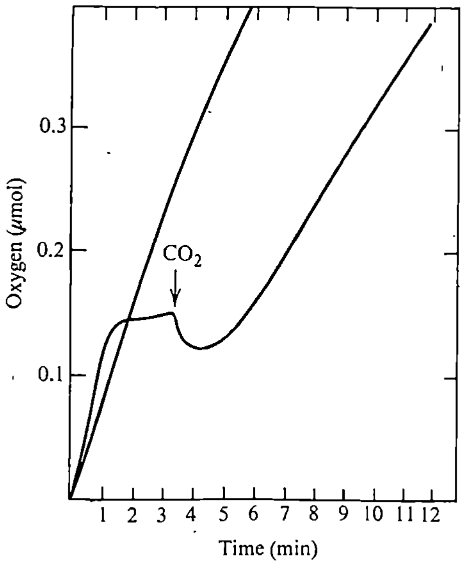

Fig. 2 CO_2-dependent oxygen by envelope-free chloroplasts. As for Fig. 1 except that both reaction mixtures contained ATP (5 μmol) and R5P (3 μmol) from the outset. CO_2/bicarbonate (200 μmol) was added before illumination or as indicated.

tionally rapid formation of triose phosphate from R5P. In most experiments there was no CO_2-dependent oxygen evolution unless ATP was added in excess of that required to saturate PGA-dependent oxygen evolution. Following the addition of ATP to reaction mixtures containing limiting quantities of chlorophyll (20 μg) which have been pre-illuminated (2 min) we have observed rates of evolution as high as 175 μmol/mg chlorophyll/h. When there has been no possibility of prior accumulation of PGA from R5P and CO_2 (for example, when R5P and $NADPH_2$ have been added simultaneously at the onset of illumination) the maximum rates were nearer 80 μmol/mg/h but under these conditions it was often impossible to obtain much faster rates with added PGA as substrate (Fig. 1) and it is probable that accumulation of PGA is not the only factor which contributes to the highest rates observed.

Our results show that it is possible to reconstitute a system in which completely envelope-free chloroplasts will support a carbon dioxide-dependent oxygen evolution and that this system requires added ATP and R5P. For maximal rates it is necessary to increase either the bicarbonate concentration or the Mg^{2+} concentration substantially beyond the respective optima for intact chloroplasts. Indirectly, our observations confirm and extends those of Whatley *et al.*[15] who first demonstrated CO_2 fixation by broken chloroplasts fortified with CE. Our approach is essentially similar but in the light of recent knowledge we have also been able to vary the nature and concentration of additives in such a way that we were able to obtain better rates (assuming an incubation period of 1 h, the figure given by Whatley *et al.* for CO_2 fixed with R5P corresponds to a rate of 8 μmol/mg chlorophyll/h).

Without the constraints imposed by physical compartmentation and biochemical regulation it is improbable that it will ever be possible to reconstitute, in one simple suspension of illuminated envelope-free chloroplasts, a system capable of operating the entire Benson–Calvin cycle, as a cycle. That long sequences of the complete system can be made operable, however, indicates that these are not (in themselves) dependent on an intact structure, except to the extent that structure defines the environment within the chloroplast in which the reactions normally occur. Further investigation of the reconstituted system could clearly lead to a better understanding of these environmental requirements including those which govern the affinity of the principal carboxylating enzyme for its substrate[16].

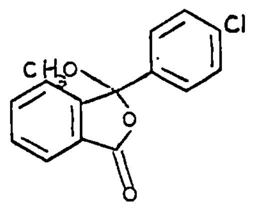
Elimination of the Response to Gravity of Lettuce Seedlings

While investigating the effects of certain lactones on the germination of lettuce seeds I have found that 3-4′ chlorophenyl 3-methoxy phthalide (I) modifies the growth of seedlings. Jones *et al.* found that this compound and other derivatives of 2-benzoylbenzoic acids—either as the free acid or as lactones—affected the growth, geotropic and phototropic behaviour of seedlings.

Radicles and hypocotyls of most seedlings are strongly orthogeotropic[2,3]. Synthetic growth regulators with physiological action like that of IAA (β indol-3-yl acetic acid) affect root and shoot growth, sometimes making these organs grow in an unexpected direction. Antitropistic effects can also be induced by morphactins (derivatives of 9-hydroxy-9-carboxylic acid fluorene)[4], N-α-naphthyl phthalamic acid (NAP)[5], and tri-iodo benzoic acid (TIBA)[6].



(I)

Table 1 Orientation of Radicles and Hypocotyls of Lettuce Seedlings Treated with 3-4′ Chlorophenyl 3-Methoxy Phthalide (I) (Effective Concentration Saturated Aqueous Solution)

	Degrees from horizontal (negative upwards) Radicle	(positive downwards) Hypocotyl
Control	$+74.06 \pm 4.79$	-94.94 ± 1.52
Treated	-20.50 ± 5.18	-0.44 ± 2.57

Compound (I) eliminates the geotropic response of the seedling, and the direction of growth is then determined by the initial orientation of the embryonic axis. Lettuce, cultivar Grand Rapids, or mustard seedlings were grown either on seed test paper which was loaded with (I), or from seed which had been soaked in a saturated aqueous solution of (I) at 4° C for 48 h. (Seed test paper 90 mm by 0.4 mm thick can be loaded with a given weight of physiologically active material in an organic solvent. After this has evaporated water is added to provide an aqueous milieu equivalent to a given molarity. Although this may seem to be greater than saturation concentrations the fat content of the seed ensures that the active material is present at an endogenous level corresponding to the stated molar concentrations. Control substratum was treated with the solvents used.)

Seeds were placed on the paper so that the radicle pointed in the desired direction. Because small seeds adhere readily to seed test paper, I usually positioned seeds on the paper lining the base of the Petri dish and then set the paper vertically. Using another method, I folded seed test paper (90 mm × 0.4 mm thick) to give a centre upright fold secured by two paper clips. Seeds were inserted into the apex of the fold and held in any desired position. These assemblies were placed in plastic trays (15 cm × 20 cm) containing about 50 ml. of deionized water. The seeds germinated and the seedlings developed at 20° C in darkness. Phototropic curvature was induced in 72 h dark grown seedlings derived from vertically oriented embryos, radicle down, by irradiating unilaterally with a 40 W tungsten bulb, run at mains voltage (240) 75 cm from the seedlings. In all experiments on phototropism at least nine, and usually sixteen, individuals were measured. Each of these experiments was performed at least twice. Observations on the statoliths of the hypocotyl of mustard were made on freshly cut sections stained in aqueous iodine.

Elimination of geotropism by compound (I) was demonstrated by placing sixteen lettuce seeds at appropriate compass points on vertically positioned Petri dishes, with radicles facing outwards. The paper was loaded with (I) to a final concentration equivalent to 10^{-4} M. Fig. 1 shows these plates after 72 h at 20° C. Clearly (I) affects seedlings so that the direction of growth of the axis is determined by the original orientation. Fig. 1 also shows that the plumular hook does not form in treated material, and is only manifest in control material when the axis is off centre or inverted—note the appearance of the lowermost seedling in the control dish.

A better measure of the response of the seedlings to (I) was obtained by placing seeds horizontally and measuring the angle between the radicle or hypocotyl and the horizontal axis. Above horizontal attitudes are prefixed by a negative sign to agree with conventional nomenclature of orthogeotropic behaviour. Table 1 lists one set of results.

To compare growth by radicles and hypocotyls of treated seed, seeds were distributed on seed test paper as described, the paper being loaded with appropriate mixtures.

Table 2 shows that the growth of radicles of treated seeds was reduced by about 20% while the growth of hypocotyls was reduced by about 40%. As IAA is involved in tropic responses and gibberellic acid (GA) in extension growth, the effect of coapplication of each of these with (I) was examined. Table 2 shows that 10^{-4} M GA overcomes the slight inhibition of growth caused by (I) without any effect on the elimination of the geotrophic response. IAA severely decreases the extension of the radicle, as expected, but there is evidence that at 10^{-5} M it can re-establish normal geotrophic behaviour at the expense of growth in some radicles.

Phototrophic behaviour is affected less by (I) (Table 3). The slower response of the treated material may be a result of the reduction in extension growth that (I) causes, and it is possible that the compound was used in a concentration less than that which would have eliminated phototrophism. The results of Jones *et al.*[1], while not strictly quantitative, indicate that these compounds affect phototropism less than geotropism.

A possible point of action of (I) on the geotropic response is the statolith, which many people think is a central feature in the perception of gravity[2,3]. If statolith starch were lost,

Table 2 Growth, Geotropic Response and Development of Plumular Hook in the Young Axis of Lettuce Seedlings Treated with (I), GA, and IAA Singly and in Combination

	Radicle			Hypocotyl			
	Geotropic response		Length	Geotropic response		Length	Plumular
	+ve	none	(mm)	−ve	none	(mm)	hook
Control	30	0	20.10 ± 0.916	30	0	5.00 ± 0.352	+
10^{-4} M (I)	0	31	16.13 ± 0.897	0	31	2.87 ± 0.225	−
10^{-4} M (I)+ 10^{-5} M GA	0	32	16.03 ± 0.823	0	32	4.09 ± 0.341	−
10^{-4} M (I)+ 10^{-4} M GA	0	31	20.19 ± 0.500	0	31	4.97 ± 0.359	−

Table 3 Phototropic Curvature of Lettuce Seedling Hypocotyls grown in the Presence of a Saturated Solution of (I)

Length of exposure to light (h)	Degrees curvature from vertical Treated	Control
7.5	5.8 ± 2.46	29.3 ± 1.53
24.0	41.1 ± 7.27	51.5 ± 2.85

then the axis could not perceive the stimulus[7], or if the starch grains could not move under gravity than it might be expected that there would be no curvature when the axis is placed off vertical. Fig. 2 shows that the starch grains in the endodermis of mustard hypocotyl, often considered to be statoliths, are present in treated material, and move in response to gravity. They can be seen congregated along the basal wall of the cell in vertically grown hypocotyls, but are less distinctly oriented in seedlings which were growing horizontally.

According to the Cholodny–Went hypothesis, curvatures result from the misorientation of an organ in the gravitational field, or from unilateral illumination, because the unequal distribution of auxin across the width of the organ gives unequal bilateral growth in the region of cell elongation[8,9]. At least for lettuce seedlings (I) can prevent curvature in a gravitational field but not in the case of unidirectional illumination. If the Cholodny–Went hypothesis is accepted, and the phototropic curvatures of seedlings treated with (I) result from unequal bilateral distribution of auxin, then it might be argued that the establishment of this bilateral asymmetry in auxin concentration is *per se* not affected by (I). The effect of (I) on geotropic sensitivity of seedlings must be sought elsewhere.

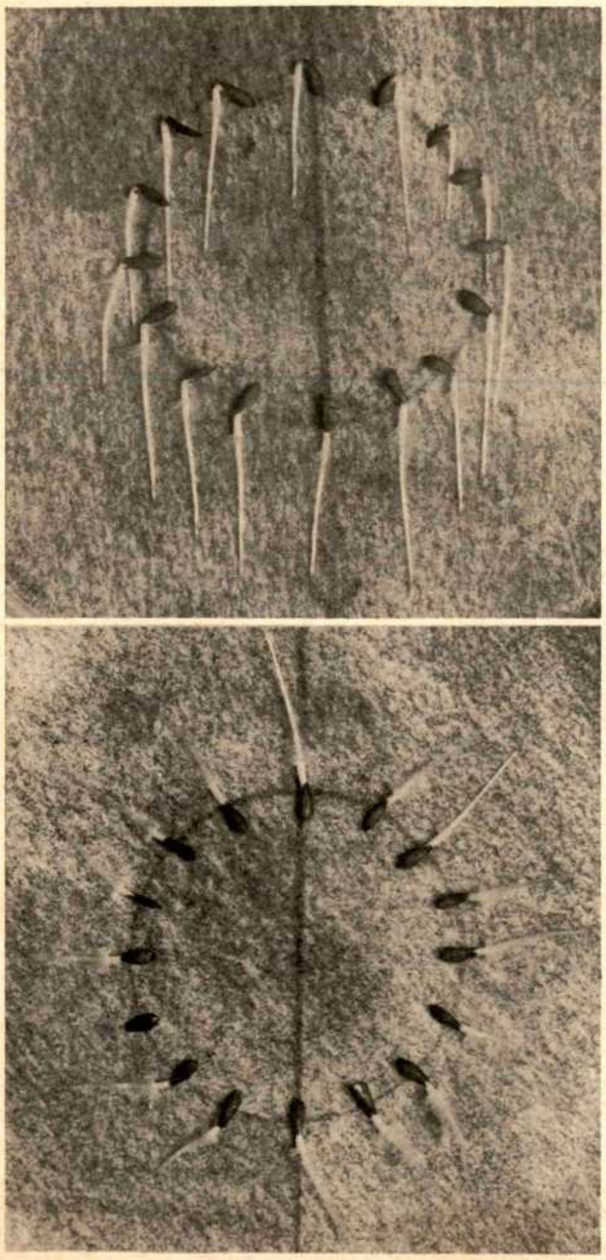

Fig. 1 Seedlings from lettuce seed in which embryonic axis is positioned with respect to given compass points. Upper—control. Lower—treated with 3-4′ chlorophenyl 3-methoxy phthalide.

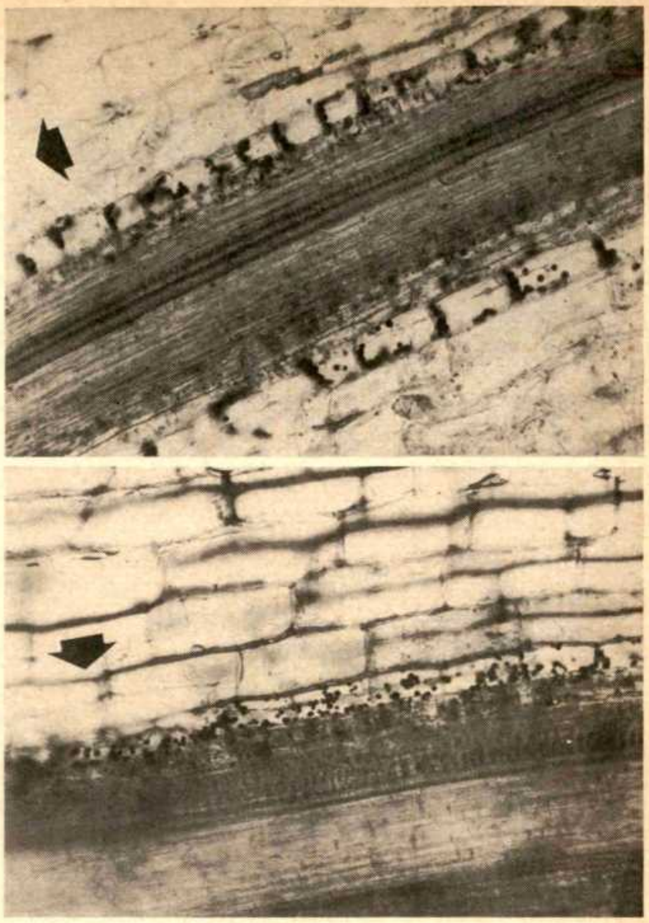

Fig. 2 Statolith orientation in hypocotyl endodermis of mustard. Arrows indicate direction of gravity.

Audus suggests that geotropism is a catenary process with several interconnected links, each requiring to be completed before the phenomenon can be expressed properly[2]. The first link relates to the site of perception, and if this is the statolith then (I), which has no observable effect on the starch grains of the endodermal cell of the hypocotyl of mustard, is unlikely to act directly on the statolith. I do not know which link in Audus's chain of events is affected by (I), but this compound clearly provides a useful tool for the study of this phenomenon.

The reversal by GA of the slight growth inhibition caused by (I) in the roots and hypocotyls suggests that (I) competes with endogenous GA for the site of action of this hormone. This is in agreement with the idea that candidate antigibberellins should occur among unsaturated lactones[10], which include coumarin[11], ramulosin[12] and patulin[13]. It is well known that these and other unsaturated lactones are potent physiologically active compounds in many classes or organism[14]. So far, however, such lactones seem to be restricted in their antigibberellin activity, being most noticeably active in the lettuce seed germination assay. Inhibition of GA-induced elongation of organs is less common. Perhaps the inhibition of elongation by (I) is sufficient to mask the growth differential across the elongating organ in geotropism but not in phototropism, though the less rapid attainment of the new position in unilaterally illuminated hypocotyls is possibly a reflexion of the reduced rate of growth, and if the inhibition were greater then phototropic curvature might not occur. Even in untreated material phototropic curvature supervenes on geotropic response of hypocotyls suggesting that light is much more potent in establishing unequal distribution of auxin than gravity, and it is possible that (I) is unable to maintain equality of auxin concentration in a unilateral light field.

The material used in this investigation was a gift from Dr A. H. Berrie, ICI Dyestuffs Division, Manchester.

Mitotic Cycles in Dicotyledons and Monocotyledons

THE duration of the mitotic cycle in comparable tissues of different plant species is closely correlated with the amount of nuclear DNA[1,2]. In a survey of seven species Van't Hof[2] showed that the average duration of the mitotic cycle in root tip meristems increases at the rate of 0.3 h/pg of DNA. Our own data agree in general with these results, but we have found certain exceptions. For example, where the increase in DNA is brought about by the addition of B chromosomes the duration of mitotis is increased to a disproportionate extent[3]. We have also found an unexpected difference in the relation between nuclear DNA and the duration of mitosis in monocotyledons as compared with dicotyledons.

Table 1 and Fig. 1 show, as expected, the increasing duration of the mitotic cycles with increasing DNA. They also show that the rate of increase is of the same order in both monocotyledons and dicotyledons. There is in one respect, however, a marked difference between monocotyledons and dicotyledons. For the range of DNA values covered by this survey the complete mitotic cycle is, on average, almost 4 h longer in dicotyledons.

It is pertinent to inquire whether this consistently large difference between the two classes of angiosperms is attributable to any particular phase of mitosis or whether all phases are equally affected. From Table 1 and Fig. 1 it is evident that there is no difference in the duration of the synthesis (S) phase. Neither were there significant differences in the G2 and division phases. From Table 1 it is clear that the difference between monocotyledons and dicotyledons is accounted for largely by the variation in G1, that part of interphase preceding synthesis.

There is evidence that the extension of G1 in dicotyledons may be associated with the degree of chromosome coiling during division. Table 1 shows that the DNA density of chromosomes at metaphase of mitosis in the dicotyledons is almost twice that in monocotyledons, the chromosomes being more highly coiled. It therefore seems reasonable to suggest that in dicotyledons the uncoiling of chromosomes before synthesis would require a longer time and a longer G1 than in monocotyledons. The difference in chromosome organization which distinguishes the two groups may, in turn, stem from one of two genetic causes. The first is a difference in the basic archi-

Importance of Synchrony of Ear Emergence in Plant Breeding Programmes

In plant breeding, there is a general trend to apply the term "synchrony" to intra-plant variance or inter-tiller variance of a character like ear emergence. Thus, plants with the least intra-plant variance are considered more synchronous. The importance of synchrony of tillering in breeding programmes and the procedure for studying it is not yet well defined. To investigate this topic further I have studied six genetically distinct varieties of spring barley which have been bred in the past with little or no evidence of conscious selection for synchrony.

Table 1 Correlation Coefficients between Grain Yield per Plant and the Intra-plant Variance (Synchrony) of the Four Component Characters Studied

Variety	Correlation coefficients between grain yield per plant and Synchrony of ear emergence	Synchrony of height	Synchrony of the number of grains per ear	Synchrony of weight of grains per ear
'Archer'	−0.14	−0.39	−0.59	−0.71 *
'Impala'	0.79 †	0.17	0.51	0.60

'Sultan'	−0.18	−0.17	−0.22	−0.10

* Significant at the 5% level.
† Significant at the 1% level.

A randomized block design comprising five replications was used for laying out the field experiment in 1969. Observations on grain yield per plant, days to ear emergence, plant height, the number of grains per ear and weight of grains per ear were recorded for each individual tiller of a plant. Individual plants were spaced 5 cm apart in normal field conditions. Two approaches were used to study synchrony, one using intra-plant variance and the other using regression coefficients of the mean value of a particular tiller on its own tiller number. The tiller numbers were given in the order of their ear emergence. In the absence of a more appropriate term, synchrony has been used to describe characters other than ear emergence to reflect intra-plant variance, the higher synchrony denoting least intra-plant variance.

The correlation coefficients between grain yield per plant and the intra-plant variance used as synchrony of the four characters studied are given in Table 1 for each variety. If the synchrony of ear emergence was negatively correlated with grain yield (as would be desirable if the genotypes were higher yielding and had least intra-plant variance for ear emergence), then the association was also negative between the synchrony of other characters and grain yield per plant. Of the six varieties studied only 'Rika', 'Sultan' and 'Archer' have shown this trend, and the intra-plant variance for all the characters is also low. Moreover, the synchrony of all the characters in three of the six varieties seems to be positively associated with the synchrony of ear emergence.

The regression slopes obtained by regressing the mean value of a particular tiller on its own tiller number can be used to judge the synchrony of a variety for the character in question. The idea is that the subsequent tillers of a synchronous variety should show phenotypic expression of a particular character which is similar, if not identical, to that of the first few tillers. Thus the genotype showing the least or no regression slope is

Table 2 Regression of the Mean Value of each Individual Tiller on its Number for Different Characters estimated for Six Varieties of Spring Barley

b, Regression coefficient; S_b, standard error of b.

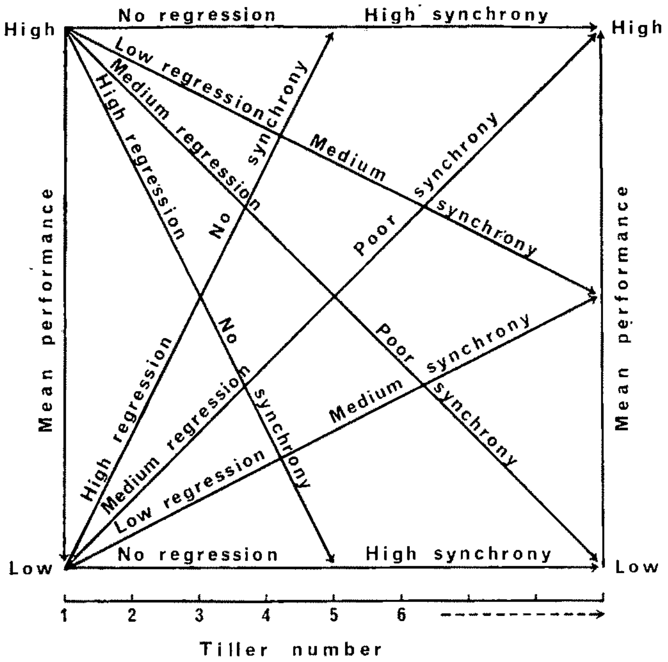

Fig. 1 A generalized scheme for studying synchrony.

the most synchronous. Accordingly, a generalized scheme for studying synchrony is presented in Fig. 1. A two-way approach is presented, where characters like ear emergence and height are recorded in ascending and descending order, respectively. Thus, the sign of the regression slope is not relevant, and it is the magnitude of the slope which determines synchrony. As Table 2 shows, 'Rika', 'Sultan' and 'Archer' expressed least regression slopes for the four characters studied. 'Rika' had the lowest regression slopes and was the most synchronous, whereas 'Sultan' and 'Archer' expressed medium synchrony. 'Spratt' was the most non-synchronous variety.

'Rika', 'Sultan' and 'Archer', which showed synchrony of ear emergence and other characters, might well be exploited. It would be desirable, however, to confirm the trend in a wide range of environments and the genetic basis of synchrony needs careful investigation. Of the two approaches used for studying synchrony, that involving regression coefficients is simpler and more informative and could be used in the future.

Reports of the effectiveness of the component approach to selective breeding are becoming available for cereal crops such as wheat[1-4] and barley[5,6]. These studies have provided considerable evidence in favour of component breeding and it has been established that selection on the basis of grain weight without ignoring grain yield would lead to improvements. I have now found that synchrony of tillering, which can be judged at the stage of ear emergence or even earlier in plant development, could also be used as a selection criterion for improving yield in plant breeding programmes.

Evaluation of Bicuculline as a GABA Antagonist

THERE has been controversy recently about the reliability of bicuculline as an antagonist of the putative inhibitory transmitter γ-aminobutyric acid (GABA) in the brain[1-3]. Although the effects of bicuculline have so far been explained in terms of its combination with the GABA receptor, bicuculline might also affect the removal processes for GABA and the synthesis and release of endogenous GABA. We have therefore made quantitative analyses of the effects of iontophoretically applied bicuculline on the responses of neurones to GABA and have also estimated the effects of bicuculline on the concentration and turnover of GABA in the brain, GABA uptake and the synthetic and degradative enzymes glutamate decarboxylase (GAD) and 4-aminobutyrate : 2-oxoglutarate aminotransferase (GABA-T).

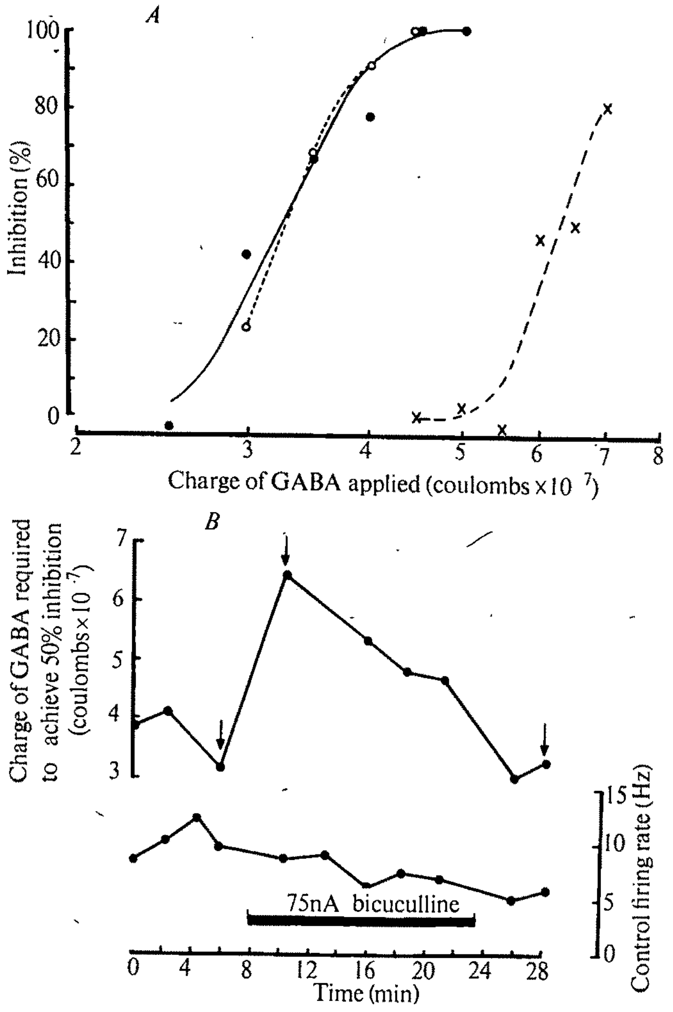

Fig. 1 *A*, Dose-response curves of percentage inhibition of cell firing against coulombs of GABA applied at a constant current of 10 nA. The cell was 1.33 mm deep in the suprasylvian cortex of a cat and was driven by continuous application of 75 nA glutamate. ●, Control response; ×, response during continuous application of 75 nA bicuculline; ○, recovery response. *B*, Plot of coulombs of GABA required to achieve 50% inhibition of the firing rate of the same cell as above during repeated 10 nA applications of GABA before, during and after a 75 nA application of bicuculline. The arrows indicate the values taken from the curves in *A*. Bicuculline clearly antagonized the action of GABA but had no effect on the control firing rate of the cell.

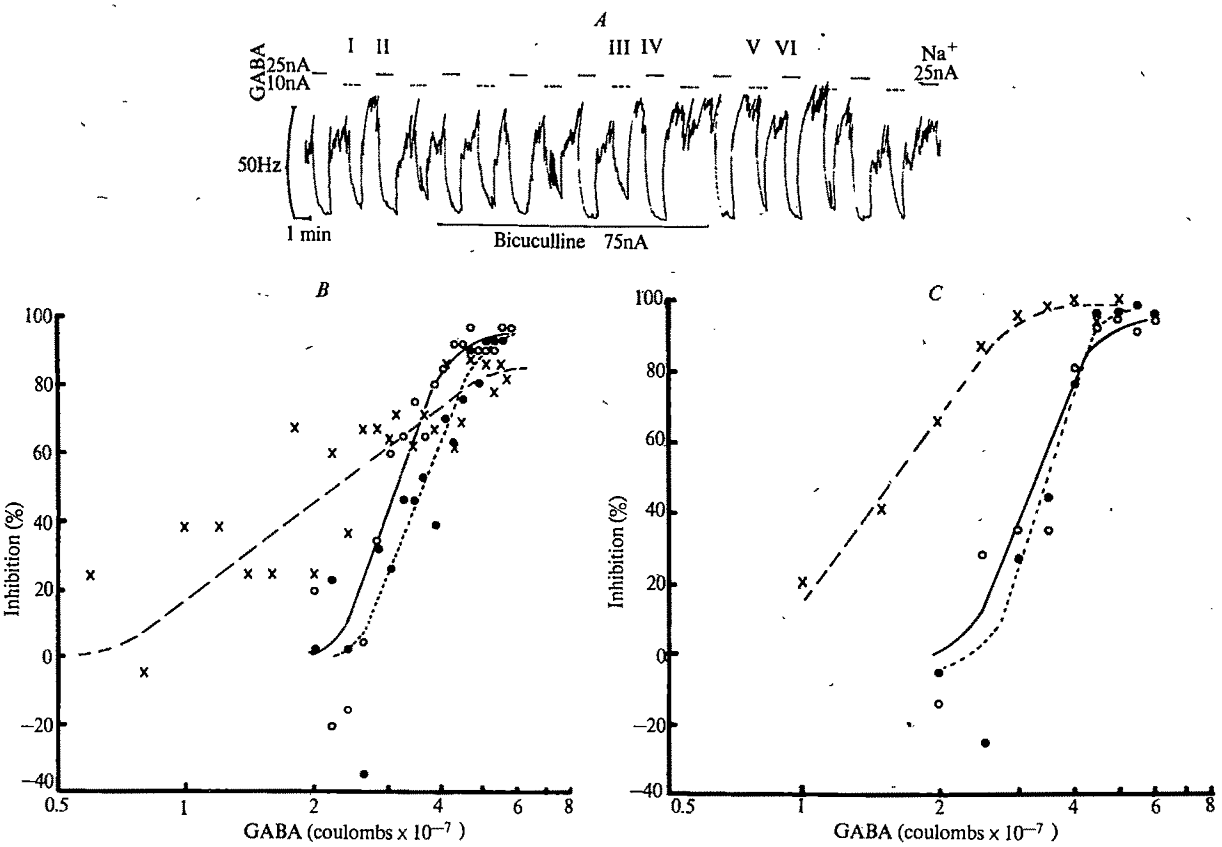

Fig. 2 *A*, Analogue rate-meter record of the firing of a cell driven by continuous application of 25 nA glutamate at a depth of 1.82 mm in the suprasylvian cortex of the cat. GABA 10 nA and 25 nA was applied as indicated by the bars above the trace. Bicuculline 75 nA was applied continuously during the period indicated by the bar below the trace. Responses labelled I–VI are plotted in the form of dose-response curves in *B* and *C*. *B*, Responses I (—○—), III (- -×- -) and V (. . .●. . .) plotted as percentage inhibition against coulombs of GABA applied at a constant current of 10 nA. Responses were calculated from the interval-time spike counter record (not shown) which was obtained simultaneously with the rate-meter trace shown above. *C*, Responses II (—○—), IV (- -×- -) and VI (. . .●. . .) to a constant current application of 25 nA GABA plotted as in *B* above.

In iontophoretic experiments, sixty cortical cells have been studied in twelve cats anaesthetized with 50% nitrous oxide in oxygen and 1% halothane. Drugs were applied and extracellular spike potentials recorded through standard five and seven-barrelled glass micropipettes with tip diameters 5–7 μm as in previous studies[4]. The extracellular spike potentials were counted with an interval-time spike counter and also displayed on an analogue rate meter. Cells which did not fire spontaneously were driven by continuous application of glutamate or DL-homocysteate. The inhibitory effects of GABA were analysed by constructing dose-response curves of percentage inhibition of cell firing against the coulombs of GABA passed.

We have confirmed the experience of Curtis *et al.*[1] that bicuculline can reversibly antagonize the depressant effect of GABA on cortical neurones (for example, Fig. 1). This was not a consistent finding, however, for, in common with Godfraind *et al.*[2] we sometimes found that the response to GABA was potentiated in the presence of bicuculline. For example, in the experiment shown in Fig. 2, we applied two currents of GABA alternately. Inspection of the analogue rate-meter trace (Fig. 2*a*) shows that the response to 10 nA GABA was eventually blocked after about 15 min continuous application of bicuculline, whereas the response to 25 nA GABA was not blocked. Closer inspection of the trace, however, reveals that the onset of the response to both currents of GABA was accelerated throughout the application of bicuculline. This potentiation is more clearly shown in the dose-response curves plotted for certain of the GABA applications in Figs. 2*b* and *c*. The effects of bicuculline were completely reversible and indicate that it can both potentiate and antagonize GABA on the same cell, depending on the relative concentrations of the two substances.

In ten cells (five spontaneous, five driven), the responses to

Table 1 Effect of Bicuculline on the Rate of Disappearance of ^{3}H-GABA from the Cerebellum, Cerebral Cortex and Whole Brain of the Rat

Area	Route	Dose	$t_{½}$ h between 2–8 h (95% confidence limits) Control	Bicuculline	P value
Cerebellum	i.c.	12.5 μg	1.25 (1.00–1.50)	2.95 (2.49–3.41)	<0.05
Cerebral cortex	i.c.	12.5 μg	3.21 (2.75–3.71)	8.40 (7.62–8.98)	<0.02
Whole brain	i.p.	2.5 mg/kg	2.88 (2.57–3.19)	4.30 (4.09–4.59)	<0.05
	i.c.	12.5 μg		3.68 (3.36–4.00)	<0.02

^{3}H-GABA (10 μCi) was injected intracisternally (i.c.) immediately after the injection of bicuculline. The animals were killed at times between 2 and 8 h after injection and the ^{3}H-GABA remaining in the brain was measured. From the regression of log. ^{3}H-GABA concentration on time, $t_{½}$ was calculated by the formula: $t_{½}$=(log 2)/slope. In whole brain of rats injected with bicuculline 2.5 mg/kg intraperitoneally (i.p.) 2 h after injection, the total ^{3}H-GABA content was 78,260 ± 6,382 d.p.m. (mean ± s.e.) which was not significantly different from control rats at 2 h, 62,320 ± 5,820 d.p.m. Controls were injected with an appropriate volume of solvent.

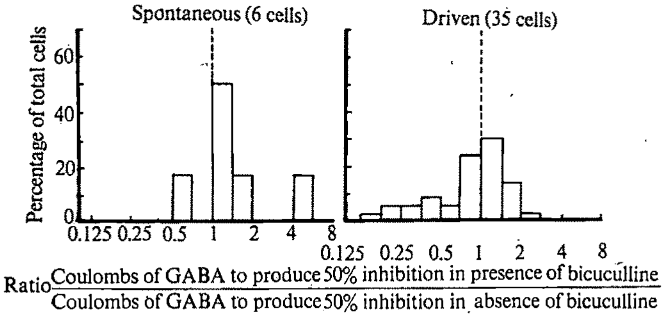

Fig. 3 Frequency distribution of the effect of bicuculline on the responses of cat cerebral cortical cells to GABA. A quantitative estimate of the effect of bicuculline was obtained from the ratio of the coulombs of GABA required to give 50% inhibition of the firing rate of a cell in the presence and absence of bicuculline. A ratio of more than 1 indicates antagonism of GABA and a ratio of less than 1 indicates potentiation.

GABA were sufficiently antagonized by bicuculline such that the inhibition due to the selected current of GABA failed to reach more than 80% in the presence of bicuculline. In a further forty-one cells, more quantitative estimates of the effects of bicuculline were made. In these cells, lateral shifts in the dose-response curves could be measured since the applied current of GABA was sufficient eventually to cause complete inhibition of firing in the presence of bicuculline. An analysis of the shifts in the dose-response curves (Fig. 3) reveals that bicuculline had a greater tendency to antagonize the effects of GABA than to potentiate them in cells which were spontaneously active. In cells driven by glutamate or DL-homocysteate, there seemed to be an approximately equal occurrence of potentiation and antagonism of the action of GABA in the presence of bicuculline.

The effects of bicuculline on the enzymes responsible for the synthesis (GAD) and degradation (GABA-T) of GABA were studied in rats, using the assay techniques of Roberts and Simonsen[5] and Hall and Kravitz[6], respectively. There was no significant effect of bicuculline on the activity of glutamic acid decarboxylase (GAD) in brain homogenates exposed to 1 mM bicuculline *in vitro* and no effect was seen in brain homogenates prepared from rats which had been previously injected with bicuculline, 2.5 mg/kg intraperitoneally or 12.5 µg intracisternally. There was a small inhibitory effect of bicuculline on the activity of GABA-T in brain homogenates exposed to bicuculline (1 mM) *in vitro*, the activity of the enzyme being 82% ($P<0.02$) of the control value. It was not possible, however, to show any inhibition of GABA-T in brain homogenates prepared from rats which had been previously injected with subconvulsive doses of bicuculline (2.5 mg/kg intraperitoneally or 12.5 µg intracisternally) nor did these doses of bicuculline have any significant effect on the endogenous GABA concentration in the brain, as measured by the method of Jakoby and Scott[7].

Since brain tissue has a powerful uptake mechanism for GABA[8], the action of GABA released from nerve terminals or applied iontophoretically onto neurones may be terminated by re-uptake into nervous tissue. Bicuculline appears to have no effect on this mechanism since the uptake of ^{3}H-GABA by cortical slices from rat brain exposed to bicuculline (0.14 mM) was not significantly different from that in controls.

To obtain some idea of the effect of bicuculline on GABA turnover, a tracer dose of ^{3}H-GABA was injected intracisternally into the rat and the rate of disappearance of ^{3}H-GABA from the brain was followed[9]. Subconvulsant doses of bicuculline significantly increased the half-life of ^{3}H-GABA in the brain between 2 and 8 h after injection (Table 1). The total amount of ^{3}H-GABA in the brains of the bicuculline treated animals 2 h after injection was not significantly different from controls, suggesting that the half-life of ^{3}H-GABA during the first 2 h was not altered. The interpretation of these results is difficult at present, as the functional significance of the two phases of ^{3}H-GABA disappearance from the brain is not yet understood. The increased half-life of ^{3}H-GABA between 2 and 8 h is unlikely to be due to inhibition of GABA-T since this effect was not seen in animals treated with AOAA (Collins and Neal, unpublished results). It is possible that bicuculline affects the neurally evoked release of GABA from nervous tissue *in vivo*, although the spontaneous efflux of ^{3}H-GABA from slices of rat cortex is unaffected by incubation with bicuculline (1 mM) for periods up to 1 h.

We have shown that iontophoretically applied bicuculline has more than one effect on the responses of cortical neurones to GABA. The potentiating effect of bicuculline is unlikely to be due to its weak inhibitory action on GABA-T or to inhibition of uptake. Other workers[10], however, have found that bicuculline can potentiate the effect of stimulating inhibitory pathways and have explained this as antagonism of an inhibitory influence on the inhibitory pathway being stimulated. A similar explanation for the potentiation of iontophoretically applied GABA does not seem to be feasible and the possibility remains therefore that this could be due to a direct non-specific effect of bicuculline on the post-synaptic membrane.

The antagonistic effects of bicuculline on the responses to GABA are probably due to a post-synaptic action, but a pre-synaptic component cannot yet be completely excluded in view of our results on GABA turnover. The potency of bicuculline as an antagonist is low, less than a doubling of the amount of GABA applied being required to overcome the antagonism. This should be compared with a ratio of 3.4 in the case of glycine and strychnine[11] and a very much larger ratio still in the case of acetylcholine and atropine (Clarke, Davies and Straughan, unpublished results). Thus, it appears that locally applied bicuculline is not a potent or reliable enough antagonist of GABA in the cerebral cortex to be used for confident identification of GABA-operated synapses or evaluation of the physiological role of GABA in that part of the brain.

This work was supported by the Medical Research Council through a grant to D. W. S. A grant for equipment from the Wellcome Foundation is acknowledged as is a grant for equipment from the SKF Foundation to M. J. N. R. G. H. is a Wellcome research student.

BOOK REVIEWS

Berzelius: His Life

Jacc Berzelius: His Life and Work. By Erik J. Jorpes. Translated from the Swedish by Barbara Steele. Pp. 156. (University of California: Berkeley and Los Angeles, 1970.) n.p.

THIS is an unimaginative, but useful, book which will be of value principally as a summary of what is already familiar to students of the chemistry of the first half of the nineteenth century, but is not readily available in a single small volume. The author describes Berzelius's life as a succession of exercises, with little attempt to put any particular piece of work into a historical context, so that one is left with a feeling of: "So that is how it looked to Berzelius day by day, but what was his life really all about?"

The story of any man's life is always a story about something else as well, and Berzelius's life was really all about a great revolutionary movement in human thought (roughly contemporary with the French Revolution and its aftermath, but more far reaching in its effects on mankind as a whole). This was the great advance in human thought which brought quantitative considerations into man's knowledge and control of the material substances of his environment. But Dr Jorpes is no philosopher of chemistry. (Indeed, do we have one today? How useful for us all if there were.) He prefers to present lists of Berzelius's work in each of his several practical fields. His theoretical work and the important controversies it aroused get short treatment and even that without much comment, so we get very little justification for Berzelius's reputation in the eyes either of his contemporaries or of his modern critics.

Perhaps Dr Jorpes, being a countryman of Berzelius, sees him close to, as a fellow medical man, as a fellow member of Swedish institutions, and so finds no need to draw a heroic portrait. Here we see the main value of this book. Most studies of Berzelius in languages other than Swedish have necessarily concentrated on his great influence, and, seeing this to be very great, have given us small flat portraits of a genius. Dr Jorpes gives a larger, rounder picture of a plain, likable, modest, determined, sensible man, sometimes witty, sometimes preoccupied, sometimes sick and sad, magnanimous in his private life even if he could be, on uncharacteristic occasions, grudging and resentful in his public scientific life. In his middle age he was man enough to attract as his wife a much younger woman above his station, and weak enough to be swayed by her to dismiss the phenomenal Anna, cook, housekeeper and laboratory assistant.

Dr Jorpes hints here and there at aspects of Berzelius's life which would be worth extended study. He was very conscious of the problems of communication. He knew the linguistic obstacles for even a widely travelled Swede, yet he was aware that this was far less of an obstacle to scientific development than the insularity of attitude of which he accused English chemists, not excluding Davy.

In Berzelius's works we can see the dual role of mineralogy both pulling chemistry along the road of quantitative systematics, and yet hampering its progress towards a grasp of the importance of internal structure. Someone might investigate this. And we have not yet discerned all the differences between what electricity meant to chemists and to physicists in Berzelius's time.

To some extent he was the man of a book, spending a great deal of time that might have been spent in the laboratory in writing and revising a compendious textbook. Although much translated and widely used, it seems to have had far less influence than his novel yearbooks, which set the pattern for those progress reports which kept scientific controversy active and wide ranging when communication was slow.

His epitaph could be written in a few technical terms like isomerism and catalysis, but any chemical formula would serve just as well, for it was he who devised the literal notation which gave chemistry H_2O and $CaCO_3$ and all the intelligibility such formulae imply.

As a supplement there is reprinted (in German) the summary of Berzelius's analytical work during 1808–21, which H. G. Söderbaum originally gave in his Kahlbaum Monograph, *Jac. Berzelius' Werden und Wachsen* (Leipzig, 1899). This, more than any mere description, shows Berzelius's enormous productivity in his best years.

The book is aptly illustrated and well indexed. The translator seems to be as competent in the subject matter as she is in the language of the original.

F. GREENAWAY

Chemical Tribute

Chemical Dynamics: Papers in Honor of Henry Eyring. Edited by Joseph O. Hirschfelder and Douglas Henderson. (Advances in Chemical Physics, Vol. 21.) Pp. xxxiii+816. (Wiley–Interscience: New York and London, April 1971.) £10.75.

THE reviewer of this volume is in something of a quandary. Should he review Henry Eyring the man, Henry Eyring the scientist, the contributions of Henry Eyring or the contributions to the volume under review? Convention would dictate the last of these four possibilities. But the reviewer craves the indulgence of the readers while he says a word about the other three. In an age when society, and in particular the young, have shown a degree of revulsion from science, the question might well be asked whether or not this is due to the manner in which it is often presented—cut and dried, pre-packaged and apparently untouched by human hands. One speculates whether science should not be presented as a living thing, made by human beings subject to all the frailties of the species. Rarely is a paper presented to show the often haphazard lines along which the work developed. Only the crystal clear logic of the final analysis is presented, cold and remorseless. This is not science as most practitioners know it. A book like the present volume goes a long way to restore humanity to science, in the many glimpses we are given by the various contributions of Henry Eyring the man, the teacher and the scientist. And the picture that emerges is not only that of a great scientist, but of a great human being.

It would be wrong to suggest that all the papers will be of interest to everyone. Indeed, the wide spectrum covered is yet another tribute to the catholicity of interest of Henry Eyring. The papers are divided into six sections: molecular quantum mechanics (edited by A. A. Frost); theory of reaction rates (edited by K. J. Laidler); properties of molecules (edited by W. Kauzmann); theory of liquids (edited by D. Henderson); biological applications (edited by F. H. Johnson), and engineering applications (edited by C. J. Christensen). As might be imagined, the largest section is that dealing with the theory of reaction rates, which consists of fourteen varied contributions spanning a wide area from the mechanism of electron energy transfer from excited mercury atoms to paraffins, to the theory of non-Newtonian flow. The second largest is the theory of liquids, which ranges from molecular beam studies (as a means of evaluating intermolecular potentials) to the theory of plastic crystals. The sections on molecular quantum mechanics and properties of molecules overlap somewhat, as might be expected. Biological applications also cover a wide area, from protein conformations to the dynamics of life. No less varied are the engineering applications, which include the synthesis of diamond and the theory of detonation.

As will have been observed from what I have said, the volume accurately mirrors the scientist in honour of whose seventieth birthday it was produced. The man-made terms, mathematician, physicist, chemist, biologist, are too narrow to describe Henry Eyring. In browsing through this volume, the reader is brought face to face with a scientist, a man dedicated to enlarging the understanding of the working of nature, using techniques drawn from many disciplines. And this may well prove an inspiration to the young worker who feels that in the past he has been confined within a rigid but arbitrary discipline. Few scientists, whatever their interest, could fail to benefit from recourse to this volume.

ALLAN MACCOLL

Science and Indian Development

Science in India: Institution-Building and the Organizational Systems for Research and Development. By Ward Morehouse. Pp. xvi+144. (Popular Prakashan: Bombay, 1971.) Rs 25.

Physics in India: Challenges and Opportunities. (Proceedings of the Conference on Physics, Education and Research, June 1970.) Pp. iv+323. (National Council for Science Education: New Delhi, 1971.) Rs 10; $4; £1.25.

THE recent interest in the social implications (both good and bad) of science and technology has reached its culmination in what may well be the most significant social problem of all—overshadowing such currently fashionable fields as environmental pollution, the arms race and technological unemployment—that is, the possible use of Western techniques in helping to resolve the problem of chronic poverty endemic in well over two-thirds of the world's population. The argument runs as follows: since one of the principal factors influencing the very rapid rise in the standard of living of the Western "developed" nations has been the effective application of techniques derived from advances in the natural sciences to the productive process, it is necessary for the underdeveloped world to make every effort to foster science so as to achieve the same ends. Couched in such simplistic terms the process seems easy, but in practice the transplantation of what is to a large extent an alien social process, in spite of colonialism, has proved fraught with difficulties and has in some cases helped to exacerbate those symptoms commonly associated with underdevelopment, for example open and disguised unemployment, urban squalor and neglect of the land. Clearly the field is ripe for research.

Ward Morehouse's *Science in India* is a preliminary account arising out of a research programme currently being carried out at the Administrative Staff College, Hyderabad, on the organization of science and technology in India. The book has two principal aims. First, to provide the beginnings of a theoretical framework which will act as a basis for assessing the impact of scientific organizations on Indian development. Second, to provide an empirical account of the organizational structure of Indian science.

Taking the second aim first, Dr Morehouse has given us a valuable summary of the various bodies connected with Indian science, their respective functions, history, modes of finance, links with the socio-economic environment and relationships with the political power structure. For anyone intending to work in this field, his account must be necessary reading, drawing together, as it does, a wide variety of material from disparate sources. The author's attempts to provide a theoretical framework, however, are rather weaker not so much for what is said but for what is omitted. According to Dr Morehouse a scientific "organization" will only be effective in contributing to development once it has become an "institution". How shall we know when it becomes an institution? Well, when it begins to interact meaningfully with the socio-economic environment and evolves a cohesive dynamic of its own. This type of functionalism, besides evincing partial circularity of reasoning, does not seem to hold much promise for the resolution of the many problems which characterize Indian science today. In particular it does not give us criteria for deciding when a scientific "institution" is not helping development. Nor is there more than a cursory attempt made to define what is meant by "development".

These criticisms do not attach so much to the proceedings of a recent conference on physics education in India (*Physics in India: Challenges and Opportunities.* This conference, sponsored by Indian and American governmental and educational institutions at Srinagar, set out to discuss the principal problems connected with physics teaching and research in India and how these might be resolved. The report consists of a series of papers which stress the need for curricular reform in schools and universities, improved laboratory and library facilities, and a more rational use of teaching staff. In addition the need for education to be more broadly based and more intimately related to developmental objectives is emphasized and there are a number of interesting papers on the brain drain and unemployment of graduates, especially that by Parthasarathi. Again this volume is probably of chief interest to the specialist but could usefully be consulted by those concerned with wider aspects of social and economic development.

NORMAN CLARK

Swansea Survey

Swansea and Its Region. Edited by W. G. V. Balchin. Pp. xx+391+58 plates. (Swansea University: Swansea, 1971.) £2.50.

THIS is the traditional volume prepared on the occasion of the annual meeting of the British Association for the Advancement of Science, in this case at Swansea. A similar volume was prepared for the meeting at Cardiff in 1960 and the two together, although a decade apart in time, provide a South Wales survey.

During the past decade the BA handbooks have grown and the present volume is about twice the size of that prepared for the Cardiff meeting. It also has had the advantage of a geographer editor who is experienced in thinking in regional terms. In a review of this length it is impossible to give attention to each of the twenty-five chapters, even if any one person could be competent to assess them individually. It is to the general structure of the volume, therefore, that these comments must be directed although this means that many excellent, individual contributions may appear to be ignored.

In its general make-up the volume suffers from the nature of its origins. Presumably the earliest productions were meant to be simple guide books to the host cities and their environs, but they have evolved into full scale regional surveys. Unfortunately the handbooks fail to throw off the old role as guides and also a commitment to represent most of the sections of the association. The result is that the volume is not a true regional survey but a hybrid product. The contributions to this volume fall into three categories. The first reflects the old guide book character where local institutions are enumerated and described. Perhaps the chapter on the education service is the best example; for it is a straightforward account of facilities, but with no mention of problems. Have the new comprehensives avoided becoming one-class neighbourhood schools? What are the problems posed by the Welsh language? Indeed, is it taught at all, for it is not mentioned? Is it compulsory and to what level? Also in this same category is the account of the University College, and that of the City of Swansea, which is very far removed from modern urban studies. The second category is the "review of research" approach which devotes its space not to the region *per se* but to the research carried on in the locality. No chapter falls completely into this category, although that on zoology comes nearest to it. One could also place within it the very oddly located part five of the book, which deals with the Lower Swansea Valley Project. This important piece of work certainly merits discussion but it appears as an apparent climax at the end of the volume whereas it might have been more appropriately linked with "conservation". The third type of chapter is that of regional description and interpretation, directed to the local area itself. This quite properly forms the bulk of the book and is admirably done. Even so there is a lack of balance in that social structures are dealt with most briefly in some twelve pages as against some one hundred and twenty on the natural environment.

It is in this general area that I would make my basic criticism. The anthracite area of the coalfield, although not the whole of the Swansea region, has a very distinctive "character". Perhaps the basic feature is that it is the only part of Wales which is both industrialized and substantially Welsh speaking, a point which is never clearly made. It is all the greater pity that no attempt was made to demonstrate these characteristics when the person who could do it best, Professor T. J. Morgan, contributes but a brief chapter on place names, although according to the programme he presented a paper to section H of the association on the peasant culture of the Swansea Valley. This is, after all, to Welshman the land of Gwenallt, but none of that seeps into the book.

There are two further points which are disconcerting. The first is that no attempt is made to define the Swansea region, particularly in terms of its metropolitan structure. It is understandable that, for example, geologist and economic geographer might not be content with the same bounds, but it is a little odd to find the chapter on climate, exclusively concerned with Swansea itself, while that on botany includes the whole of Carmarthenshire and south-west Breconshire. This at a point where interrelations might be expected. The other disconcerting feature is that there is no direct urban survey of Swansea itself, no growth plan, no land use map, no study of "social areas". This survey of the city has been a conventional feature of nearly all the handbooks and it is certainly not lack of ready material which is the reason.

But perhaps my strictures are unfair. Critics too frequently demand a volume different from the one before them or ask for extensive and, for practical reasons of cost and bulk, impossible additions to the existing volume. If this were a coherent regional survey there is much that one could cut out from this volume and much that would need to be added: but of course it is not, it is a British Association handbook and is thereby committed. Perhaps a conclusion is that the purpose of the BA handbook be reviewed. I conclude, therefore, by reiterating my comments on the high quality of the work that has gone into this book. The editor writes in his introduction that no recent survey of the Swansea area exists and I am sure that many people, for many different purposes, will have recourse to the material contained in *Swansea and Its Region*.

H. CARTER

Caloric Theory

The Caloric Theory of Gases from Lavoisier to Regnault. By Robert Fox. Pp. xiv+378. (Clarendon: Oxford; Oxford University: London, May 1971.) £5.

EDWARD FRANKLAND'S comment that "it is by no means necessary that a theory should be absolutely true in order to be a great help to the progress of science" is now a commonplace among historians of science. It is one of the chief purposes of this detailed and technical study to demonstrate the sophistication and complexity of the caloric theory, at least as far as the gaseous state was concerned, and to reveal how successful its conceptual framework proved. The notion that caloricists were wrong headed and obscurantist was a late-Victorian view developed, understandably enough, in the wake of thermodynamic triumphs. In part, it was a Royal Institution saga devised by John Tyndall in praise of its founder Count Rumford. But, as Dr Fox cogently argues, Rumford appears in the history of caloric theory only by default since his experiments were unoriginal and "off the point", for they were directed only against the weaker Irvinist model of heat rather than against the stronger continental theory of Lavoisier and Laplace. Indeed, the latter's correction of Newton, and absorption of adiabatic phenomena in the derivation of the velocity of sound in 1816, two years after Rumford's death, was a major triumph for the caloric theory of gases.

The basic assumption of the caloricists from the 1770s onwards was that gas particles were held in stationary (not vibrationary) positions by repulsive forces between them which were produced by the presence of an imponderable fluid of heat which either surrounded, or fitted between, the gas particles. Heat itself, like ponderable matter, was conserved. This model was basically Newtonian, modified by the discoveries of pneumatic chemists, and fused with eighteenth century views on fire. However, Dr Fox's book is more than an internalist study of an outmoded theory and its experimental justifications. His own interest is obviously in the character of nineteenth century French science, particularly in the general scheme of scientific investigation he calls "Laplacian", and whose institutional basis at Arcueil was recently explored by Dr Crosland. According to this research programme, all physical phenomena were to be explained in terms of short range attractive and repulsive forces. This general interpretation enables the author to highlight and contrast the activities of the mathematical Laplace, the engineering-orientated Carnot, and the arch-calorist Avogadro who, in Italian isolation, remained tragically unaware of his work's discredibility to both physicist and chemist.

The author attributes the downfall of the caloric theory to a complex of causes, including the rise of Berzelian electrochemistry and the Fresnelian wave theory of light. Readers will find the pertinence of these new theories are too briefly analysed in contrast to the main contention that the most significant cause was philosophical and institutional: "an overall change of the style of French science between 1815 and 1830" which was anti-Laplacian. Comte's positivism reflected this change of mood, while the failure of Dulong and others to find viable alternative theories in the 1820s and 1830s led to widespread agnosticism towards theories of heat and atomism except as pedagogic aids. Regnault's brilliant, but tedious, experimental work is seen as a symbol of the decline of French theoretical physics. It follows, as Dr Fox plausibly argues, that the rise of the kinetic theory of gases in Britain and Germany during the 1850s was almost completely unrelated to the downfall of caloric theory which had effectively occurred two decades before.

This is an important monograph and deserves to be read for the historical questions it raises about nineteenth century science as much as for its definitive account of a forgotten physical theory. W. H. BROCK

Analytical Geochemistry

Analytical Geochemistry. By Lord Energlyn and L. Brealey. (Methods in Geochemistry and Geophysics, Vol. 5.) Pp. xv+426. (Elsevier: Amsterdam, London and New York, 1971.) £9.25.

THIS book attempts to describe a wide variety of chemical and physical analytical procedures of use to geochemists. While chemical methods are described in some detail, the treatment of physical methods is disappointing, and out of date in many instances.

The introduction contains a curious selection of geochemical topics. Igneous and metamorphic geochemistry are discussed only in terms of classification, with details of the well established "CIPW norm" and "Niggli equivalent norm". Although hydrothermal processes are briefly mentioned there is virtually no reference to modern work, even to such excellent texts as *Geochemistry of Hydrothermal Ore Deposits* edited by H. L. Barnes. A very brief, dated section on chemical solubility products and an introduction to fluidization phenomena are followed by interesting observations on the role of organic solvents in sedimentary geochemistry. The latter topic reflects the senior author's interests, and includes considerable reference to his own work.

The second chapter outlines the principles of qualitative analysis of rocks and minerals and is particularly noteworthy for the detailed description of the little known technique of membrane colorimetry. This technique incorporates a variety of methods for the transfer of chemical images from flat surfaces of metal, rocks and plants.

Quantitative chemical analysis is covered by the third and fourth chapters. The third chapter describes the main rapid methods of analyses of silicates, carbonates and phosphates in sufficient detail for the book to serve as a bench manual. The fourth chapter is a lengthy account of the chemical determination of minor elements in which the occurrence, detection and estimation of over fifty elements are described element by element.

The fifth to ninth chapters cover emission spectrography, flame photometry, X-ray spectrography and diffraction and fluorimetry. In each case the brief description covers basic principles, equipment and procedure. As an introduction for geologists with a limited chemical background knowledge these chapters may serve some purpose. However, even in this context it would have been useful to outline the relative speed, precision and general applicability of each technique rather than cite limited, specific examples of their application. Some of the pitfalls of these techniques are understated, particularly matrix effects which are of prime importance in optical and X-ray spectrography and in X-ray diffractometry. A fuller description of matrix effects would have been of benefit to the beginner, particularly if ways of circumventing or overcoming such problems were outlined or, at least, referenced. There is, indeed, little reference to modern literature; nothing more recent than 1962 in relation to emission spectrography, or 1961 for X-ray spectrography! The latter is a technique in which enormous advances have been made in the last decade, for example the equipment shown in Figs. 70 and 71 is now essentially obsolete.

The final chapter, on chromatography, is more thorough and includes an outline of the basic principles, followed by detailed descriptions of paper and thin-layer chromatography, gas or vapour-phase chromatography and pyrochromatography. The latter technique, developed by Lord Energlyn (W. D. Evans), includes an interesting account of geochemical applications.

In spite of the wide variety of techniques discussed in this book there are notable omissions, particularly important being atomic absorption spectrometry, which is rapidly gaining status as a major analytical technique in geochemistry. The lack of reference to modern work reduces the value of this book as an introductory text, since many physical methods of analysis have changed to such an extent that the methods and hardware of ten years ago are essentially redundant. Priced at £9.25, this book cannot be considered value for money. D. M. HIRST

Maths and Music

The Acoustical Foundations of Music. By John Backus. Pp. xiv+312. (John Murray: London, March 1971.) £3.50.

MANY physicists have been interested in the physical principles of music, in how sounds and the particular quality of sounds are produced by musical instruments, in the admixture of sounds and the effect of the surroundings on what one hears, and in the many other problems connected with music, including the physiological questions about hearing and the voice. It is a fascinating subject for physicists who are interested in music or musicians who want to have some idea of "how things work".

This book is directed to musicians and particularly to those "with no scientific background and no mathematical equipment past the high school algebra they have already forgotten". The author goes on to say "thus they are representative of musicians generally". Is this so? One hopes not, but even if it is, twenty pages of elementary mechanics, including careful definitions of length, time and mass, seem rather unnecessary. This determination to keep mathematics to a minimum precludes the use of trigonometric functions and logs (although logs are explained in an appendix) and this leads to rather cumbersome explanations of several topics, for example, the various musical scales.

Given this limitation, the author describes the main features of the subject very well, but this has been done before by a number of authors. It is in the discussion and explanation of finer details that both musicians and physicists find most interest, because the fundamentals are in most cases fairly easy, but the exact description of what happens is often extremely complicated. Here the author is concerned to show, without too much complication, how some of these problems can be tackled and the results that have been obtained. He is also concerned to refute the "fallacies and superstitions that music could better do without". Most of these onslaughts seem to be fair comment but in the case of piano touch there is a point which seems not to have been made. The physicists' argument, strongly expressed by the author, is that when the hammer strikes the string it is "completely separate from the impelling mechanism attached to the key" and that "it follows that the pianist cannot independently control the quality of a single note on the piano by the manner in which he strikes the keys". The first statement is true, but the second does not follow because the stem carrying the hammer will bend and the bending is proportional to the acceleration while the final velocity depends on the integral of the acceleration. It is doubtful whether the experimental work done in the 1920s was of sufficient accuracy to resolve this point and it should be added to the very many unsolved problems which the author points to as requiring further investigation.

This constant reminder of how much work is waiting to be done is one of the very good features of this book, as is the treatment of wind instruments, so often neglected in books of this sort (the author plays the bassoon), and also the extensive bibliography, much of it of recent work, which will so much ease the path of those interested in the pursuit of some of these topics.

NATURE Volume 233 OCTOBER 8 1971

Research Councils on the Brink

EVIDENTLY the research councils which administer government expenditure on basic research in Britain are becoming edgy. In the past few days, both the Natural Environment Research Council (see page 364) and the Science Research Council have taken the publication of their annual reports as opportunities to complain that the Dainton report on the organization of civil scientific expenditure should be made public. What the research councils are afraid of is that the supposedly moderate recommendations of the Dainton committee will be replaced by more radical proposals when the review being carried out by Lord Rothschild is completed. The issue is important not merely because the research councils between them spend roughly one eighth of the money spent on research and development in Britain but also because their effectiveness depends on the intimacy of their connexion with their constituents—the large company of professional scientists who work in British universities, research institutes and in industry at large. If the government hopes to carry with it the scientific profession, in the reorganization which is now impending, it must do everything it can to let the people concerned appreciate the reasoning behind its decisions To be sure, it may in the end be decided that the Dainton recommendations are not acceptable to the government. They may not be radical enough, for example. In those circumstances, however, it will be much better for everybody concerned, the government included, if the constituents can see the differences between the government's arguments and those of the Dainton committee. And if this proposition is accepted, there is of course no reason why the Dainton report should not be published immediately, without waiting for the Rothschild review. To that extent, the research councils are right to complain.

Whether they have prepared themselves sufficiently for the reorganization that lies ahead is unfortunately a different matter. Several developments in the past few weeks suggest that the councils are a long way from a strategy for the administration of government expenditure on basic science in Britain.. To be sure, the Science Research Council a week ago was talking of closer collaboration between the councils but there is very little to boast of yet. Each of the four research councils has, for example, an interest in supporting graduate students at British universities. In the year just past, for example, the Science Research Council had 5,700 graduate students on its books, the Medical Research Council had 600 pensioners on various kinds of courses, the Natural Environment Research Council had 633 graduate students on its books and the Agricultural Research Council followed its traditional policy of spending very little on studentships. In this pattern, of course, the Science Research Council has a dominating position. Although the other councils tend to take the view that one of the most effective ways of influencing the development of university science is to set up research units and institutes of various kinds, studentships are also powerful levers. Many heads of university departments are prepared to jump through hoops they would have avoided for the sake of providing places in their departments for graduate students. But is it sensible that the process of awarding these grants should be divided for practical purposes between three of the councils in circumstances in which there must plainly be a great deal of overlap? Is this not a field in which the best way to collaborate is to centralize?

In the spending of government money on basic research, there is also a need for the research councils to strike a better balance between research grants and other forms of expenditure. In the year just past, the Science Research Council spent a total of £15.7 million on research grants and studentships, roughly 30 per cent of its total expenditure. The rest of its money went on research institutes which provide the universities with research facilities of various kinds, some of them abroad. The Natural Environment Research Council seems less able to part with money—in the year just past, just under 12 per cent of its much smaller budget was spent in this way. Twenty-five per cent of the council's whole expenditure went on research grants, fellowships and research units in the universities. The proportion of the agricultural money spent in universities, harder to identify, is more like that spared from the budget of the Natural Environment Research Council. Is it really necessary that so much of the money set aside by the government for basic research should be spent outside the universities? Is it really wise that all the councils should be busily giving hostages to fortune by taking on their books research institutes and laboratories which could just as well be operated through and by the universities? In the flush of pleasure which there has been in the past few years at the increasing rationality with which the research councils make decisions, the question has been overlooked whether they have struck the right balance between the roles of sponsor of university research and midwife to it. It would be a reasonable intermediate goal to ask that the research councils between them should spend half of their budgets as cheques to universities or to students.

One obvious difficulty is that this concept of how basic research should be organized will not suit all of the research councils. The Agricultural Research Council will no doubt be the first to protest that basic research in agriculture cannot always be carried out in a university atmosphere. To be sure, if the history of agricultural research in Britain were reconstructed, it is entirely

Foreigners at CNRS

THE leading article in *Nature* on September 17 (**223**, 152; 1971) implied that the Centre Nationale de la Recherche Scientifique does not employ scientists from outside France. In fact a substantial number of the scientists on the CNRS payroll come from outside France. The Editor of *Nature* apologizes for this unintended and unjustifiable slur.

possible that spendid establishments like that at Rothamsted would have grown up more closely linked with some university department or another, but nobody at this stage would wish to unscramble that omelet. Whether there is a strong case for the formal independence of laboratories such as the Institute of Animal Physiology from their nearby universities is much less certain. Much the same arguments would no doubt be advanced by the Medical Research Council on behalf of some of the institutes which it controls—here again only a particular analysis of the present functions and future potentialities of the several institutions can inform a sensible decision. There is an urgent need for a clearer distinction between the basic research, in agriculture, medicine or the natural environment, which should be carried out by universities and that which must of necessity be carried out in separate research institutes. Three important questions of organization stem from this question, and perhaps the most difficult and interesting is that of how to decide the function of universities and similar institutions in the pattern of basic research. In the past few years in Britain, it has been customary and even justifiable to say that university research has been too uninterested in the practical consequences that may result. This is why the Science Research Council has been trying to persuade university departments and their graduate students to take a greater interest in research with an industrial slant. In doing so, however, it has also helped to confirm the impression that the universities are not particularly interested, and thus to justify the claims of those who say that money for basic research relevant to the long-term needs of industry should best be channelled to other kinds of institutions than the universities. Is it not time for a reappraisal of this view? Should not the universities now be regarded as potential administrators of relevant research? After all, the government (or its predecessor) has willed the universities; is it not sensible to try to make the fullest use of them? No harm would be done if the Rothschild review were to suggest a scheme for giving the universities much more money and a much greater responsibility for the health of British science.

Another question concerns the relationship between the research councils. There is an important distinction between the technical research on which a part of the energy of the Agricultural Research Council and the Medical Research Council is spent and the long-term work which they support in the universities. On the other hand, where the sponsorship of university work is concerned, the four research councils have even more in common than they are prepared to admit when boasting of their fondness for collaboration. In the circumstances there would be a great deal to be said for some kind of concentration. After all, the four research councils between them spend more than £4 million a year on headquarters administration, and even if much of this goes on the kinds of committee meetings which give working scientists a sense of participation in the decisions which affect them, this is a large part of what the councils as a whole have to spend. At worst, a reorganization of the research councils which reduced their number from, say, four to three would save a certain amount of public money, would make possible a clearer separation between the work that can be done in universities and that which must be done outside and would at the same time provide a framework for better collaboration with other government departments. In all the circumstances, this is a line that Lord Rothschild should be prepared to follow in his review.

Phosphates are Free Again

THE pantomime two weeks ago in Washington when the Administration's three high priests of the environment—Mr Russell E. Train, the chairman of the Council on Environmental Policy, Mr William D. Ruckelshaus, the director of the Environmental Protection Agency, and Dr Jesse L. Steinfeld, the Surgeon-General—gathered to announce that detergents containing phosphates might be lesser evils than some of the materials which have appeared on the market in the past few months on the environmental ticket should be a warning to all who leap before they look. Especially with Dr Charles Edwards, the head of the Food and Drug Administration, in attendance, it must have been painfully apparent to all concerned that the United States is rapidly becoming a prisoner of its own whims in dealing with the environment. After all, Dr Steinfeld was by all accounts the one who helped, in the days of Mr Robert Finch, to persuade the then head of the Food and Drug Administration, Dr Herbert J. Ley, that cyclamates should be taken off the market in a trice. Later that year, the Food and Drug Administration was playing its own politics by agreeing that cyclamates might be sold over the counter as non-prescription drugs. It was Dr Edwards who in the end had to attempt making sense out of nonsense when Congress eventually caught up with the scandal.

Why is the United States Administration so prone to errors of this kind? The haste with which herbicides such as 2,4,5-T were restricted just over a year ago was entirely unseemly—at that point, the experiments on which were based the claim of teratogenicity were about as convincing as would be a demonstration of spontaneous generation in a high school laboratory. To be sure, the FDA and everybody else has the Delaney amendment hanging round its neck like an albatross, although there is a case for saying that the Administration could shed its curse if only somebody would stand up and say that the Delaney amendment is altogether too crude a guide to good practice. After all, why should materials be entirely prohibited once it has been shown, in feeding experiments with laboratory animals of any kind—even cancer-prone hamsters—that there are carcinogenic possibilities? Surely, enough has been learned since the fifties for more sophisticated judgments to be possible.

Unfortunately, however, there is no compulsion to explain why the Administration appears to be prepared to act forcefully against the persistent pesticides, DDT and things like that. The report by the DDT advisory committee to the Environmental Protection Agency, published last week (see *Nature*, **233**, 299; 1971), was reasoned but incomplete. What the committee did was to add to the conclusions of the Mrak Commission, published at the end of 1969. Its general conclusion was that the amounts of DDT and other pesticides now found in soil are unlikely to be removed by natural processes in the immediate future. It follows that there is no immediate prospect of a rapid decrease of the amount of these materials in the standard American diet and therefore very little chance that concentrations of pesticides in fatty tissues will quickly decline. In short, persistent pesticides are likely to persist for the next twenty years or so. What seems to be inferred from this is that while there cannot in the circumstances be an urgent need to stop the use of DDT and similar materials, this is a goal at which to aim. The weakness in the argument is that very few of the advisory committee's data have been collected from outside the United States. This in turn implies that there are at present no means of knowing what would be the condition of American soil a decade or so from now if the immoderate use of persistent pesticides which characterized the fifties were in the seventies to give way to a discriminating but potentially valuable use of a family of pesticides which is, after all, one of the most effective known. In short, here again is a field in which the Administration may act too soon and too fiercely.

Why should this be? The case of the phosphate detergents contains an explanation. For close on a decade, phosphates have been pilloried as if they were endowed with all the malevolence of the organisms of infectious disease—plague, for example. This point of view stems from the recognition that a great many lakes in North America which had been severely damaged by insupportable quantities of organic waste material were nevertheless allowed to grow algae in vast amounts because of the phosphates and nitrates contained in sewage effluents, treated or otherwise. To be sure, nobody would seriously pretend that phosphates by themselves are a sufficient cause of what is called eutrophication. But the fact that phosphates (not nitrates) are often the limiting nutrients in algal growth has given phosphates a bad name, and on the principle that honest taxpayers unwilling to pay for proper sewage treatment plants or sewerage systems may wish to salve their consciences by doing something for the common cause against pollution, there has been a great outcry against detergents which contain phosphates. Several states have already banned the sale of detergents containing phosphates. Several manufacturers have made small fortunes by marketing alternatives in the name of what they call ecology. Congress was about to gird its loins for a full-scale attack on them. Only sheepishly did the environmental high priests step in with a belated warning that the fire could easily be more uncomfortable than the frying pan.

The moral is simpler than most. In the past year, the Environmental Protection Agency has disappointed some of its wilder supporters by cultivating a proper sense of pragmatism. As things have turned out, the agency has become an empirical amalgam of those parts of the Department of Health, Education and Welfare and the Department of the Interior which used to worry about air and water pollution. Nobody knows how soon it will be strong enough or eager enough to take the Atomic Energy Commission by the scruff of the neck. Nobody knows how soon the Administration will give it responsibility for the Food and Drug Administration. To tell from the agency's second annual report, published a few weeks ago, with its careful attempt to demonstrate that getting rid of pollution will cost money, the agency has determined to fight a discreet battle, keeping in the process what is called a low profile. The trouble is, of course, that such a strategy leaves the initiative to others. On this occasion, the agency has been able to divert Congress from an expensive blunder only in the nick of time. What it needs to become is a much more active agency able on occasion to say that the devil you know may be better than the devil that comes in a well-designed packet marketed by people who know that the environment is now the most popular cause of all. In other words, the agency must try to become one for saying that it may often cost very large amounts of money to win small and even imagined benefits, and that it may often be wiser to live with some minor sources of pollution than to seek to abolish them. Mr Ruckelshaus could save himself a lot of time at press conferences like that two weeks ago if he would follow such a policy.

100 Years Ago

NATURE

RECENT UTTERANCES

THE Oracle has spoken. In fact several Oracles have spoken. Let us take them seriatim. From the lips of two of the most enlightened members of the Cabinet we have had at last an authoritative expression of the desirability — nay more, of the absolute necessity — of scientific education for the country at large. Addressing his constituents at Bradford on Monday the 2nd inst. in a speech to which we have already alluded, on the occasion of the opening of the new Mechanics' Institute for that town, Mr. W. E. Forster, the Minister for Education, as he ought to be styled, made use of the following emphatic language :—" The old grammar-school teaching was almost framed upon the advantage that Latin and Greek well taught gave to the boys ; now, we find that the boys cannot do without the use of more general knowledge than is given by Latin and Greek ; that there must be a knowledge of modern languages. But there may be also a feeling that we ought to know something of the daily facts of life, and the rudiments of Science. There, again, I speak from a sense of my own want, and I have often thought how much more useful I might have been —at any rate, how much stronger I might have been—if I had had given to me a 'scientific education, such as I think we may now hope that our children will attain." And again : " We now believe that we have taken measures by which we may secure elementary education to all children of all classes in our borough, and throughout the country, and, consequently, those who attend this institution will have the foundation of a training that will enable them to fulfil the original idea of its promoters," that is, " to give mechanics scientific knowledge."

OLD WORLD

ASTRONOMY

New Face at the RGO

SPECULATION about the next Director of the Royal Greenwich Observatory has been stilled by the announcement that Professor Margaret Burbidge has accepted the post. Reaction among staff members of the observatory is one of pleasure that an astronomer of such distinction will be directing the RGO in the near future.

Asked what it felt like to be the first woman director of the RGO, Professor Burbidge said on Monday "I find the prospect very interesting especially since there is a great move to do something about the position of women in science." But she also pointed out that there is a better tradition of accepting women in astronomy than in other physical sciences.

Before moving to the United States in 1951, Professor Burbidge was Assistant and Acting Director of the University of London Observatory. She is perhaps best known for her work on quasars, largely carried out in collaboration with her husand, Professor Geoffrey Burbidge. Much of the apparent tardiness of the Science Research Council in announcing the appointment may, indeed, be attributed to the difficulty of offering such a post to one half of such an eminent astronomical couple. Both Geoffrey and Margaret Burbidge have spent the past few summers in Cambridge (since the inception of the Institute of Theoretical Astronomy) and the new director says that her husband will probably divide his time between California and Cambridge after she takes up the post next summer. No formal decision on this can be made, however, until the future of astronomy in Cambridge is itself decided. The present uncertainty about the Institute and Cambridge Observatories will be resolved in discussions starting at Cambridge on Tuesday, October 12.

The future of the Royal Greenwich Observatory is also undecided. One vital question is whether the observatory will have direct control over the proposed British observatory to be established in the Mediterranean area (see *Nature*, **232**, 289; 1971). Because the new director is unable to take up her appointment immediately, it seems that it will be some months before decisions will be made known about this new observatory. But whatever developments there are in the observational plans for Greenwich, it seems certain that the close links forged recently with the group of theoretical astronomers at the University of Sussex will be maintained. Professor Roger Tayler, Director of the Astronomy Centre at Sussex, said this week that he hopes the present collaboration with the RGO will continue and expand in the future.

ATOMIC ENERGY

Swan Song?

THE annual report of the United Kingdom Atomic Energy Authority, published on Wednesday this week, shows an increased proportion of work done in collaboration with industry and government departments but carried out with a smaller staff (House of Commons Paper 552, HMSO, £0.85.)

On April 1, 1971, the day after the period covered by the report, the Production Group of UKAEA was transferred to British Nuclear Fuels Limited, the Radiochemical Centre at Amersham was converted into The Radiochemical Centre Limited and a newly-formed National Radiological Protection Board took over responsibilities previously held by the authority in the field of radiation hazards and their effect on health and twenty-nine members of its staff. Since then it has been announced that the Weapons Group, including the Atomic Weapons Research Establishment at Aldermaston, will be transferred to the care of the Ministry of Defence, probably by the summer of 1972 (see *Nature*, **232**, 434; 1971). This leaves the authority with the Reactor and Research Groups and 19,802 employees as at April 1, 1971, compared with 29,427 on March 31, 1971. This number will be reduced by a further 6,000 when the transfer of the Weapons Group is effected and the principal continuing function of the authority, according to the report, will then be "the further development of nuclear energy for the generation of electricity . . . and the continuation of the underlying work necessary to support this activity".

The research and development budget for the past year shows a decrease from £59.4 million in 1969–70 to £58.5 million. Money spent on the reactor programme decreased from £43.3 million to £41.9 million with a change of emphasis in the support for the gas cooled reactors—the Mark III reactor support being increased by £1.9 million to a total of £5.2 million with a corresponding decrease in the support for the Mark II system.

Support for other research remained substantially unchanged at £12 million compared with £12.8 million the previous year, nearly all the decrease originating from decreased support for back up nuclear projects. Expenditure on non-nuclear research, however, increased by £0.6 million to £3.6 million. The authority's net expenditure during 1970–71 was £37.1 million compared with an estimated £42 million this year. The gross expenditure of the authority during 1970–71 was £95.3 million, offset by £57.2 million in receipts—£20.5 million in defence settlement payments, £9 million in sales and £8.6 million in agency services and receipts under research agreements. Sales this year are estimated to bring in £6.9 million.

Success in the sale of nuclear fuel abroad is also reported, with three contracts for supplying uranium hexafluoride to the United States won during the year as well as two contracts for supplying the material to Sweden and Switzerland. Other overseas contracts were won in Canada, Germany and Japan. The upward trend in enriched uranium production in recent years is now bound to level off following delays and changes in the programme for commissioning nuclear power stations in Britain.

Support for the plasma research laboratory at Culham amounted to £4.1 million last year. Maybe it is in this laboratory that increased effort should be concentrated in future years to harness the power of nuclear fusion. It is reported that results along these lines are encouraging and that "continuing attention was given to the technical problems of envisaged generating systems using fusion reactors". It is possible that the revenue lost to the authority by the formation of the new companies will eventually be replaced by income arising from the commercial development of the work currently in progress at Culham.

RESEARCH COUNCILS

Rallying of the Clans

HARD on the heels of the Science Research Council's comments on the Dainton report (see *Nature*, **233**, 298; 1971) come those of the Natural Environment Research Council in its own annual report published last week (HMSO, £0.85). The council says it learned "with relief" that the Council for Scientific Policy had decided to conduct an inquiry under Sir Frederick Dainton into the organization of civil science as "the continual reviews and proposals for reorganization of science, of the kind that the council (NERC) has been subjected to for most of its existence, are necessarily disturbing". The council warns, however, that concepts and plans for the advance of scientific knowledge must not be "unduly dictated by the immediate practical problems". Like the Science Research Council, NERC believes in the "basic good sense of the Research Council system" and that "the principles on which decisions are eventually to be based ought first to be the subject of wide and free debate".

The council also speaks plainly on the matter of finance. The council's objective of bringing the environmental sciences to a position which, with only a modest growth rate, will allow it to keep pace with the demand for basic knowledge about the natural environment has not yet been achieved, and the council claims an average level of funding about one-third higher than last year is required (just under £14 million). With cuts in research expenditure in the offing the council also warns that too sudden a reduction of growth is likely not only to waste previous investment and cause a loss of confidence, but also to damage, possibly irreparably, the attainment of the balance between the demand for knowledge and the research capability to meet it.

The council's new committee structure is outlined in the report, the changes being made because the council felt it was becoming isolated from important issues and from the directors of its institutes. Five preparatory groups for the fields NERC covers have now been given the task of thoroughly investigating policy issues before they are put to the council; the groups bridge the gap between the various institutes, but they have no executive power, the actual implementation of these policies, once approved by council, being the province of the institute director and his advisory committee. NERC feels this structure is both more flexible and better able to clarify the issues involved than the old system of eight standing committees whose terms of reference were too narrow to consider interdisciplinary policy problems.

The council's working party on computers has concluded that the cost of hiring computer time for the council is approaching the cost of buying computers; NERC expects to spend £3 million on computers over the next five years, but no decision to buy has yet been taken, pending discussion with the Computer Board and the Inter-Research Council Computer Review Committee, set up to plan and coordinate computer use by the councils.

Of the council's £14 million expenditure, £975,000 went on research grants at universities and other institutions, and £1.52 million on grant-aided laboratories and units. Among the council's own establishments the Institute of Geological Sciences received the largest amount (£3.36 million), with the Nature Conservancy and British Antarctic Survey getting £1.96 million and £1.76 million respectively. The total spent on NERC's eleven establishments was £9.89 million, the field with the largest expenditure being Marine Sciences at £4.29 million.

CIVIL SERVICE

Fulton Fulfilled

THE announcement last week of the restructuring of the Scientific Civil Service has the full approval of the Institution of Professional Civil Servants. This step towards implementing the Fulton recommendation of a unified structure throughout the Civil Service has been long awaited by the IPCS and Mr Colin Waters, the Institution's Assistant Secretary, said this week that they were very much in favour of the reorganization and that they would like to see more of the Fulton recommendations on career management and prospects implemented as soon as possible.

The details of the merger of the Scientific Officer, Experimental Officer and Scientific Assistant Classes into the Science Category are given in Table 1. The old nine class structure is replaced by a streamlined five class structure that becomes retroactive to January 1, 1971. Of the other Civil Service categories the Administration Category has already been reorganized while discussions on the future of the Technology Category are still in progress with a decision expected at the latest by early 1972. The Civil Service Department stresses that the restructuring will increase efficiency and improve promotion prospects. Lord Jellicoe, minister in charge of the Civil Service, said that "the way is now open . . . for us to push on with improved career management to ensure that the individual scientist as well as the Service benefits from the full and timely development of talent". Mr William McCall, General Secretary of the IPCS, said last week that the new structure "represented worthwhile improvements over the arbitration tribunal's award" (see *Nature*, **232**, 594; 1971).

The IPCS is now keen to make further progress towards a unified grade structure within the Civil Service and is hoping that the Science and Technology categories can be merged in the near future. The Civil Service Department is not enthusiastic at present about further merging of these categories although it has agreed in principle to the Fulton recommendations of a unified structure. A spokesman for the CSD said this week that the department agreed to the principle of exploratory negotiations to examine the practicability and desirability of a unified grading below the under-secretary level. He also said that one of the problems associated with merging the present three categories would be the determining of salary scales by comparison with pay in outside organizations—a practice that the CSD is committed to. The IPCS, however, is now committed to changing the system following the recent pay tribunal. Mr Waters pointed out that the difference in salary between the Science and Technological Categories—a Principal Scientific Officer at the top of the scale earns £108 less than his equivalent in the Technology category, an inconsistency soon to be magnified in a pay review for the Technologists—cannot be perpetuated after the merger.

Table 1 New Civil Service Science Category

New grades	Existing grades		
Science Category	Scientific Officer Class	Experimental Officer Class	Scientific Assistant Class
Principal Scientific Officer (£3,100–£4,100)	Principal Scientific Officer	Chief Experimental Officer	
Senior Scientific Officer (£2,303–£3,255)	Senior Scientific Officer	Senior Experimental Officer	
Higher Scientific Officer (£1,810–£2,350)		Experimental Officer	
Scientific Officer £1,120–£1,900)	Scientific Officer	Assistant Experimental Officer (over 21)	Senior Scientific Assistant
Assistant Scientific Officer (£550–£1,395)		Assistant Experimental Officer (under 21)	Scientific Assistant

TRANSPORT

Wheels Keep on Turning

THE news that the Transport Committee of the Science Research Council has accepted the chief recommendations of the council's Transport Panel will be of little comfort to those academics who originally opposed the recommendations.

The transport panel was established in May 1968 to consider the role of the SRC in supporting university research in transport, to suggest the function of university research in the context of the national effort, and to develop for it a coherent policy. The report recommends that university transport research "should be treated as a priority area for finance and manpower", and proposes that the council's financial commitment should rise from £140,000 in 1968–9, to £550,000 by 1973–4. The transport panel says that universities already play a valuable role in transport research but their work is criticized for being too fragmented. The solution proposed is the SRC's standard one—concentration of effort.

The report suggests that three centres be established, one each for transport planning, transport management and control, and transport technology. A smaller marine transport centre is also an urgent requirement as "there is a clear lack of any university group studying the transport problems associated with ports and shipping". The centres will provide multi-disciplinary teams to study the problems of transport research on a theoretical rather than an experimental level but 25 per cent of SRC funds will still be available for research outside the centres.

The four centres have already been selected by the committee, but they are not being officially revealed until the Department of Education and Science has given approval. The proposal to create centres met with appreciable opposition from the Universities Transport Study Group (which claims members in about 35 universities) when the first draft of the report was offered to them and other interested bodies for comment. Many of the fears then expressed have been allayed by the council's assurances that researchers outside the centres will not become ineligible for support once the centres start operating.

In spite of these assurances a number of academics still believe transport research does not require concentration of the type proposed, but feel finance should simply be given to those with promising ideas, rather than to centres which it is piously hoped will then attract ideas. It is felt that if the wrong universities are made centres they will not attract the best people—good academics will not follow after bad.

The SRC's answer, based on experience in other fields, is that the centres will prove attractive, and will draw new high class brains into transport research —which is one of the panel's main hopes. It also hopes that the long term programmes of the centres will attract short term contract work from industry and government departments (as has happened in the control engineering centres), which will in turn help the long term work. The status of the centres, however, will not be permanent and new centres will arise and old ones fall as and when necessary.

To be sure, academics welcome the moves, feeling that rationalization is required to provide larger teams and to prevent duplication of effort. The reaction of bodies outside the academic world is enthusiastic—British Rail, the Port of London Authority, and the Ports Council, for example, all welcome the idea.

It will be interesting to see if the implementation of the report's proposals eventually silences the critics, and indeed to see if the SRC will be able to afford the increased support it proposes.

RESEARCH COUNCILS

Plans for Manpower

THE Science Research Council has it in mind to limit the number of new postgraduate studentships (for research and for the shorter advanced courses) available next year to 3,850, the same number as were taken up at the beginning of this month. This is spelt out in the SRC report for 1970–71 (HMSO, £0.65), in which the present financial and employment situations are cited as the chief factors that have to be taken into account when the council makes its final decision. What are the likely effects of this and how will the composition of the postgraduate research population be altered?

Table 1 Numbers of SRC Research Studentships

	Chemistry	Total
1967–68	1,516	5,058
1968–69	1,529	5,322
1969–70	1,480	5,498
1970–71	1,515	5,727
1971–72	476*	2,230*

*New studentships commencing October 1971.

The number of research studentships in some subjects has remained static or has even been reduced during the past few years, in spite of increases in the total number of awards. In chemistry, for example, the number of SRC studentships held during the past few years has fluctuated and the number in 1967–68 is the same as in 1970–71—although about thirty studentships are now separately awarded in enzyme chemistry and polymer science. (The statistics in Table 1 include the cooperative awards in pure science (CAPS) which are expected to number 210 for all subjects in 1971–72.) The recent SRC chemistry report showed, however, that university chemistry departments have about 1.9 research students and graduate assistants for each staff member compared with about 1.2 per staff member in other subjects; the report goes on to recommend that the total number of SRC research studentships in chemistry should not be changed substantially in the near future.

An increase in the number of research studentships in computing science—from 101 to 110 between October 1969 and October 1970—is recorded in the annual report and the new computing science awards taken up this month number more than 50. The total number of studentships held in nuclear physics has remained almost constant at about 200 for the past two years but the total in other branches of physics has dropped slightly from 594 in 1969–70 to 582 in 1970–71; total numbers in the biological sciences have increased from 836 to 909 in the same two years.

The proportion of British research students funded by the SRC is about 50 per cent overall and the remainder are supported chiefly from university, industrial and private sources; the SRC's relative contribution does not appear to fluctuate very much—although there is a slight upward trend —probably because financial pressures usually bear on industry and on the SRC at the same time. Any levelling off in the availability of SRC training awards will probably mean that the number available in some subjects will not grow as quickly as in the past and that other subjects will suffer decreases in the numbers of awards allocated to them.

CONCORDE

Industrial Innovation

ONE third of the sub-contractors and suppliers to the British Aircraft Corporation for the Concorde project obtained spin-off benefits as a result, according to a report from the Centre for the Study of Industrial Innovation (*Aspects of Spin-off*, £0.50).

The report is the result of a survey among 161 of the 600 companies engaged on work for Concorde. Spin-off is taken to be not only the transfer of products developed for Concorde into other fields, but also the less tangible benefits such as the introduction of more effective quality control, or of new processes which have wider applications.

Spin-off in the tangible sense of new products was limited to only 14 per cent of the companies involved. The report also says that several companies, particularly when referring to the less tangible effects of spin-off pointed out that the benefits are likely to disappear if the project does not go into full production. Companies involved in the Advanced Passenger Train development, which the centre also consulted in the course of the survey, expressed similar views.

The report attacks the assumption that spin-off could be used in part as justification for projects that otherwise are uneconomical, and points out that "for the majority of companies supplying the Concorde programmes the work was of a straightforward type not involving commercial or technical conditions any more strenuous than those normally met".

The dependence of supply firms on Concorde varied considerably, contracts ranging from £3.7 million to £320, and the report also found that the economic dependence of companies on Concorde work was surprisingly low—only one quarter of firms had order-values of more than one-sixth of their annual turnover, and only six firms of more than half. A further quarter had order-values of only one per cent of their annual turnover.

The survey was only concerned with assessing how many companies benefited from spin-off as a result of work on Concorde, and in the types of spin-off experienced—no attempt being made to assess the economic value of the spin-off. The centre refused to hazard a guess at the percentage value of the spin-off from the £500 million spent on Concorde to date, and without any guide to this the figures in the report are less meaningful. Its conclusions are in the main only those expected, some of them so obvious as to be barely worth making—for instance that sub-contractors who supply specifically designed non-standard items benefit more from spin-off than suppliers who provide standard items. The centre says that more studies are needed to assess the economic value of spin-off, at the same time suggesting that it may never be quantifiable—because so much of it is intangible—in terms that can be taken into account in the cost/benefit analysis of large programmes. The centre hopes, however, that its report will provide a yardstick against which some sort of assessment of the economic value of spin-off can be made.

EDUCATION

No A-level Electronics

THE study of electronic systems in school sixth forms is apparently regarded by the Schools Council on the Curriculum and Examinations as excessively vocational and specialized. As a consequence, the council has not allowed the Associated Examining Board to set an experimental A-level examination based on a syllabus devised by Professor G. B. B. Chaplin and his colleagues of the Department of Electrical Engineering Science at the University of Essex.

Work on the syllabus started in 1966 and the project came to fruition when members of the Electrical Engineering Science Department began to teach a sixth-form course at Colchester Royal Grammar School in 1970. The Associated Examining Board considered that the syllabus would provide a reasonable basis for an A-level examination and duly sought permission from the Schools Council to set an examination for the eight boys in the first year sixth form who have been taking the course as an extra subject. The Schools Council handed down its decision on the grounds that the course did not satisfy the criteria by which the suitability of A-level courses is judged; one of these is that courses "should not be largely or wholly of a narrowly vocational character".

Professor Chaplin emphasized last week, however, that the electronic systems course is by no means a pre-university training for electronic engineers but that it is a non-specialist course which would be equally useful to those not going to university. He also pointed out that the syllabus had been enthusiastically received by teachers attending vacation courses within his department.

The syllabus is divided into three parts—communication systems, control systems and computer systems—each of which is prefaced by some consideration of the relevant human functions, such as hearing, seeing, feedback and problem solving. Although the course concentrates on the underlying principles of electronic systems, the characteristics of electronic devices themselves can be examined in more detail as appropriate. Experimental work is an integral part of the course and includes, for example, measurement of the frequency response of the human ear and simple experiments with servomechanisms.

Professor Chaplin is not unduly discouraged by the attitude of the Schools Council and it is planned that the second half of the syllabus will be taught to another group of boys in the first year sixth form during the coming academic year. Meanwhile it seems likely either that another approach will be made to the council in the near future or that efforts will first be made to interest more and more teachers in the idea of a course on electronic systems—possily through the Association for Science Education and the National Electronics Council.

Appointment

MRS MARGARET THATCHER, Secretary of State for Education and Technology, announced this week the appointment of Professor R. C. O. Matthews as chairman of the Social Science Research Council in succession to Mr Andrew Shonfield. Professor Matthews, Drummond Professor of Political Economy at Oxford, will take over from Mr Shonfield on January 1, 1972. He is at present a member of the SSRC and is chairman of the council's Economics Committee as well as being a member of the Central Advisory Council for Science and Technology, the Council of the Royal Economic Society and the Executive Committee of the National Institute of Economic and Social Research.

Miscellaneous Intelligence

SWEDEN is reported to be the first West European country to introduce Chinese as an optional subject at the secondary school level. Twenty pupils at a Stockholm school are now studying Chinese as their third foreign language, after English and German or French. Most pupils at the equivalent level of education in Sweden study Spanish as their third language, and roughly 1,300 take Russian.

THE University of Leicester experiment to determine the precise position of the source GX3+1 was successfully flown from Woomera in Australia on September 26. It is hoped that the data obtained on this flight will lead to an improvement in the position known for this X-ray source from 2 arc min to better than 0.25 arc s in the coordinate measured. This is achieved by determining the exact time at which the source disappears when it is eclipsed by the Moon. The flight took place aboard a Skylark sounding rocket, which was stabilized and "locked on" to the strong X-ray source Sco X-1 during the four minutes of observing time. The experiment and the Scorpius sensor were provided by the group working under Dr K. Pounds at Leicester. The determination of a precise position for GX3+1 may lead to its identification with an optical object; first results indicate that the flight was a complete success.

NEW WORLD

Safeguard Survives Another Attack

by our Washington Correspondent

THE Safeguard anti-ballistic missile system (ABM) seems to be rapidly losing its vulnerability to attack, at least from forces in the Senate which are ranged each year against the project's budget. Its vulnerability to Soviet missiles is still, however, open to question. Two years ago, the crucial decision on whether to provide funding for the first phase of deployment of Safeguard was decided by a casting vote from Vice-President Spiro T. Agnew; last year, supporters of the ABM defeated another attack on Safeguard's funding by a vote of 52 to 47, and last week the Administration mustered 64 senators against an amendment seeking to prevent any more money being spent on the ABM system. The amendment gained only 21 supporters.

Safeguard has been hardened to attack in the Senate not because it is thought to be any more capable of providing effective defence of selected missile silos in the United States, but because it is claimed to be essential to the negotiation of an agreement in the Strategic Arms Limitation Talks, the fifth round of which has recently ended in Helsinki. A lesser reason for the ease with which Safeguard gained Senate approval last week was that the Senate Armed Services Committee had already cut the Administration's budget request by $161 million and restricted full-scale deployment of the system in 1972 to the two sites where preparations are already most advanced—at Grand Forks in North Dakota and at Malmstrom in Montana. In addition, the Whiteman Air Force Base in Missouri and the Warren Air Force Base in Wyoming are to be prepared to receive the Safeguard system at a later, so far undetermined, date. The Armed Services Committee also blocked funds designed for deploying ABMs around Washington.

The effect of the Senate's adoption of the Armed Services Committee's bill is to increase the authorization for Safeguard from the $3,700 million that had been approved up to May 31, 1971, to $4,800 million. (The latest estimate of the full cost of setting up ABM defences around Grand Forks, Malmstrom, Whiteman and Warren is now reckoned to be about $7,100 million.) Four of the twelve sites originally planned for ABM defence have been given the go-ahead by Congress, with full scale deployment limited to only two, and the immediate purpose of the system has been restricted to the defence of Minuteman missile silos against Soviet attack.

Since September 1967, when the Sentinel system—the forerunner to Safeguard—was first announced by the Pentagon, the objects of and justification for the ABM have constantly shifted. First designed to provide a light area defence against the possibility of attack by Chinese missiles, the system was later reworked to provide protection for US missiles against Soviet attack, the object being to provide sufficient defence against a first strike to preserve intact enough offensive missiles to cause "unacceptable damage" to the Soviet Union. The Pentagon maintained, however, the option of using Safeguard to provide a light area defence against missiles directed at centres of population if the need arises.

Whatever its proposed role, however, supporters of the system have effectively argued that it is an essential bargaining chip at the Strategic Arms Limitation Talks (SALT), to be used as leverage for concluding an agreement on the limitation of offensive weapons. That argument even won over Senator John Sherman Cooper, a vigorous critic of the ABM and co-sponsor of the amendment that failed by only one vote to stop the project in 1969. Cooper this year decided to vote against the amendment offered by Senator Harold E. Hughes, seeking to block funds for Safeguard, because although Safeguard "remains a system inadequate to defending the Minuteman missile force, the SALT talks are at a stage now where an agreement on the limitation of ABM is attainable".

Critics of the ABM system have in the past based their opposition on three chief propositions: that it will not work, that it is unnecessary and that it is a destabilizing factor in the arms race. Supporters have countered that the Soviet Union's offensive missiles are reaching the stage at which they have the capability of destroying a large proportion of the United States' missiles on the ground by a surprise first strike. Strengthened by the fact that the Soviet Union is also deploying an ABM system around Moscow, the Pentagon argues that if numbers of US missiles are substantially reduced by a first strike, the Moscow ABM defences may be able to cope with the few Minuteman missiles left for retaliation, and the United States' offensive weapon therefore ceases

Nuclear Maginot Line

"IN the course of hearings and debate on this purposed system, except for the claim that it might cure cancer, I have heard almost every conceivable argument for spending billions of the taxpayers' dollars on this nuclear maginot line.

"First, we were told this system was needed to defend the United States against a possible attack from the Chinese. At the same time we were also told that it would provide little if any protection against the obviously far greater missile threat from the Soviet Union.

"The absurdity of this argument became apparent and the proponents of the ABM then switched to a new rationale to attempt to justify its existence.

"The name of the system was changed from Sentinel to Safeguard and its primary mission was changed from area defense to defense of the deterrent; that is, maintaining our second strike capacity. It was argued that its deployment was vitally necessary to protect our Minutemen from the ever-growing Soviet arsenal of SS-9s.

"Anyone familiar with how small indeed is the number of defensive missiles in this system could not help but question the degree of protection it might provide against a possible nuclear attack from the other superpower. Unfortunately, however, the Defense Department refuses to declassify the number of Sprints and Spartans planned for each complex.

"It would appear these officials realize that if they do release even approximate numbers, they will substantiate the claims of those who say the system can be easily overwhelmed through very little additional effort on the part of the Soviet Union; hence the entire system is unprecedented waste of money."

—Extract from a speech by Senator Stuart Symington in the Senate debate on the amendment to block funds for Safeguard.

to become a deterrent. So, the argument goes, the ABM is needed to preserve the balance of power.

The chief flaw in that argument, according to many independent scientists, is that the Safeguard system simply will not be capable of protecting missile silos against massive attack by Soviet weapons. The original Nike-Sentinel project was abandoned essentially because it was thought to be too vulnerable to attack, yet the Safeguard system is based on similar hardware. Moreover, several witnesses before the Armed Services Committee brought up the possibility that if a sufficient number of Soviet missiles were unleashed at silos defended by Safeguard, all the anti-ballistic missiles would be used up and the silo would be left vulnerable. That argument depends in large measure on the ability of the Soviet Union to deploy sufficient numbers of offensive weapons not only to destroy defended missile silos, but also all the other silos operated by the United States.

The scientists' handling of the past debate on the effectiveness of the Safeguard system has, however, recently been called into question in a report published by the Operations Research Society of America (a report on which will be published in next week's issue of *Nature*), but in any case, the ABM was sold to the Senate this year chiefly as a bargaining chip in the SALT talks. The Armed Services Committee argued that "unilateral termination of the Safeguard programme would undermine the American negotiating posture and diminish rather than increase the likelihood of a successful and stabilizing agreement". The suggestion that the negotiating parties in Helsinki were close to agreement on anti-ballistic missiles before the session broke up last month gave more weight to the theory that to abandon construction of Safeguard at this stage would cut the ground from under the feet of Ambassador Gerald Smith, and, on the floor of the Senate at least, the viability of Safeguard took a back seat.

The negotiators in Helsinki were reportedly close to an agreement which would limit ABM deployment to 100 missiles for defence of either capital or of 300 ABMs to defend missile silos. The Soviet Union would be expected under the terms of such an agreement to complete its defence of Moscow by extending the Galosh system, and the United States would almost certainly extend the Safeguard defence of minuteman silos. The chief stumbling blocks, however, seem to be the number of ABMs to be allowed under the agreement, and also the fact that the United States has declared its unwillingness to enter into an agreement applying only to ABMs. The chief US objective at the talks is to use an agreement on ABMs as a lever to halt development of the SS-9 and sea-launched MIRV missiles. Accord is reported to be close on the ABM agreement, and hopes are high that some agreement will be struck in the next phase of the talks to take place in Vienna.

SALT apart, however, the Administration seems to share some of the scepticism of critics of the Safeguard system, for in testimony before the armed services committee, Dr Foster admitted that "if enough SS-11s were sent against a defended Minuteman field, the interceptor supply could be exhausted and the radar could be destroyed". If the deployment of Soviet missiles continues at the rate of the past year, Pentagon officials admit that Safeguard will have to be augmented by an ABM system known as Hardsite. This system relies on a greater number of smaller radars and fast Sprint rockets than Safeguard, and is thought to be less susceptible to destruction. Final cost of Hardsite, although unknown, may turn out to be rather less than that of Safeguard (see box). With serious, unanswered questions about the technical viability of Safeguard, the Department of Defense is probably as anxious as anybody for an agreement at SALT that would stop the system from being fully deployed.

MANPOWER

Jobless Engineers

by our Washington Correspondent

ONE of the first studies of the job situation among scientists and engineers since this year's crop of graduates left the universities has given little room for optimism. The study, carried out by the National Science Foundation, has found that 3.0 per cent of the engineers in the United States are out of work, and the foundation believes that the correct figure could be nearer 3.4 per cent. Derived from a questionnaire mailed to 100,000 engineers in June, this estimate compares with a figure of 1.6 per cent in the summer of 1970, and with a national unemployment rate of 5.8 per cent.

The survey found that holders of master's degrees were the worst hit among those who had been through the universities, with 3.2 per cent of their number out of a job. Holders of the bachelor's degree reported a 2.8 per cent unemployment rate, while 1.9 per cent of PhDs were out of work. A slight consolation for those engineers who had been to university and yet found themselves in the dole queues is the fact that 4.4 per cent of the engineers who do not possess a degree of any kind were jobless in the summer.

An indication of the difficulties experienced by new graduates in finding a job after graduation is the fact that 5.5 per cent of the engineers under 25 years old were out of work—not far short of the national average—while those in the age group 55–64 fared only marginally better with 4.4 per cent of their number jobless.

Other findings of the survey include:

- 78 per cent of the out-of-work engineers replying to the questionnaire gave industry and business as their last employer.
- The unemployment rate for engineers employed in space research was running at 6.3 per cent and defence at 4.8 per cent, while those previously employed in public works only experienced an unemployment rate of 1.3 per cent.
- An indication that the situation seems unlikely to get much better in the near future is given by the finding that more than two per cent of the engineers currently employed said that they had been given notice that their jobs would come to an end before July 1, 1972.

The estimates in the NSF survey should be regarded as minima because they apply only to the engineers belonging to major engineering societies, who could be reached. The response rate to the questionnaire was 65 per cent.

Short Note

Detergents

WITNESSES ranging from William D. Ruckelshaus, Administrator of the Environmental Protection Agency, to Mayor Richard Daley of Chicago shared the billing for one day of hearings held by the Senate Subcommittee on the Environment on the Administration's recent announcement on phosphate detergents. The subcommittee was told that the Administration had not, in fact, given a blanket recommendation to the housewife to switch to high-phosphate detergents, but simply that she should examine the label on the detergent packaging and purchase the product that does not require a toxicity warning. Surgeon-General Jesse L. Steinfeld said, in answer to a question from William B. Spong, the committee chairman, that he had not considered submitting an environmental impact statement to the President's Council on Environmental Quality before making his recommendations concerning phosphate detergents. The National Environment Policy Act requires that all agencies of the federal government submit an environmental impact statement on any project likely to alter the environment in any way.

NEWS AND VIEWS

Transduction of Human Cells by Lambda

THE experiments reported by Merril, Geier and Petricciani on page 398 of this issue of *Nature* will be of the greatest and most startling interest to all biologists, and if they can be independently confirmed they will have very far reaching implications indeed. For what Merril and his associates claim is nothing less than that bacteriophage lambda particles, or naked phage DNA genomes, can infect human fibroblasts, can be transcribed and translated in the milieu of eukaryotic cells and are stably inherited as the fibroblasts multiply through many generations. In short, they believe they have detected the transduction of human cells by transducing derivatives of bacteriophage lambda and fully appreciate all that that implies. This is, of course, a claim little short of the revolutionary. It is inevitable therefore that virtually all readers, having seen the title of this report, will probably find their minds flooding with *a priori* scepticism and prejudice as they begin to read the text. And as Merril and his colleagues no doubt realize and must accept, everybody will be out to find flaws in their work.

What have Merril *et al.* actually done? They have set out to test whether or not bacterial genes work in human cells. A formidable taks indeed; but to make things easier for themselves they have exploited a particular sort of human cell and two transducing viruses derived from phage lambda. The human cells were fibroblasts adapted for growth in culture and derived from a patient with galactosaemia, the inborn error of metabolism which is characterized by an absence of the enzyme galactose-1-phosphate uridyl transferase (GPU transferase) and lack of the ability to take up and metabolize galactose. The two transducing phages derived from lambda carry the *Escherichia coli* galactose operon; in one of these phages the operon is wild type and specifies an active GPU transferase (λ pgal T^+), whereas in the other it carries a mutation which inactivates the transferase enzyme (λ pgal T^-). The experiment is to infect cultures of the galactosaemic fibroblasts growing in flasks with either the particles or the naked DNA genomes of one or other of the transducing phages or with wild-type lambda phage and then assay for the synthesis in the cells of phage specific RNAs and for the appearance of GPU transferase activity, without worrying at all about how the phage particles or their DNA manages to infect the cells or about the fate of the infecting phage genomes.

The assay for phage specific RNA involves, of course, a hybridization experiment. Lambda phage DNA is denatured and immobilized on nitrocellulose filters and is then challenged with RNA extracted from the cultures which have been exposed to phage and labelled with ^{3}H-uridine or from control cultures which have not been infected. As Merril *et al.* describe, the results of such experiments indicate that by 4.5 days after infection with the phage, as much as 0.2 per cent of the total labelled RNA in the cells will hybridize with lambda DNA. By contrast less than 0.005 per cent of the RNA extracted from the controls will hybridize, and less than 0.005 per cent of the RNA from both controls and infected cells hybridizes with *E. coli* DNA. Merril and his colleagues conclude, not unreasonably, that the phage DNA is transcribed in these mammalian cells and, as critics will no doubt be quick to notice, to a perhaps surprisingly great extent if 0.2 per cent of the total labelled cellular RNA is really phage specific. But that is not all; Merril *et al.* assert, although they do not present numerical data, that this expression of the phage genome is not transient but persists at much the same level during some 40 days of culturing which included twice splitting the cultures 1 in 3.

The changes in the activity of GPU transferase, which were assayed by measuring the conversion of galactose-1-phosphate to UDP-galactose in the infected cultures, are equally startling. Extracts made at 4 days and subsequently after subculturing from eight cultures of cells infected with λ pgal T^+, which specifies an active transferase, contain from ten to seventy-five-fold more activity than extracts of uninfected cells or cells infected with λ pgal T^-, which cannot specify an active transferase. The fact that cells infected with the transducing phage λ pgal T^- do not gain transferase activity is a crucial and particularly telling control. This result makes it hard to deny the conclusion that the appearance of transferase in the cells infected with λ pgal T^+ is a direct result of the expression of the galactose operon of the infecting phage genome.

The possibility that the cell cultures might be contaminated with some microorganism is very real and cannot be lightly dismissed but several observations make it extremely unlikely. First, the appearance of transferase activity is blocked by cycloheximide which implies that the enzyme is being made by eukaryotic translation machinery. Second, the addition of penicillin, streptomycin and mycostatin does not affect the appearance of the transferase. And what is perhaps the best argument of all, Merril *et al.* failed to detect bacterial fungal or mycoplasmal contamination in their cultures when they were monitored. As they comment, if the transferase was being made in such amounts by contaminating microorganisms they should have been easy to detect but no contamination was found. One other finding which supports the case that transferase is being made and promotes cell survival is that cells infected with λ pgal T^+ survive 1–3 weeks longer in a medium in which galactose is the sole source of hexose sugars than do cells infected with λ pgal T^- phage.

Although several quibbles can be raised after a close reading of what Merril *et al.* have to say, even the most dyed-in-the-wool sceptics will be very hard put to it to find anything seriously wrong with the design and execution of these experiments. How can the conclusion that the phage genome is not only expressed but maintained for several weeks at least in the human cells be avoided? Merril and his colleagues have not yet made any attempt to determine where in the cell, in the nucleus, the cytoplasm or in the mitochondria, the phage genomes reside but no doubt more than one research group will earn its living trying to answer that and other such questions if these experiments can be confirmed. And assuming that is the case, a great deal of hard thinking will have to be put into the related questions of how the introduction of selected bacterial genes into mammalian cells, so as to alter the recipient's metabolic pathways, can usefully be applied and what hazards might arise from too indiscriminate experimentation with this system. Merril's group have thrown down the gauntlet; those biologists, who through intuition or prejudice disbelieve these results, know how they can accept the challenge.

Anomalous Redshifts Explained?

THE article by Ferencz and Tarcsai on page 404 of this issue of *Nature* will be a relief to orthodox workers in general relativity because it provides an explanation, simple in principle, for certain puzzling phenomena for which very speculative explanations have hitherto had to be constructed.

Three years ago, Sadeh, Knowles and Yaplee reported (*Science*, **159**, 307; 1968) an anomalous redshift in the 21 cm radiation from Taurus A as it passed near the Sun. The extent of the shift was 150 Hz—about one part in 10^7—but it was too great, they claimed, to be explained either by the interaction of the signal with the Sun's atmosphere, or by any effect attributable to the curvature of space time around the Sun according to the equations of general relativity and similar theories of gravitation. For two reasons this anomaly was either worrying or exciting. First, relativistic theories of gravitation are so elegant and illuminating that theorists would be more loath to part with them than with other esoteric theories. Second, the two sources of redshift in well-understood situations, recessional velocity of the source and gravitational fields, provide the best means of measuring masses and velocities of very distant objects. The first mentioned is the best reason for believing that the universe expands. It is suspected that other causes of redshift exist because it is difficult to explain the huge redshifts of quasi-stellar objects; but to find inexplicable redshifts near to the Sun was most perplexing.

Later in 1968, Sadeh, Knowles and Au reported (*Science*, **161**, 567; 1968) a repetition of this experiment and also another phenomenon of similar type. In this experiment a caesium clock was carried about on the Earth's surface and exhibited a decrease in frequency proportional to the distance moved. Again, a timing system, this time a clock instead of a photon, was showing an irreversible decrease in frequency on being moved through a gravitational field. If such a phenomenon were general it would cause the frequency of photons to diminish as they moved through space and would account for 10 per cent of the observed redshift.

Doubts were cast on the validity of this experiment by Markowitz (*Science*, **162**, 1387; 1968). Sadeh and Knowles, in collaboration with Hollinger and Youmans, had also studied the most precise clock in the sky, the pulsar CP 0950, as it was eclipsed by the Sun (*Science*. **162**, 897; 1968). By now a diminution in the frequency of its flashes was expected as its light grazed the solar limb, but none was observed.

At least three radical theories were invoked to explain the measurements. Sadeh, Knowles and Yaplee in their first article had put forward the hypothesis that photons might resemble electrons in losing the energy that they gain by falling into gravitational fields but requiring energy to climb out of them. Such a picture exaggerates the effect of the first experiment by a factor which they calculate to be about 15, explains the small result of the third but provides no clue to the disputed second.

Szekeres explained (*Nature*, **220**, 1116; 1968) the results by a unified field theory. Theories of this type ascribe the electromagnetic field as well as the gravitational field to curvature in the space-time continuum. Szekeres pointed out that if the electromagnetic field was simply proportional to the difference between the "connexions" (geometrical quantities describing displacements between parallel lines)—one for world structure, the other for the actual displacements of light waves—then frequency changes of the type observed in the first and the second experiments could be ascribed to travel through the magnetic fields of the Sun and of the Earth. Laboratory experiments reported later by Shamir (*Nature*, **222**, 362; 1969) did not support this hypothesis, however.

A third theory was that of Woodward and Yourgrau, who pointed out last year (*Nature*, **226**, 619; 1970) that the crucial point is whether or not the relative frequency shifts due to the gravitational doppler effect is frequency dependent. A comparison between the numerical magnitudes of the results of the first two experiments suggests that it is. If this is so, however, it contradicts general relativity, according to which acceleration cannot normally be distinguished from gravity. Accordingly, although Woodward and Yourgrau's model of a frequency dependent interaction fitted all the experimental data, it gave rise to much controversy.

All would be explained if the first experiment was understandable. The second experiment has not been successfully repeated and the third gave a negative result. Even the first is partially contradicted by the fact that experiments with radar pulses grazing the Sun as they echo from the Earth to the planet Mercury give results in accordance with relativity.

Exactly such an understanding is claimed in the article by Ferencz and Tarcsai in this week's *Nature*. The authors cite detailed calculations which for the first time take into account the fact that the Sun's plasma is not at rest nor homogeneous. They account for shifts in frequency well within the limits of experimental error of the first experiment. General relativity is thus vindicated.

But Ferencz and Tarcsai have not simply laid a ghost. Their technique of calculating redshifts in inhomogeneous plasmas may explain in the future the large redshifts of quasi-stellar objects. The original statement about the plasma is beginning to look like a fruitful error.

HAEMOGLOBIN

Down Among the Dimers

from our Molecular Biology Correspondent

Two steps forward to one step back is perhaps the best rate of advance that can be hoped for in a complex field. Following the recent work by Kellett on the dissociation of liganded and unliganded haemoglobin, which I discussed a few weeks ago, the situation—the dust of conflict having apparently settled—appeared to be as follows: oxyhaemoglobin exists under normal conditions of salt and *p*H in an equilibrium state between tetramers and dimers, the concentration of the latter becoming significant only at extremely low protein concentrations. There are no monomers. Deoxygenated haemoglobin is tetrameric and does not dissociate to dimers even at the lowest measurable concentrations and at high ionic strength. What has also long been accepted, and successively confirmed by a series of workers, is that oxyhaemoglobin (or carboxyhaemoglobin and other liganded forms), even at high protein concentrations, dissociates in media of high ionic strength to dimers. Norén, Ho and Casassa (*Biochemistry*, **10**, 3222; 1971), however, say not so, and are prepared to take on the world.

The method which they use is light scattering with a laser source, the long wavelength of emission averting the difficulties caused by haem absorption. The results show that down to a concentration of less than 10^{-4} M in haem, 2 M sodium chloride has essentially no effect on the molecular weight. From the invariance of molecular weight with protein concentration over the measured range it follows that the tetramer–dimer equilibrium constant must certainly be lower than about 10^{-6} mole/l. Norén *et al.* then take a hatchet to earlier work, based variously on light scattering, osmometry, sedimentation equilibrium and sedimentation velocity. Earlier light scattering results, for example, stand condemned by internally inconsistent refractive index increment measurements, which failed to reveal the considerable dependence of this parameter on salt concentration. Other evidence is likewise revealed as flawed. The moral again is that work on nonideal polydisperse systems in mixed solvents is fraught with hazards.

The notion that lamprey haemoglobin, being apparently a monomer, would present a simpler system for study has also turned out to be risible. The oxygenation properties, it was soon established, are concentration dependent, and, worse yet, there is a Bohr effect. Briehl then found that the deoxygenated form is not predominantly monomeric. A re-examination of this haemoglobin is now to be found in an article by Andersen (*J. Biol. Chem.*, **246**, 4800; 1971).

In the deoxyhaemoglobin the sedimentation equilibrium distributions can be fitted by equilibrium constants for association of monomers to dimers, and dimers to tetramers. The first process is *p*H-dependent and seems to involve a single charged group on each monomer. This at once explains the Bohr effect. The liganded haemoglobin also forms dimers at sufficiently high concentration, and apparently ultimately tetramers as well. At the haemoglobin concentration of 25 per cent in the red cell, the equilibrium constants as determined dictate that the deoxygenated pigment will be largely dimeric and the oxygenated form monomeric. Oxygenation will thus lead to dissociation of the protein. This will generate a measure of cooperativity at these physiological protein concentrations—a mechanism which may be seen as a precursor in this evolutionary prototype to that in more advanced models. In an accompanying article, Andersen and Gibson (*ibid.*, 4790) examine the kinetics of ligand binding by lamprey haemoglobin, and show that they can now be more or less quantitatively explained, assuming only that the monomer has a high and the dimer a low ligand affinity.

The cause of the earlier, and erroneous, impression that human oxyhaemoglobin would dissociate at sufficiently low concentrations to the monomeric state proved to be the ease with which, under these conditions, the iron is oxidized to the ferric state. The methaemoglobin so formed has always been recognized as being unstable.

Bucci and Fronticelli (*Biochim. Biophys. Acta*, **243**, 170; 1971) have now examined the behaviour of isolated α-chains in the ferric state. The monomers are prepared by treatment of native haemoglobin with a thiol reagent, which can be stripped off after fractionation of the two chains. When the isolated chains were converted into the ferric state, the result was not in fact methaemoglobin, but a type with the characteristic absorption spectrum of a ferric haemochromogen, in which it is supposed that the iron is linked on both sides of the haem plane to a nitrogenous base. Judged by optical activity there is some loss of ordered structure, rather on the lines found in haem-free globin. In the ferric β-chains the effects are even more drastic. Reduction of the new type to the ferrous state failed to regenerate the native structure. The ferric chains evidently exist only in this modified and monomeric condition.

ADENOVIRUS

Hybridizers Beware

from our Cell Biology Correspondent

ANYBODY who has recourse to DNA-RNA hybridization techniques, and in particular competition hybridization, would be well advised to cast more than

---

Mouse Haemoglobin made *in vitro*

IN *Nature New Biology* next Wednesday two groups, Lockard and Lingrel and Mathews, Osborn and Lingrel, describe the synthesis *in vitro* of mouse globin and haemoglobin and conclude that the 9S murine globin messenger RNAs can be translated in cell free systems derived from ascites cells or reticulocytes of species other than the mouse. At least for this messenger neither tissue specific nor species specific initiation factors seem to be required for translation.

Lockard and Lingrel describe the translation of mouse reticulocyte 9S messenger RNA in a rabbit reticulocyte cell-free system and also mention that this messenger is translated in guinea-pig and duck reticulocyte systems. By fingerprinting the product of translation and by studying its behaviour on chromatography and gel filtration they conclude that both mouse α and β globin chains are being made and therefore the 9S RNA must contain messengers for both these molecules.

Mathews, Osborn and Lingrel have used this 9S RNA to programme a cell-free system obtained from mouse Krebs ascites cells, which were originally derived from a mouse mammary carcinoma. They find that without the addition of any extract from reticulocytes both α and β globin chains are made. In short, the Krebs ascites cells contain all the factors required for the accurate initiation, elongation and termination of globin chains.

Recently Stavnezer and Huang reported in *Nature* (**230**, 172; 1971) that mouse messenger RNAs specifying the light chain of immunoglobulin are translated in the rabbit reticulocyte cell-free system *à la* Lingrel and Lockard. This result, taken together with those published in next Wednesday's *Nature New Biology*, suggests that the hypothesis that the translation of particular messengers depends on the existence of tissue-specification initiation factors may not rigorously apply to eukaryotic cells. Alternatively it can be suggested that tumour cells such as Krebs ascites cells, because they are cancerous, retain the capacity to translate a wide range of messengers and, further, that the factors in reticulocytes which initiate translation of globin messengers work also with immunoglobulin messengers.

just a glance at the contents list of the current number of the *Journal of Virology* because it contains a report on the synthesis of adenovirus 2 RNA in infected KB cells by Lucas and Ginsberg (*J. Virol.*, **8**, 203; 1971). This is also a cautionary tale with a moral extending far beyond the biology of adenovirus replication. Lucas and Ginsberg show that the results obtained from competition hybridization experiments depend greatly on the precise technique which is used.

Lucas and Ginsberg apparently began their experiments with two objects in mind; first, a re-analysis of the regulation of adenovirus 2 RNA synthesis in permissive KB cells and, second, a comparison of the current competition, or to be more accurate, presaturation hybridization techniques. They first showed by simple RNA.DNA hybridization that by 6 hours after infection in the presence of FUDR, which blocks DNA synthesis, adenovirus RNA can be detected in extracts of total cytoplasmic RNA and that if polysomal RNA is isolated virus specific sequences can be detected as early as 3 hours after infection, which is long before the replication of adenovirus genomes begins. Furthermore, in the absence of FUDR the amount of ^{3}H-uridine incorporated into viral RNA continues to increase for 20 hours after infection, by which time about 40 per cent of the total label entering the cells ends up in viral RNA.

By first prehybridizing the viral DNA with RNA made at late times and then measuring the extent to which labelled RNA made at early times can hybridize, Lucas and Ginsberg attempted to determine whether there exists a class of early RNA which is not made at late times. And by varying the experimental procedure they determined how results of hybridization experiments are influenced by differences in manipulation. The first procedure they used, which they believe is rigorous, involved treating the filters with ribonuclease after the prehybridization step as well as after the challenge step with early RNA. This procedure revealed three classes of adenovirus RNA; a class of early RNA (70 per cent of the total RNA made at early times), the synthesis of which begins before DNA replication starts, and ceases some time after such that by 18 hours this RNA can no longer be detected; a class of early RNA which continues to be synthesized at increasing rates throughout the infection; and a class of late RNA made only after DNA replication has begun.

With the two other procedures, in which the first ribonuclease digestion is omitted and the prehybridized filters are simply washed in saline, results are obtained which indicate that from 40 per cent to 98 per cent of the RNA sequences made at early times are made throughout the infection. In other words these less rigorous hybridization procedures fail to reveal the class of true early RNA which is made before DNA replicates and then switched off as DNA replication gets under way. As Lucas and Ginsberg remark, in the light of these observations there is a strong possibility that differences in experimental technique rather than biology may account for the conflicting data in the literature concerning the patterns of transcription of numerous animal viruses.

The early adenovirus 2 RNA made in KB cells has been analysed on polyacrylamide gels by Parsons and Green (*Virology*, **45**, 154; 1971) and compared with the viral RNA made in nonpermissive rat cells transformed by this virus. They have resolved the 2–6 hour cytoplasmic RNA from KB cells into two chief components (23S and 16S), which are made in the same relative amounts and to an amount five-fold greater in the presence of cycloheximide, which blocks cell and viral protein synthesis. The parallels between the pattern of transcription of adenovirus 2 and a phage like T4 are clear. By contrast in transformed rat cells adenovirus 2 RNAs in both nucleus and cytoplasm are heterogeneous in size and at least some of these RNAs are so large that they may well comprise molecules with both viral and host sequences.

PARASITOLOGY

Plasmodium Problems

from a Correspondent

Of the many species of malaria parasites available to research workers, perhaps the most widely used is the rodent species *Plasmodium berghei*. Although the species was first isolated in 1948, it was not until 1964 that its complete life cycle was elucidated and methods for routine laboratory maintenance developed. In spite of these achievements, many laboratories using the *Plasmodium berghei–Anopheles stephensi* system still experience difficulties in cyclical transmission. Frequently these difficulties seem to be attributable to concomitant infections with other organisms, in both rodents and mos-

Filament Arrays in Mammalian Smooth Muscle

During the past few years, the structure of the myosin-containing elements in mammalian smooth muscle has been providing a fertile field of research for electron microscopists, and several different types of structures have been reported. The chief protagonists in the field are Lowy and his colleagues at Aarhus University who see ribbon-like structures, and two groups in Pennsylvania headed by Rice and Somlyo, who see roughly circular filaments similar to the thick filaments in striated muscle. The discrepancy probably arises because vertebrate smooth muscle is a spontaneously active muscle and different techniques have been used to try to relax it and to preserve the structure as it exists *in vivo*.

Lowy *et al.* (*Nature*, **227**, 46; 1970) observed ribbons in muscles which had been equilibrated in Krebs solution for 3–4 hours at 0° C supporting a 10 g weight (which produced an extension of 3–10 per cent). The Pennsylvania groups, however, observed fairly regular arrays of circular thick filaments in muscles which had been stretched to 1.5 times excised length, incubated for 30 minutes in a Krebs solution and fixed either in this condition or with a relaxant added (*Nature New Biology*, **231**, 242 and 243; 1971; *J. Cell Biol.*, **49**, 636; 1971).

Furthermore, the Pennsylvania groups found that if the muscles were excessively stretched (2.1–2.6 times excised length) or incubated in hypertonic media, then ribbons were seen. They therefore suggested that arrays of circular filaments are the normal structure existing *in vivo*, and that the filaments only aggregate to form ribbons under non-physiological conditions which abnormally decrease the inter-filament spacing.

Because there were indications that the circular filaments themselves could only be seen in any numbers when stretch (up to 1.5 times excised length) was applied, Somlyo *et al.* have now investigated this problem further (see next Wednesday's *Nature New Biology*), and obtained micrographs showing arrays of circular filaments in completely unstretched muscles. Somlyo *et al.* suggest that the reason why filaments are seen in stretched and incubated preparations is simply because of better orientation along the fibre axis, and recovery from dissection trauma respectively.

The electron micrographs of Somlyo and his colleagues clearly show arrays of circular thick filaments in mammalian smooth muscles at all physiological lengths. It would be interesting to know whether the X-ray pattern *in vivo* bears out their observations: is there an equatorial reflexion arising from these filament arrays, and can the shape of the 144 Å meridional myosin reflexion be accounted for by such arrays?

quitoes. It was timely therefore that the first European multicolloquy of parasitology, which was held at Rennes from September 1 to 4, should include a section devoted exclusively to the interaction of *P. berghei* with other organisms.

Problems concerned with blood infections were covered by Professor W. Peters (University of Liverpool). Both *Eperythrozoon coccoides* and *Haemobartonella muris*, themselves parasites of red cells, may severely limit the development of *P. berghei* and other blood protozoa. Their presence, either in recipient laboratory rodents or in wild rodents, may interfere with the growth of protozoa during the attempted isolation of new strains, and may give the false impression that either the donor is uninfected or the recipient insusceptible. Both organisms can be eradicated by treatment with neoarsphenamine, which has no effect on *P. berghei*.

Infections of mosquitoes which appear to suppress development of oocysts and sporozoites were discussed by several contributors. Drs C. Draper and R. Bird (London School of Hygiene and Tropical Medicine) described a cytoplasmic polyhedrosis virus in the midgut cells of *A. stephensi* from a colony in which *P. berghei* transmissions were proving difficult. Elaboration of viruses was seen within oocysts, and some were observed inside malformed sporozoites. Drs R. Howells and E. Davies (University of Liverpool) have also observed viral particles in midgut cells and oocysts, as well as rickettsia-like organisms which seemed to interfere with *P. berghei* development because they were never seen in mosquitoes containing oocysts. Dr R. Hulls (Imperial College, London) showed that the microsporidan *Nosema algeri* can reduce the numbers of developing oocysts, and cause oocyst degeneration resulting in a severe depletion in the number of sporozoites reaching the salivary glands.

But not all concomitant infections are harmful. Dr F. E. G. Cox (King's College, London) pointed out that mice which have recovered from infections with the piroplasms *Babesia microti* and *B. rodhaini* and the dactylosome *Anthemosoma garnhami* are strongly resistant to challenge with *Plasmodium vinckei*, but not to challenge with *P. berghei*. Professor J. Jadin and his colleagues (Institute of Tropical Medicine, Antwerp) showed that the bacterial fauna of the mosquito gut could play an important part in the nutrition of oocysts. By labelling *Pseudomonas* with carbon-14 and then feeding them to mosquito larvae, they were able to demonstrate the uptake of the label into oocysts and sporozoites. Perhaps the most unusual example of interaction between parasites was that described by Dr S. Rădulescu and his colleagues ("Dr I. Cantacuzino" Institute, Bucharest), who have studied the effect of *P. berghei* on infections of *Giardia muris*. *G. muris* is a protozoan which is normally restricted to the intestine of mice, but in heavy infections can invade other tissues. A much higher incidence of tissue invasion was found in mice infected with *P. berghei*.

MAGNETIC RESONANCE

Discovery Celebrated

from a Correspondent

THE celebration of the twenty-fifth anniversary of the discovery of nuclear magnetic resonance (NMR) was a special feature of the fourth international symposium on magnetic resonance held in Israel at Rehovot and Jerusalem from August 24 to 31.

Professor Felix Bloch (Stanford University) gave an entertaining account of the thoughts which led to his part in the discovery of NMR, and of the first experiments. Hansen and Packard built the electronic apparatus and Bloch's experimental assignment was the calibration by ballistic galvanometer of the magnetic field of a borrowed lecture-room electromagnet. This calibration was evidently not quite perfectly done, with the result that efforts to see the resonance were made in vain. Finally, on switching off the magnet current to make some adjustments for the next attempt, they saw the signal drift across the oscilloscope screen. This experiment had cost only a few hundred dollars, most of which was spent on the oscilloscope. Their announcement in *Physical Review* appeared one issue later than the letter by Purcell, Pound and Torrey announcing their independent discovery. The first mutual discussion in the spring of 1946 called for integration of two different viewpoints of the same phenomenon: on the west coast they spoke of nuclear induction and precession, but in the east the terminology was of transitions and resonance absorption. Was it curiously coincidental that such a discovery should be made at just the same time by unrelated groups of workers? Professor Bloch thought not, and he instanced another striking example from the early days of quantum mechanics.

The growth of the subject from these early beginnings was illustrated by the great diversity of applications covered in the 170 contributions presented by participants from some thirty countries. High-resolution NMR spectroscopy has become an instrument that no reputable

Specificity of Non-histone Protein-DNA Complexes

IT is known that the histones are non-specific gene repressors and that they do not vary from tissue to tissue. Because DNA is also not tissue specific the important problem remaining is what type of macromolecule, or macromolecular complex, is capable of specific interaction with chromatin to maintain or change the pattern of active and inactive genes. John Paul's "chromatin" group at the Beatson Hospital in Glasgow has come down in favour of the non-histone chromatin proteins for this role, whereas James Bonner at the California Institute of Technology feels that an RNA complex is involved.

In next Wednesday's *Nature New Biology*, Chytil and Spelsberg add more weight to the non-histone protein side by showing that some of the antigenic properties of non-histone protein-DNA complexes isolated from chromatin are tissue specific.

The non-histone protein-DNA complexes were prepared from various chick organs by a mild procedure which did not result in their dissociation. They were then all tested against antisera produced by a similar complex isolated from the oviduct of chicks after treatment with diethylstilboestrol. In brief, the only reaction obtained was that from the homologous non-histone protein-DNA complex.

A similar result was obtained with the intact chromatin of the various organs. Using the native chromatin from the chick oviduct and comparing it with the results from the chick oviduct non-histone protein-DNA complex, Chytil and Spelsberg estimate that at least 20 per cent of the antigenic sites located on the non-histone protein-DNA complex remain accessible in the native chromatin.

Chytil and Spelsberg tentatively suggest that some of the non-histone protein is associated with the transcribable regions of DNA, and show, in support of this, that there is a substantial lowering of transcription when specific antibody is added to the homologous antigen (chromatin). This is an interesting demonstration of tissue specificity of a complex, isolated from chromatin, but as Chytil and Spelsberg mention, the specificity may not arise from specific proteins, but from a specific structural relationship between similar proteins and DNA. The unambiguous demonstration of tissue specificity of non-histone chromatin proteins remains a challenging problem.

chemistry laboratory can do without, and several contributions demonstrated the latest developments, which notably included Fourier transform spectroscopy—giving greatly enhanced sensitivity especially for ^{13}C and ^{15}N, and for protons in weak concentration. The fortunate owners of spectrometers based on superconducting magnets presented proton spectra with impressive resolution at frequencies greater than 200 MHz.

Wide-line NMR was strongly represented with many contributions on topics ranging from metals and magnetic materials to ferroelectrics and polymers. Of special interest was the report by Dr M. Goldman (Saclay Laboratory) of the discovery of nuclear antiferromagnetism of the ^{19}F nuclei in calcium fluoride when cooled to a spin temperature below 10^{-6} K by nuclear adiabatic demagnetization. No longer is nuclear magnetism merely a branch of paramagnetism, and no longer is the study of ordered magnetic materials the prerogative of experimenters working with materials containing unpaired electrons.

The audience had glimpses of high-resolution NMR in solids too as the broadening interactions were stripped away in copper and copper compounds by high-speed magic-axis rotation (Professor E. R. Andrew, University of Nottingham), by special pulse sequences (Dr U. Haeberlen, University of Heidelberg) and by magic sandwiches (Professor J. S. Waugh, Massachusetts Institute of Technology).

A feature of the conference was the growth of the applications of magnetic resonance to systems of biological interest. Altogether there were twenty-five contributions on enzymes, membranes, cells and cell constituents, and without doubt the next international conference on magnetic resonance (in Bombay, 1974) will see further development in this important area.

PROSTHESES

Plastics in Medicine

from a Correspondent

THE symposium on plastics in medicine and surgery which was held at the University of Newcastle upon Tyne on September 15 and 16 was jointly organized by the north-east section of the Plastics Institute and the University of Newcastle upon Tyne Medical School with the object of bringing together the medical users of plastics and the producers.

A great deal of stress was laid on the proper selection of materials which are compatible with the internal environment of the body and the questions of toxicity, chemical stability, initiation of clot formation, allergy and carcinogenesis were discussed. It was also suggested that the physical form of the implanted material may in some circumstances be as important as its chemical structure. One conclusion was that guide lines for the testing of plastics for medical application are urgently required. There seemed some doubt, for example, as to whether testing the toxicity of a plastic to a tissue culture medium is a realistic measure of its likely performance in the body.

One session was spent discussing some of the technical problems of designing membrane oxygenations and dialysing equipment for patients with chronic renal disease. Professor R. A. M. Kenedi (University of Strathclyde), together with several other speakers, stressed the importance of mechanical design and testing of prostheses which were going to be implanted into the human body. Several surgeons recounted their clinical experiences using plastic materials for reconstructive surgery and for joint replacement.

There is no doubt that this first confrontation between members of the plastics industry and the medical profession was extremely valuable. It was clear to all the participants that, generally speaking, the plastics at present used in medicine have been drawn from the commonly available materials which were not designed with such uses in mind and that therefore much requires to be done in determining the ideal specifications that will meet the doctor's requirements. Unfortunately, just formulating a requirement is not sufficient for, as Sir Harry W. Melville, president of the Plastics Institute, said, the plastics industry thinks in terms of producing 100,000 tons of plastics at a time. Thus there is a financial difficulty because not only will a great deal of money have to be spent on development in producing special materials but also the total national demand may only be for a kilogram or two of the product.

Finally, there seemed to be general agreement that a national body should be set up to collect information from both the plastics industry and the medical profession with the object of aiding the future development of the use of plastics in medicine and surgery.

Changes in Membranes during the Cell Cycle

A DIVERSITY of functions is believed to be carried on at the membranes which bound all living cells and the organelles within them. Correspondingly, electron microscopy shows a variety of membrane contours, and the constituent proteins and lipids occur in all proportions. (The rolled-up membrane forming myelin is 75 per cent lipid whereas the membrane surrounding the tiny gas bubbles in some forms of alga is entirely protein.)

Another side to this diversity is the possibility that a membrane changes during the life of the cell. Evidence that the structure so varies is reported by R. E. Scott, R. C. Carter and W. R. Kidwell of the National Institutes of Health, Bethesda, in next Wednesday's *Nature New Biology*. Known techniques are used to synchronize the cells in a culture so that, in step, the cells divide into two daughter cells, grow and duplicate essential molecules, and divide again. The cells are examined at various times after the initial division, and the structure of the membrane is seen to vary in a regular way.

The cells are examined by the method of freeze cleavage. A suspension of the cells in buffered glycerol-saline is frozen in liquid nitrogen and is cleaved at low temperature and under vacuum. A replica of the newly exposed surface is made by shadowing it with platinum-carbon and the replica is cleaned of the organic material and viewed in the electron microscope. The question, what surface is exposed by cleaving, was previously answered by the striking micrographs of da Silva and Branton (*J. Cell Biol.*, **45**, 598 ; 1970) and of Tillack and Marchesi (*ibid.*, 649). Large molecules of known appearance (ferritin and F-actin) are put on the surface of red blood cells. These molecules are not seen on the cleaved surface; they appear only after ice is allowed to sublime, revealing the cell surface adjacent to the cleaved surface. Thus the surface of cleavage is within the membrane. The complementary surfaces made by the cleaving are not identical. Rather the inside half of the cell membrane shows many more particles than the extracellular half.

Scott *et al.* report a large variation in numbers of particles during the cycles of two kinds of cell. Shortly after division the daughter cells show the lowest number of the characteristic 85 Å diameter particles per square micron of membrane. Then the number gradually doubles to the level seen before division. The numbers of particles remain in proportion on the two surfaces. Similarly there is a cyclic variation in the number of the large pores in the membrane bounding the cell nucleus. The density of pores is low shortly after division and then quickly trebles during the following growth phase. Scott *et al.* believe that the 85 Å particles are glycoprotein and lipid.

BACTERIOPHAGES

Lysogeny versus Lysis

from our Cell Biology Correspondent

THE infection of a susceptible bacterium by a temperate bacteriophage can result either in the lytic replication of the phage and the death of the host or lysogeny, the integration of the repressed phage genome into that of the host which survives the infection. But what determines in the first few minutes after infection which way the infection will go? The answer to this perennial question, according to Hong, Smith and Ames (*Proc. US Nat. Acad. Sci.*, **68**, 2258; 1971), is the intracellular concentration of cyclic AMP, that ubiquitous regulatory molecule. They reach this conclusion from investigations of the influence of the physiological state of *Salmonella typhimurium* on lysogenization by the temperate phage P22.

Mutants of this bacterium which have defective adenylate cyclase (the enzyme which catalyses cyclic AMP production) or defective cyclic AMP receptor protein (the protein which when active binds cyclic AMP and activates RNA polymerase) are lysogenized by P22 at considerably lower frequencies than wild type *S. typhimurium*. This is also true of *rif* mutants of this bacterium which have an altered β subunit of RNA polymerase. Hong *et al.* suggest that it is no coincidence that these three classes of mutants not only reduce the activity of RNA polymerase but also cause the infecting P22 phage to replicate and lyse the cells rather than to lysogenize them.

They believe that in wild type cells cyclic AMP, by binding to the cyclic AMP receptor protein, activates wild type RNA polymerase to transcribe the phage genes, the expression of which establishes lysogeny. The amount of cyclic AMP in the cells will determine between lysis and lysogeny. Because of catabolite repression when there is an abundant supply of energy and little cyclic AMP, lytic replication will occur, but when energy is in short supply and there is a high concentration of cyclic AMP, lysogeny will predominate. The selective advantage of such a regulatory system to the phage is obvious and, as Hong *et al.* comment, other groups have made, and are about to publish, similar observations and conclusions made with other host and phage combinations; cyclic AMP is therefore probably the deciding factor in all infections by temperate bacteriophages.

In the same issue of the *Proceedings* (*ibid.*, 2185, 2190), Reichardt and Kaiser and Echols and Green describe in detail the genetic elements that regulate the synthesis of λ phage repressor protein which is required to establish and maintain lysogeny of *Escherichia coli*. The story that emerges from their work is that there are two pathways leading to the synthesis of λ repressor which is specified by the *CI* gene. This gene apparently has two promoter sites *prm* (promoter for repressor maintenance) and *pre* (promoter for repressor establishment). Two proteins specified by the genes *CII* and *CIII* activate the *pre* promoter during the establishment of lysogeny by binding to a DNA site *cY*. Mutants of genes *CII* or *CIII* of site *cY* prevent the transcription of gene *CI* and hence the synthesis of repressor and the establishment of lysogeny.

Once repressor has been made with wild type λ phage using the *pre* promoter and lysogeny has been established, the smaller amounts of repressor required to be made continuously to maintain the lysogenic state are transcribed from the *prm* promoter which becomes active when repressor molecules made from the *pre* promoter bind to an operator site *Or*. The *pre* promoter activated by *CII* and *CIII* gene proteins is more efficient, in the sense that it allows greater amounts of repressor to be made, than the *prm* promoter activated by repressor itself. This dual pathway therefore allows the phage to make repressor in large quantities early in the infection and so to establish lysogeny and in smaller amounts subsequently. Echols and Green certainly do not exaggerate by saying that "the pattern of regulation for even so simple a creature as phage λ can be relatively complex".

More about Radio Emission from Air Showers

RADIO methods of studying extensive air showers are comparatively new: the first announcement that radio pulses had been detected in coincidence with the shower particles was made by Jelley *et al.* in 1965 (*Nature*, **205**, 327; 1965). Several features of the emission now seem to be firmly established. First, the principal cause of the emission is the transverse deflexion of the shower particles by the Earth's magnetic field—the so-called geomagnetic mechanism; and second, the pulses are large enough to be detectable only because of coherence—in other words, because of the superposition in phase of radiation coming from different stages in the shower development. The radiation pattern on the ground—the radio pulse lateral distribution—is essentially a diffraction pattern determined by the longitudinal development of the shower, and a promising way to study the longitudinal development is through the radio emission. A major astrophysical interest at the present time is the chemical identification of the high-energy cosmic ray primary particles that produce extensive showers in the atmosphere, because this has an important bearing on the problem of cosmic ray origins. It seems that a study of the longitudinal development through the radio emission will contribute significantly to the solution of this problem.

It is therefore of more than passing interest to have a thorough understanding of the mechanism by which the radio emission is produced. Geomagnetic deflexion is certainly the dominant process, but other possible mechanisms have been suggested, and it is important to know quantitatively their relative importance. A careful study by Prescott and his colleagues in Calgary (see the next issue of *Nature Physical Science*) gives a first answer to this question.

The starting point is the knowledge that geomagnetic deflexion is greatest when a shower moves with its axis at right angles to the Earth's magnetic field lines and is zero when the axis and the field lines are parallel. The experimental aim is to plot the radio pulse amplitude as a function of the sine of the angle θ_g, between the shower axis and the field lines, keeping other parameters constant. From the graph, the residual amplitude is determined when $\theta_g=0$. For a pure geomagnetic mechanism this amplitude would be zero.

The experiment is complicated by the fact that showers with different θ_g usually have different zenith angles as well. So although two showers have the same number of particles at sea level, their total energy can be different, and the shower maxima can be at different distances from the radio antenna. Unless a correction is made for these differences, it is inadmissible to attribute changes in observed radio pulse amplitude entirely to θ_g. Prescott and his collaborators consider this problem in detail and use other experimental information to determine the necessary corrections. They also make allowance for the background noise level, subtracting this quadratically from the measured amplitude to obtain the true amplitude of the radio pulse.

The measurements were made at a frequency of 22 MHz on showers of size $\sim 10^6$ particles, or shower energy $\sim 10^{16}$ eV. A residual pulse height was found at $\theta_g=0$ of amplitude 14 ± 6 per cent of the amplitude when $\sin\theta_g=1$. This component of the radio emission cannot be attributable to geomagnetic deflexion, and Prescott *et al.* speculate that it may possibly be caused by the quasi-Čerenkov charge excess mechanism which was one of the first mechanisms to be considered as the source of the radio emission.

NUCLEAR PHYSICS

Oxford Meeting

from a Correspondent

THE Institute of Physics conference on nuclear and particle physics (Oxford, September 22 to 24) was attended not only by a good representation of British institutions but also by a pleasing number of European nuclear physicists. It thus achieved a standing aim of any such meeting, namely to promote within it the numerous informal discussions on which the subject feeds. The proportion of contributions on nuclear reactions seemed smaller than hitherto, perhaps reflecting some shift in effort. In the nuclear structure papers there was a numerical majority of more than 2:1 in favour of light nuclei (say $A<50$) over heavy nuclei (say $A>70$).

On the first day, Professor H. J. Mang (Technical University, Munich) reviewed the problem of making the collective model respectable, physically and mathematically. For some time the collective model has enjoyed much success in "explaining" the properties of many nuclear excited states in terms of the quantized rotations or vibrations of a drop of nuclear fluid. The ultimate aim, of course, is to relate apparent collective motion to individual particle motion and inter-nucleon focus. A unified model, however, which embodies both the collective (macroscopic) and single particle (microscopic) motions thereby reaps the problem of redundant variables, that is, it has more co-ordinates than necessary to specify a nuclear state. Perhaps few nuclear physicists would abandon a relatively successful model in deference to this mathematical nicety. Professor Mang indicated, however, that a more sophisticated and satisfactory model could reproduce the results of, for example, the *ad hoc* phenomenological variable-moment-of-inertia model.

Dr A. Lane (AERE, Harwell) surveyed non-statistical effects in resonance reactions. The compound nucleus theory of nuclear reactions, where the reaction between two nuclei proceeds through states of the aggregate intermediate nucleus, has been available for a long time. Often the nuclear quantities which arise—the spacings and widths of the compound nucleus energy levels and the magnitudes and phases of reaction scattering amplitudes—are determined by so much unknown nuclear detail that they have been traditionally subject to an overall statistical analysis. As Dr Lane has emphasized, departures from the statistical theory are of special interest and beg physical explanation. For example, a doorway state (a brief engagement between nuclei before complete wedding) may explain the observed correlation between cross-sections for different nuclear reactions which proceed through the same compound nucleus. Dr Lane gave examples of other apparent correlations, too numerous to give here, and ideas which may explain them. It seems that this subject has gained impetus from more and improved data.

Professor G. Goldring (Weizmann Institute of Science, Rehovot) spoke about the hyperfine interactions of nuclei in highly ionized atoms. The angular distribution of decay gamma rays from an excited nucleus may be perturbed when the nucleus recoils in a highly ionized atom out of a target. The perturbation arises from the precession of the nucleus caused by the interaction of its excited state magnetic moment with the atomic magnetic field. This phenomenon provides an interplay between atomic and nuclear physics. Dr Goldring concentrated on results of recent work with light recoil ions. He reported an elegant experiment in which the angular distribution of gamma rays from an excited state of ^{18}O was found to be dependent on the charge state of the recoiling oxygen ions. This was done by counting γ-rays in coincidence with ^{18}O ions which were separated in their various charge states by a magnetic spectrometer. The angular distribution associated with the 6^+ ionic charge state was not attenuated whereas that associated with the 7^+ ion usually had its one electron in the 1s atomic ground state. It was inferred that this followed from the rough rule that electron exchange in the target is most likely when the orbital velocity of an ionic electron equals the velocity of the moving ion. Thus if the atomic states of the electron are well separated in energy (that is, the lower states), it may be possible to populate preferentially a particular state by proper choice of recoil velocity.

From the point of view of the high energy physicist, the meeting was a stimulating experience. The most interesting facet was perhaps the devotion of a whole day to a review, in four talks, of the present status of some of the problems in the field of astrophysics. It seems that the parochial attitudes common in nuclear and particle physics are not reflected in astrophysics, and that any physicist interested in escaping from the rat race of, say, particle physics would be a welcome credit to the ranks of those people studying the astrophysical implications of their work. High and low energy nuclear and particle physics have vital parts to play in accounting for many of the phenomena. Professor D. Sciama (University of Oxford) discussed the growing evidence that the origin of the universe lies in the "hot, big bang" rather than in the alternative form of a steady state. The evidence comes from studies of the integral number intensity distribution of radio sources, the redshifts in quasars and the galactic background of microwave radiation. All point to an evolving universe as one goes back in time. It is also evident from a knowledge of the relative abundances of hydrogen and helium that nuclear genesis requires more than thermonuclear reactions to account for these abundances; neutrino reactions at temperatures in the region 10^9–10^{10} °K can lead to the known He/H abundance ratio.

Aspects of high energy astrophysics that have emerged with the discovery of pulsars, the study of X-ray and γ-ray spectroscopy, and, of course, the

---

Cosmic X-rays not from Galaxy Clusters

THE importance of diffuse cosmic X-rays to cosmology lies in the agreement of most theories that this background must contain a significant contribution from sources at a redshift of $z=1$. According to most models the degree of isotropy in this X-ray background provides an insight into the isotropy of the universe at the epoch corresponding to $z=1$. But the scale of fluctuations observed over the sky is not consistent with any origin for the radiation in clusters or superclusters, and refinements in technique have now resulted in a lower limit of 5×10^5 sources spread uniformly across the sky, if the radiation does indeed originate in discrete sources. If the sources are assumed to have constant absolute luminosity, rather than constant apparent luminosity, this limit is raised to 4×10^6 discrete objects, according to the latest evaluation of the statistics by Schwartz *et al.* in next Monday's issue of *Nature Physical Science*.

The rocket detector used in this work operated in the range 2–32 keV, roughly comparable with earlier work on the isotropy in the 10–40 keV range (Wolfe and Burbidge, *Nature*, **228**, 1170; 1970). It seems clear that the supercluster or cluster models for the origin of the diffuse cosmic X-rays cannot stand up in the light of the work of Schwartz *et al.* and Wolfe and Burbidge, at least in the naive form of a direct proportionality between cluster density and X-ray intensity. The limits set by the latest work provide the constraints to which any alternative models must conform.

need to explain the nature of the acceleration of cosmic rays to very high energies were reviewed by Dr M. Rees (Institute of Theoretical Astronomy, University of Cambridge). According to Dr Rees, the possible identity of some pulsars with neutron stars suggests that there is no need to look further than neutron stars for an accelerating mechanism for cosmic rays; an estimate of the potential difference between the pole and equator of a neutron star is $\sim 10^{16}$ eV. (Food for thought among high energy physicists might be found in the comparison of the energies available in cosmic rays—upward of 10^{15} eV per particle in many cases—with those from the highest energy man-made accelerators.) The nature of neutron stars was considered from the point of view of a solid state physicist by Professor P. W. Anderson (University of Cambridge and Bell Telephone Laboratory), who showed how considerations from this field of physics which deals with normal matter can lead to speculations about the nature of the matter in white dwarf and neutron stars. Starting from basic ingredients, that is, a knowledge of the gas, liquid and crystalline solid states and superfluidity, Professor Anderson postulated a model for the structure of a neutron star. It is a relatively cool object ($\sim 10^8$ °K) and, at the surface, is thought to be composed of matter of white dwarf densities. Passing inwards towards a core there are liquid and solid phases and then a gas phase which has superfluid properties. The nature of central core region is not defined, but is thought to contain nucleons in their excited states (hyperons).

The role of the nuclear weak interaction has long been recognized in speculations about the source of stellar energy, and Professor L. Radicati (University of Pisa) discussed this work. It now seems clear from the work of Dr R. Davis (Brookhaven National Laboratory) that solar neutrinos are emitted at a rate less than the original theoretical estimate (by a factor of 2 to 3) and, because cross-sections can be confidently predicted from present knowledge of the weak interaction, the conclusion is that the temperature of the Sun is lower than previously predicted. Some discussion of the nature of the production processes involving neutrinos in stellar environments (at temperatures 10^8–10^{10} °K) was also presented. It is clear that details of the physics of these and other weak interaction reactions can be sought by further astrophysical observations, in particular by work on the cosmological abundance of the elements.

Professor L. Van Hove (CERN, Geneva) considered the production mechanisms of high energy particles involving the strong nuclear interaction. There is considerable information already contained in bubble chamber photographs of multi-body processes, and by analysing such events for correlations between pairs or triplets of particles, details can be extracted of the intermediate resonance states or exchanged particles in the various interactions. The theory of this field is very complex. "World data tapes" could be searched to elucidate any theoretical model having as its basis, as Professor Van Hove pleaded, the important criteria of "simplicity" and "power of prediction". The experimental analysis of data from reactions such as $pp \rightarrow \pi^- p \Delta^{++}$, $pp \rightarrow \pi^+ \pi^- pp$, and $\pi^- p \rightarrow 2\pi^- \pi^+ p$ has already shown that patience and attention to detail pay considerable rewards in this field and more such analyses will follow in future. Professor Van Hove included in this talk a brief report of the first work to come from the CERN Intersecting Storage Rings (ISR) for protons of 28 GeV energy. (The equivalent energy of a machine where the protons strike a stationary proton target in the laboratory would be more than 1,600 GeV.) The two-body elastic scattering reaction $pp \rightarrow pp$ is well known to have a differential cross-section in the forward direction given by $d\sigma/dt \sim e^{Bt}$. Work on the intersecting storage rings shows that B seems to be continuing to increase up to the highest energies ($B \sim 12$ (GeV/c)$^{-2}$ at the equivalent momentum in the static target case $\sim$ 1,600 GeV/c). This implies that the pp diffraction pattern is continuing to shrink, although greater accuracy in determining B is necessary to establish whether or not the rate of shrinkage with energy is decreasing to zero as energy tends to infinity.

The importance of detailed experimental data on differential cross-sections, polarization and asymmetries in strong interaction production processes was stressed by Dr G. L. Kane (Rutherford High Energy Laboratory, Didcot) in talking about the Regge and duality models of high energy collisions. Some experimental work, particularly in relation to pion interactions with polarized targets, has been done, but it seems that more detail is needed to satisfy the theorists and the insatiable appetites of their computers to sort out the theoretical aspects. In this connexion, a plea was made for experimental work both above and below 5 GeV for data on pion–nucleon reactions leading to elastic $d\sigma/dt$, and on polarization effects in and charge-exchange scattering, and also for a study of polarization effects in strange particle production.

Electromagnetic interactions and hadron production in photon and electron interactions were discussed by Professor R. E. Taylor (Stanford Linear Accelerator Center and CERN) and Professor G. Salvini (Frascati and University of Rome). Professor Taylor described a series of elegant scattering experiments from SLAC on elastic and inelastic scattering of electrons from all types of nuclei ranging from protons to gold, from which there are indications that nuclei exhibit no Glauber shadowing effect of the type observed for the strongly interacting particles. This may prove to contradict some earlier work on the nature of photons, in which the total photoabsorption cross-section of nuclei was measured and the results of which indicated that photons exhibited at least some partial shadowing effects in heavy nuclei. Further work is clearly required to clear up this possible anomaly from these two types of experiment. Professor Salvini was especially concerned with the experiments carried out on the electron storage rings, and in particular, those from the Frascati machine "Adone". It is impressive how such a machine works to give new and "clean" data on a variety of processes which would not be so readily interpretable or, in some cases, would not even be studied if the interaction had taken place between an electron and a proton. In the case of testing quantum electrodynamics (QED) over ever smaller distances, the deviation from the Coulomb law ($\sim 1/r$) can be written in the form $1/r[1 \pm \exp(-kr/\hbar)]$ and the lower limit on k is now 6 GeV from Frascati $e^+ e^-$ data. In boson pair production the pion form factor seems to be steadily decreasing up to the highest q^2 studied, and in the fermi pairs $p\bar{p}$, the proton form factor limit is ~ 0.02 that predicted from Dirac theory.

Professor D. H. Wilkinson (University of Oxford) gave an account of β-decay data which threaten the idea of the charge independence of nuclear forces. According to the last mentioned concept isobaric nuclei have states which, apart from the interchange of protons and neutrons, have wave functions that are otherwise identical. Thus, for example, ^{12}B and ^{12}N may be regarded as mirror nuclei and the β decays of these two to ^{12}C should be closely related. The ratio of the probabilities of the β transitions from ^{12}B and ^{12}N in fact differ slightly but significantly from that prescribed by charge independence. There are reasons to expect residual differences between the decays of members of an isobaric multiplet, but the largest of these, the so-called binding energy effect, is nowhere near large enough to explain the observed difference. Nor is the ^{12}B–^{12}N example alone. Roughly speaking, the average observed effect in p-shell nuclei is some three times larger than the average which could be theoretically accounted for.

Egg Transfer in Domestic Animals

L. E. A. ROWSON
ARC Unit of Reproductive Physiology and Biochemistry, University of Cambridge, 307 Huntingdon Road, Cambridge

This article is based on the Hammond Memorial Lecture which Mr Rowson delivered in December 1970 and reviews some of the present trends in egg transfer in domestic animals.

ALTHOUGH the first successful experiments on egg transfer were carried out by Walter Heape of Cambridge late in the nineteenth century, the technique was almost totally disregarded both as a method of livestock improvement and as a tool for reproductive research until after the Second World War. When one considers the enormous value of the technique in genetics and studies on reproductive physiology, this fact is quite astonishing. Egg transfer is, however, now used as a routine technique for research in many small mammals and during the past ten or fifteen years has been extensively used for studies in the larger domestic species, particularly the sheep, goat, pig and cow. In the polytocous species such as the small mammals and even the pig, it is not normally necessary to induce superovulation in order to provide the requisite number of eggs for experimentation but in most of the domestic species this is an important requirement.

Superovulation

Two chief sources of gonadotrophins have been used. In the small mammals and in some of the earlier work on the domestic species, gonadotrophins of pituitary origin were extensively used and were obtained either from the horse, pig or sheep. Their use in the larger animals was, however, rather expensive and to obtain optimum results it was usually necessary to give repeated injections during the follicular phase of the cycle. The alternative source, gonadotrophins obtained from the serum of mares pregnant between 50 and 80 days (PMSG), is readily obtainable more cheaply and is effective when administered as a single injection. The follicular response to such gonadotrophins was consistently satisfactory but the ovulatory response often left a great deal to be desired. Many animals developed large numbers of follicles of which either only a few or none at all ovulated and this phenomenon seemed to vary with differing batches of PMSG; some induced both follicular response and ovulation very efficiently but others induced only the first of these. This problem has not yet been completely solved, but it is beginning to look as though the ratio of the two components of PMSG (that is, the follicle stimulating hormone (FSH) and the luteinizing hormone (LH)) may be important. It is well known that a proportion of both cattle and sheep injected with PMSG do not exhibit oestrus at the expected time or, even if they do, the eggs are in some cases unfertilized. It has also been clear for several years that the injection of such gonadotrophins may cause the premature ovulation of a follicle which is present in the ovary at the time of injection and it seems likely that this effect is related to the LH content of the injected gonadotrophin. In such circumstances either the animal would not exhibit oestrus or the effect of the FSH component would cause sufficient follicular response for oestrus to occur but the progesterone secreted by the newly ovulated follicle might adversely affect fertilization. This effect could be explained in a number of ways, including failure of capacitation or failure of sperm transport to the site of fertilization. It is quite common in these conditions to find an absence of spermatozoa in the zona pellucida of the ovulated eggs.

Once a satisfactory batch of PMSG has been identified, however, it is very efficient, provided that the animal is not overstimulated. In the cow and sheep, for example, it is inadvisable to stimulate the animal to produce more than about twenty ovulations because stimulation beyond this point seems to upset completely the physiological mechanisms of the reproductive tract and the proportion of unfertilized eggs increases rapidly. It is usual, therefore, to aim at an ovulation rate of about ten eggs per animal in these species. The response also varies from species to species; for example, a dose of 1,200 IU of PMSG given to a medium to large sheep will produce a response similar to a dose of 2,000 IU given to a cow weighing six or seven times as much. In most species it is unnecessary to give exogenous LH to obtain ovulation if normal oestrus is exhibited.

Recovery of Eggs

To obtain optimum results after egg transfer it is necessary to transfer the egg to a site where it would be expected to be in normal physiological conditions; because transfer to the uterus is simpler than transfer to the oviduct, it is usual to attempt to recover the eggs at a time when they have entered or are just about to enter the uterus. The timing of this will vary with the species, but is usually 4 to 5 days from the onset of oestrus in the cow and sheep and rather earlier for the pig. A surgical approach is necessary if maximum recovery of egg is to be achieved. This involves a simple laparotomy; the introduction of a fine cannula into the ovarian end of the oviduct and the injection of the flushing fluid into the ovarian portion of the uterus. The eggs are collected in special cups which can be placed directly under the microscope without further manipulation; the state of cleavage of the recovered eggs can then be identified. In the horse and pig there is a valve-like structure at the utero-tubal junction and it is not always possible to carry out retrograde flushing; in such cases it is usual to clamp off the top portion of the uterus, flush the oviduct towards the clamp and insert the recovery tube in the tip of the uterus, so that the fluid containing the eggs can be milked back into the collecting cup. Although this technique seems rather crude, egg recovery is as efficient as recovery by the direct flushing method. About 90% of the eggs shed can usually be collected. The most effective flushing medium varies with the species—for the sheep it is homologous serum, for the pig Tyrode plus a little albumen and for the cow TCM 199.

Transfer and Synchronization

The technique of egg transfer is simple—the egg is merely picked up in the medium selected, using a Pasteur pipette attached to a 2 ml. syringe, and the tip of the pipette stabbed through the uterine wall; the egg is then expelled directly into the lumen. A minimum of flushing medium is used, seldom more than 0.1 ml.

The stage of the cycle of the donor and recipient animals must be closely synchronized to obtain optimum pregnancy rates. The degree of variability which can be tolerated is known to be ±2 days in the sheep and ±1 day in the cow; the best results are obtained, however, when oestrus in donor and recipient occurs on the same day (Fig. 1).

The results obtained in cases of exact synchronization are remarkably good and are possibly influenced by the fact that any unfertilized, abnormal or retarded eggs are rejected and not transferred after egg recovery from the donor animal.

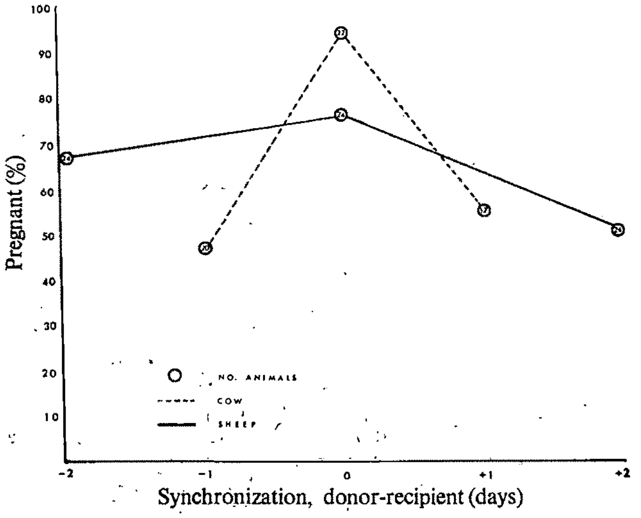

Fig. 1 The effect of varying the degree of synchronization of oestrus on fertility in cattle (———) and sheep (- - -). Numbers of animals are given in the figure.

If the eggs are to be transferred on the day of recovery it is quite satisfactory to store them in the flushing medium in an incubator at 37° C. Sheep pregnancies have been achieved successfully after up to 72 h of storage at 8° C, but the percentage of successful transfers decreases rapidly after 24 h. It has also been shown that the transfer of fertilized eggs of the pig, cow and sheep to the oviduct of the rabbit will result in their continued normal development for longer periods; they can then be recovered and successfully retransferred to suitable recipients. This shows that the requirements for culture of eggs of these species are not very specific and augurs well for *in vitro* culture of such eggs. The use of the rabbit as an incubator would permit the export of large numbers of eggs, for example, of cattle at very little cost, to various parts of the world. The transfer of such eggs after prolonged storage in the rabbit does, however, mean that development of the conceptus will only take place to a certain stage, after which it dies; the membranes are eventually expelled or resorbed. The ultimate solution to the problem of egg storage will lie in deep freezing.

Non-surgical Transfer

Most of the successful work carried out on egg transfer involves a laparotomy and the surgical recovery and transfer of the egg. Access to the uterus of the cow by way of the cervix is quite easy, but attempts to obtain pregnancies after the transfer of eggs in this way have been very disappointing. There are two reasons for this. First, the luteal phase uterus of the cow is very susceptible to infection and the introduction of any organism—very likely when the non-surgical approach is used—will cause pyometritis. Second, the insertion of a catheter, which might be used to introduce the egg, has a stimulating effect on the cervix and uterus so that uterine contractility is enhanced; eggs deposited in this way are frequently expelled and are found in the vagina within a few hours of their deposition. This effect is believed to be caused by the release of oxytocin from the pituitary as a result of the cervical and uterine stimulation, but we have so far been unable to confirm this. We are endeavouring to find an explanation of this phenomenon and to find ways in which the problem of egg expulsion can be overcome.

Reproductive Physiology

The technique of egg transfer has been used in the large domestic animals to study various fundamental and applied problems of reproductive physiology. One of the most interesting aspects has been the use of egg transfer in experiments on utero-ovarian-embryo relationships. The factors concerned with the initiation and formation of the cyclical corpus luteum are well known, but those associated with regression are far less clearly understood.

The uterus is known to be closely involved in the process because hysterectomy in the domestic animal results in persistence of the corpus luteum for prolonged periods and grafting of the removed endometrium between the flank muscles will restore cyclical behaviour and normal corpus luteum regression. The question which arises, therefore, is how the embryo overcomes the normal regression; it would seem from the repeated injection of embryo homogenates into the uterus that it acts in an anti-luteolytic manner. In an attempt to establish at what stage the presence of the embryo within the uterus is essential to prevent corpus luteum regression, eggs have been transferred at later and later stages until it is no longer possible to maintain the corpus luteum as one of pregnancy. In the sheep with a 16 to 17 day cycle the embryo must be present within the uterus by day 12½, otherwise regression cannot be prevented. Similar requirements have not been worked out in detail for other domestic animals, but there are indications that a relatively earlier presence of the embryo within the uterus is necessary in the cow and pig.

There is a remarkable unilateral utero-embryo-ovarian relationship in the cow and the sheep, which has been demonstrated by the use of egg transfer. If, for example, an egg is confined to the uterine horn adjoining the corpus luteum, the pregnancy continues normally; but if a similar egg is confined to the contralateral horn, pregnancy never occurs and the corpus luteum of the non-pregnant side regresses normally. This can be shown to be a unilateral luteolytic effect by removal of the non-pregnant horn adjoining the corpus luteum; the pregnancy will then continue normally. The situation is slightly modified in the case of the pig, for if a similar situation is created by confining embryos to one uterine horn, the lytic effect of the non-pregnant side will eventually result in regression of both sets of corpora lutea. The unilateral nature of these effects would suggest that it is the uterus itself rather than an indirect effect through some other gland which is responsible for lysis. It has been recently shown that radioactive material within the uterine vein is present in higher concentration in the ovarian artery, which runs in close apposition to it, than in other parts of the circulation; this suggests some form of direct transfer or communication between vein and artery although this has not been demonstrated anatomically and would involve a blood flow against the normal pressure differences.

Maturation and Culture

For the study of maturation and *in vitro* fertilization and for the satisfactory culture of eggs, laboratory techniques can only be a guide and it eventually becomes necessary to transfer eggs treated in this way to assess viability and the continuation of normal development. In experiments to assess the fertility of frozen semen it is often convenient to use the two oviducts separately, one as a control, to be injected with normal semen, and the other as a receiver for the experimental sample. Eggs transferred to each oviduct can then be examined and compared. The possibility of using the oviduct connected by fine tubes leading to the exterior as an *in vivo* means of fertilizing follicular eggs, both within and between species, is being investigated.

The demonstration that excellent pregnancy rates after transfer could be achieved with TCM 199 as a storage and flushing medium for cow eggs was followed by an attempt to increase production in this species by the introduction of two eggs into one uterine horn to produce twins. The first experiments were disappointing and only 12.5% produced twins. It was later found that when the two eggs were both deposited in a single uterine horn, migration of one egg did not occur and both implanted on the side; there was consequent competition for nutrients and death of one of the embryos frequently occurred. One egg was deposited in each horn during later experiments and a twinning rate of 73% was obtained. The economic implications of this finding are obvious and a vigorous attempt is being made to solve the problem of the reduced pregnancy rate obtained by non-surgical transfer of eggs so that the twinning technique can be put into practice.

Chimaerism in Cattle

Fusion of the foetal membranes occurs very early in pregnancy in many cattle twins and there is an interchange of haemopoietic and other types of cell between the embryos. The testes cells of the male in mixed sex twins contain many of the *XX* variety, but it is not yet established whether germ cells of this type continue through to actual spermatozoa. It seems likely that such a situation would occur in the case of chimaeric male calves. If so, it would mean that a proportion of the offspring of one twin may genetically be by the brother and this could seriously interfere with the accuracy of progeny tests, in which such bulls are used for artificial insemination. The percentage of twins born is not high (usually about 2 to 3%), but from our earlier experiments it was obvious that one of a pair present within a single horn frequently died by day 60 of gestation; as fusion of membranes occurs well before this stage, the fact that a cow has a single calf does not, therefore, mean that it did not start life originally as a twin. Twin ovulations have been estimated to be as high as 11% in the cow by some workers.

Our experiments on twinning open up a simple method of determining whether one twin can sire his brother's offspring. We have been able to transfer the egg of one breed of cattle to one uterine horn and that of a different breed to the other, using breeds which would colour mark their offspring. The use of such twins to inseminate a fairly large number of females should establish with certainty whether the interchanged germ cells of the chimaeras are capable of carrying through spermatogenesis. The use of similar sets of females will also be of interest because one can determine if the mixture of blood types has any effect on milk production and quality by producing twins of widely differing production characteristics such as the Jersey and Friesian. Such chimaeras are also tissue tolerant, so it should also be possible reciprocally to interchange half of the udder and to study milk production at the cellular level with the blood supply remaining constant.

Larger Litters

Transplantation has been used quite extensively to investigate the possibility of increasing the litter size, particularly of the sheep and to some extent of the pig.

Initial experiments involving the transfer of either two or five eggs to recipient sheep indicated that the uterus had a severely limiting effect on the number of offspring which would continue development and it became obvious that the problem was not solely one of availability of sufficient eggs. Lawson has recently investigated this problem in breeds of sheep of normally high, medium and low fertility, by the transfer of five eggs from a common genetic source to each group. At the time of transfer the potential fertility of each group was obtained by counting the number of corpora lutea (indicating the number of eggs shed). This work showed that the high and medium fertility breeds were producing eggs at almost their maximum potential, but that the uterus of the low fertility breed was capable of carrying about twice the maximum number assessed by corpora lutea counts. The last of these is the chief breed of sheep in New Zealand and clearly selection on the basis of high ovulation is necessary if litter sizes are to be increased. Although the litter size of the pig can be increased to some extent, the same uterine limitations apply as described previously for the cow and sheep.

Selection for an overall increase in litter size does, therefore, involve many factors, and in the cow and sheep, for example, there are great variations in cotyledon numbers; these are obviously of importance in multiple births and an examination of their inheritance would be worthwhile. This can only be done at slaughter and would, therefore, require superovulation and removal of fertilized eggs from such animals so that they could be transferred to recipients if a high cotyledon count was found.

Identical Twins

Although identical twins are rarely produced by domestic animals, they are invaluable for research and the possibility of producing them artificially has been enhanced by work on small mammals and the pig. It has been shown that the removal of all but one blastomere of even a four or eight-cell egg can result in normal offspring after the transfer of that egg to a suitable recipient. In principle, therefore, the transfer of removed blastocysts to emptied zonae could lead to the production of identical offspring, but a number of problems have arisen, the chief one being that the blastomere injected into the new zona is very liable to be exuded through the crack made at the time of injection. Attempts are being made to overcome this loss by temporary transfer of such eggs to the rabbit oviduct which coats them with a layer of mucin (Fig. 2); these experiments are still in progress. An alternative approach which seems to be successful in the small mammals is to divide the blastocyst and then to culture the two halves before transfer until they become spherical again. Attempts to use this technique have not yet been made in the domestic animals.

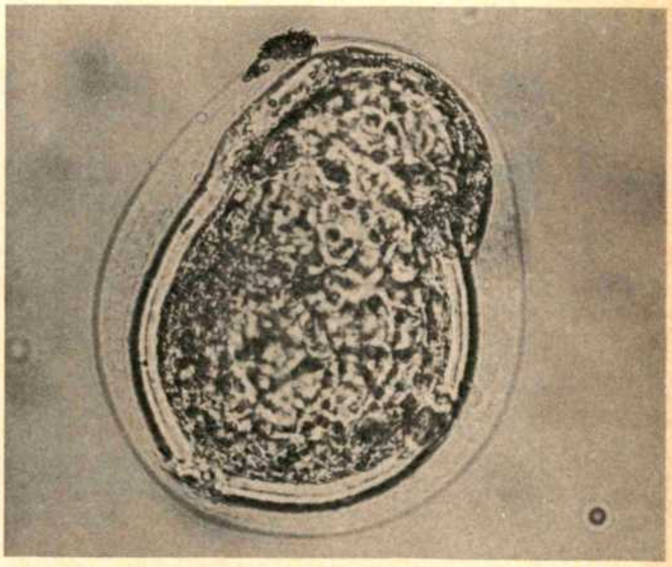

Fig. 2 A sheep blastocyst injected with cells (lower left) when at the eight cell stage and transferred to the rabbit oviduct to become sealed with a mucin coat.

It is clear that the value of egg transfer has only relatively recently been fully realized and there is little doubt that it will be extensively used as a tool for research in reproductive physiology in the future.

Global Atmospheric Research Programme

B. J. MASON
Meteorological Office, Bracknell

This worldwide programme is making a contribution to the numerical simulation and prediction of the global atmosphere.

THE Global Atmospheric Research Programme (GARP) together with the closely associated operational World Weather Watch (WWW) constitutes an ambitious, long term, international programme involving practically all the countries of the world. It aims at improving knowledge and understanding of the global circulation of the atmosphere, the physical basis of weather and climate and the production of weather forecasts of greater reliability and range. The conception of such a programme was fostered by two major developments. First, there were advances in the science of meteorology making the subject that was once largely descriptive and empirical steadily more quantitative and firmly based on the disciplines of experimental physics and fluid dynamics, largely through the development of physico-mathematical models to simulate and predict atmospheric motions. Second, there was the introduction of artificial Earth satellites with their potential for observing the global atmosphere and for providing rapid worldwide communications. The programme is being sponsored jointly by the World Meteorological Organization and the International Council of Scientific Unions, and so involves both government organizations and the academic community.

Objectives of GARP

The objectives of GARP centre chiefly on the improved understanding of the physical and dynamical processes that determine the global circulation of the atmosphere up to heights of 30 km. This includes both the statistical properties which should lead to a better understanding of the physical basis of climate, and the transient behaviour as manifest in the large scale fluctuations which control changes of weather. This implies three requirements. First, the formulation of improved physico-mathematical models of the global atmosphere. Second, the design and implementation of an optimum global observing system that will supply the input data for the theoretical models. Last, provision of adequate facilities, including the most powerful computers, to process the observational data and to test the adequacy of existing models for describing the global circulation and determining its predictability, thus providing a sound scientific basis for longer range weather forecasts and a rational basis for the design and implementation of a fully operational global observing system.

Before describing the aims and plans for GARP in more detail, it seems appropriate to review the present status of numerical modelling of the global circulation, of numerical weather prediction, and of the global observational system on which GARP programmes will have to build.

Numerical Simulation

During the past decade, the traditional, empirical and subjective methods of forecasting the evolution of weather systems for one to three days ahead have gradually given way to objective mathematical predictions based on a firm structure of physical theory that treats the atmosphere as a vast compressible fluid with energy sources and sinks. The theory is based on the physical principles of conservation of momentum, mass and energy, on the Newtonian (Navier-Stokes) equations of motion applied to a parcel of air, the first law of thermodynamics, and the equation of state of a gas.

The behaviour of a dry atmosphere containing no water substance may be described by a set of six differential equations involving six dependent variables—the three components of the wind, the pressure, density and temperature of the air, all expressed as functions of space and time. Starting from a given initial situation and specified boundary conditions, the problem is to solve a system of simultaneous non-linear partial differential equations in three spatial dimensions with time as the fourth independent variable. In fact, the equations are formulated in such a manner that they allow the time variations of the above quantities to be determined from their spatial variations. Thus, in principle, if we can observe the initial values of all six variables at a network of discrete points filling the entire or a large part of the atmosphere, we can compute the initial time rate-of-change of each variable from the governing equations and then extrapolate over a short time interval to find a predicted value at each point in the network. Repeating this process step by step, we can build up a forecast of the fields of pressure, wind, temperature and so on.

In practice, the meteorologist measures the horizontal winds (by tracking balloons with radar), the atmospheric pressure and temperature, but not the vertical component of the air motion since this is usually too small to measure directly although of the greatest importance in controlling cloud and rain forming processes. To overcome this difficulty and, at the same time, eliminate the density of the air as a variable from the equations, we use pressure rather than height as the vertical coordinate, regard this as an independent variable and introduce, as a dependent variable, the contour height, which is the height of a constant pressure (isobaric) surface. Maps of contour heights are very similar in configuration and in their relation to the winds to maps of the corresponding pressure fields. The thermal structure of the atmosphere is described in terms of the thickness of the layers between isobaric surfaces, the thickness being proportional to the average temperature of the layer. In this system the vertical velocity of the air is represented by the rate of change of atmospheric pressure, and is defined entirely by the horizontal wind field.

So far we have considered only a dry atmosphere. To include the effects of evaporation, condensation and precipitation of water we have to add equations for the continuity of moisture and modify the energy equation to include the latent heat released by condensation. Such a model is being developed in the Meteorological Office by Bushby *et al.*[1,2] to simulate the behaviour of a moist atmosphere on a finer scale than in any current operational prediction model. Observed fields of pressure, temperature, wind and humidity derived from radiosonde ascents are being used to study the dynamics of individual depressions and fronts and to make quantitative predictions of their rainfall for periods of up to 48 h ahead. Computations are made over an area of 6,500 × 5,000 km centred on the British Isles and covering most of Europe with over 12,000 grid points spaced only 50 km apart with each dependent variable being computed at alternate grid points and for ten vertical levels between 1,000 mbar and 100 mbar. The computations include the heights of these pressure surfaces, the mean temperatures of the nine layers, the horizontal and vertical components of the wind and the humidity and condensed water at the seven levels below 300 mbar above which the atmosphere is assumed to be dry. The model makes allowance for the effects of topography (for example, the Alps, Welsh, Scottish and Scandinavian mountains), for the frictional drag of the land and sea on the air, for horizontal eddy diffusion, and some adjustments are made to the vertical thermodynamic stability to cater for the influence of convective clouds that are smaller than the grid length. (The simulation of these sub-grid scale and boundary layer phenomena is described in more detail later.)

Preservation of computational stability requires the equations to be integrated in time steps of only 90 s so that a forecast for 24 h ahead involving about 10^{10} numerical operations takes 11 h on the ATLAS computer, but will only take 0.5 h on the IBM 360/195 machine which the Office will acquire later this year.

The results obtained so far from a limited number of experimental forecasts encourage us to believe that the Meteorological Office should soon be able to issue these quantitative and quite detailed forecasts of rainfall on a daily basis after the new computer becomes operational.

Meanwhile, much simpler models having a horizontal resolution of only 200–400 km and only three to six levels in the vertical, and which do not attempt quantitative prediction of rainfall, have been used for several years in several countries to make twice-daily predictions of the broad features of the pressure (contour height), temperature (thickness) and wind fields, the position and evolution of synoptic-scale systems such as depressions and anticyclones, for up to three days ahead, and for the greater part of the northern hemisphere. They have produced significant improvements in the prediction of the contour, thermal and wind fields at aircraft levels, and although improvements may not be so evident in the forecasts of surface conditions where the complex boundary layer processes are much more important, the computer products have introduced a greater degree of continuity, consistency and confidence in the weather forecast, especially in the outlooks for the second and third days, than was possible with the traditional subjective methods.

Experience gained both in the Meteorological Office and by the United States Weather Service from partly numerical and partly empirical methods of forecasting for five to seven days ahead suggests that there should be no inherent difficulty in predicting numerically the behaviour of synoptic-scale systems for at least one week given adequate observations to define the initial state. Accordingly, the Meteorological Office is now adapting the ten level model described here to an octagonal grid centred on the north pole and covering the northern hemisphere with a grid length of about 150 km, and plans to use this to make predictions for five to seven days ahead with the aid of the new computer.

In assessing the possibilities of forecasting for even longer periods, it is necessary to recognize the limitations likely to be imposed by the intrinsic indeterminism of atmospheric behaviour, as well as by those of the initial observations and the defects of the models. The promise and simultaneously the limitations of our present observations and models are demonstrated by recent long term integrations on sophisticated hemispheric models carried out by Smagorinsky *et al.*[3] in the United States and by Corby *et al.*[4,5] at the Meteorological Office. Both models incorporate the effects of radiative heating and cooling, the release of latent heat by condensation, the transfer of heat and moisture by advection, convection and turbulent diffusion from the underlying land and ocean surfaces, the effects of topography and surface friction, and the consequences of thermal contrasts between land, sea and ice surfaces.

Smagorinsky *et al.*, using a nine-level model, carried out two predictions for up to fourteen days. The movements of the planetary long waves, only five or six of which girdle the hemisphere, were generally successfully forecast, with a close correspondence between the forecast and observed positions of the main troughs and ridges, especially at the 500 mbar level where the correlation coefficients between the two sets of patterns remained above 0.5 for thirteen days from the initial time in one case, and for nine days in the other. In general the predicted contour patterns were too smooth in the middle scale so that the intensities of the depressions and anticyclones were underestimated while the strength of the tropospheric westerlies was overestimated. The forecast temperatures were too low, and the forecast rainfall too high, especially in the tropics. In spite of these defects, these first attempts at two week predictions from real but often inadequate initial data must be regarded as a major scientific achievement, particularly as the model was able to predict the birth of some second and even third-generation extra-tropical cyclones.

Furthermore, the group at the Meteorological Office has

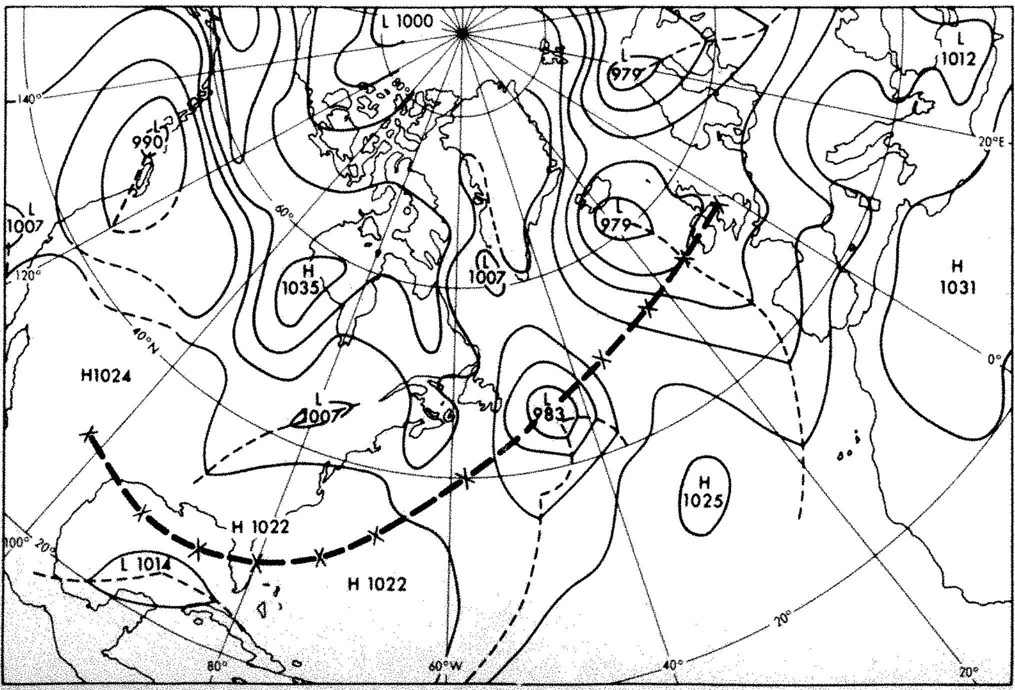

Fig. 1 The mean sea level pressure as predicted by the Meteorological Office model of the global atmosphere for the thirty-seventh day after the start of the integration. The heavy dashed line shows the track of a depression between day 30 and day 40, the crosses marking the predicted positions of its centre on successive days.

integrated a five-level model for up to sixty-five days and finds that once it has overcome the initial reluctance to generate sufficient eddy kinetic energy (a fault shared by most models, perhaps because of inadequate spatial resolution), it continues to generate new and very realistic cyclones every few days for several weeks. The detailed three-dimensional structures of cyclones produced by the model after thirty days are remarkably realistic, as illustrated in Figs. 1 and 2, with Fig. 2 showing the temperature, wind and humidity distributions within a cyclone seven days after its birth on day 30. These computations suggest that the behaviour of the atmosphere on the synoptic and larger scales may be determinate, in principle, on the time scale of at least two weeks and probably longer.

The extent to which these hopes will be realized in practice will largely depend on the solution of a number of scientific and technical problems. The first is connected with the formulation of much more realistic and detailed models of the global atmosphere and the second with a much improved global coverage of observations, especially over oceanic and tropical regions to allow adequate description of the initial mass, motion and moisture fields that provide the starting point for the numerical integrations. Last, there is a need for much more powerful computers than are currently available. These requirements largely define the objectives of GARP.

Problems in Numerical Simulation

I shall now consider some of the major deficiencies and difficulties encountered in building numerical models of the global circulation of the atmosphere. The basic problem is to formulate realistic physico-mathematical models that will adequately represent the complex physical and dynamical processes that are likely to control developments on the appropriate space and time scales. In other words, the model must properly represent the relevant or significant scales of motion and their non-linear interactions but smooth (or filter) out all the individual smaller scale motions that may introduce "noise" into the system while allowing for their overall contribution to transport and energy conversion processes by methods of statistical averaging.

In practice, the size of the smallest systems that can be individually represented in a model is limited by the spatial density of the initial observations and by the available computer power, both of which influence the design and resolution of the computational grid. Most current numerical models suffer from inadequate spatial resolution and are unable to represent adequately the meso-scale and smaller scale systems that may contribute materially to the production of eddy kinetic energy. On a deeper level, the model can accommodate explicitly only those phenomena that are adequately represented by the basic hydrodynamic and thermodynamic equations, that is, systems large enough to be strongly influenced by the Earth's rotation and to obey the hydrostatic equation. Thus in the numerical simulation of synoptic-scale and larger scale motions, many smaller scale phenomena have to be parameterized preferably in terms of observable, large scale dependent variables. These phenomena include: molecular-scale processes, such as radiative transfer as a function of the larger scale distributions of CO_2 O_3, water vapour, cloud and aerosol particles; micro-scale processes, such as turbulent exchanges of heat, momentum and water vapour in the planetary boundary layer, internal turbulent diffusion and dissipation, and convective transports; meso-scale phenomena, such as frontal circulations, orographic disturbances, and deep convective systems that are especially important in the tropics. GARP identifies three principal areas in which mechanisms operating primarily on the meso-scales

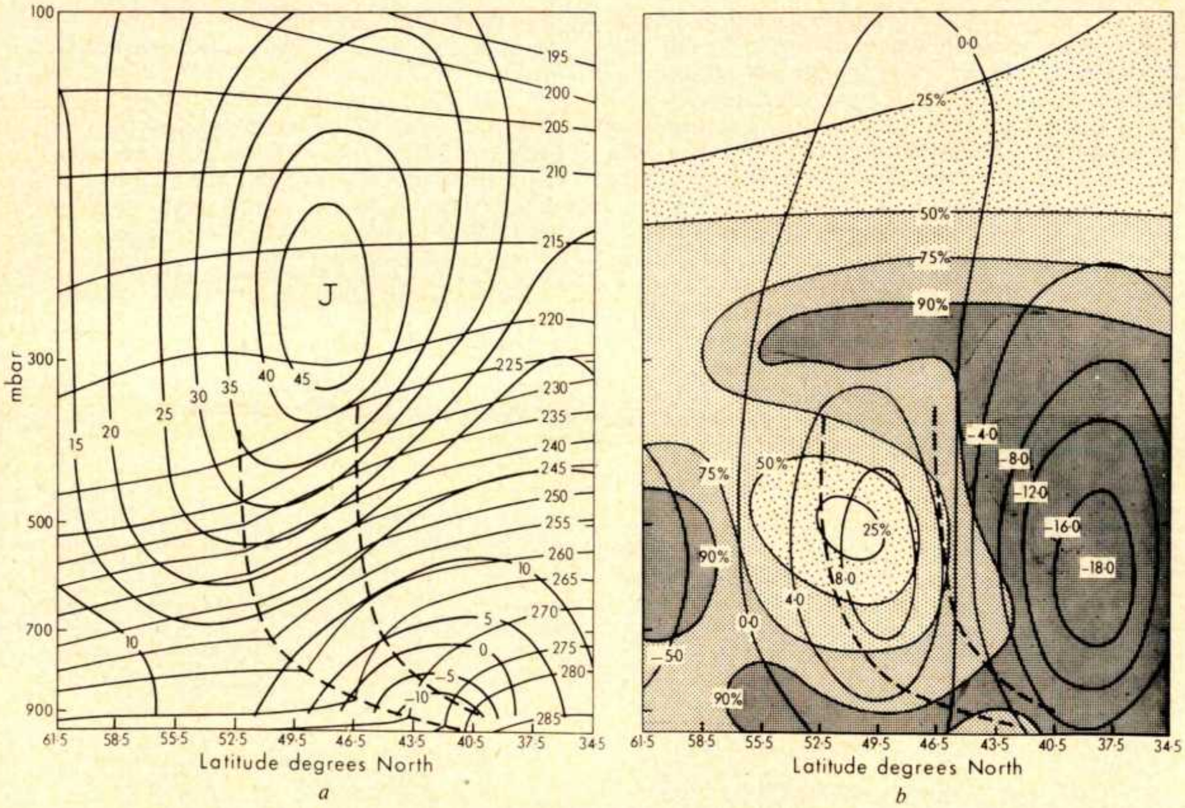

Fig. 2 *a*, Vertical cross-section of the atmosphere at 55° W for day 36 showing the predicted distributions of temperature and zonal wind near the warm front of the depression referred to in Fig. 1. A jet stream with winds exceeding 45 m s^{-1} ($\sim$90 knots) at about 250 mbar ($\sim$35,000 feet) is marked J. The wind is plotted at intervals of 5 m s^{-1} and the temperature at 5 K intervals. *b*, The same cross-section as in *a* but showing the distribution of vertical motion (negative values indicate upward motion, positive values downward motion) at intervals of 4 mbar h^{-1}, and of percentage relative humidity. There is a deep mass of rising moist air ahead of the frontal zone (shown dashed) with a region of subsiding dry air ahead of the front at middle levels but surmounted by moister air at high levels simulating the spread of high cloud ahead of the front.

and smaller scales (that is, < 500 km) are probably of vital importance in the energetics of the global atmospheric circulation. These concern: the evolution of convective cloud systems in the tropics; the turbulent exchange of heat, momentum and water vapour between the ocean surface and the overlying atmosphere; and the study of similar transfer processes in the atmospheric boundary layer over land.

Studies of Tropical Convection

All three areas mentioned above combine to be of major importance in the tropics where the large scale circulations, for example, the easterly trade-wind intertropical convergence zone (ITCZ) circulation, are maintained primarily by the release of latent heat of condensation in deep, moist, convective systems on a range of scales below 1,000 km.

Pictures from satellites reveal that over the tropical oceans cumulus and cumulonimbus clouds, individually 1–10 km across, tend to group into meso-scale convective units up to 100 km in diameter and that these, in turn, form "cloud clusters" of 100–1,000 km diameter that are generally associated with the troughs of lower-troposphere wave disturbances of characteristic wavelength 2,000–10,000 km, or with the ITCZ. It is likely that the latent heat released by cumulus convection in the ITCZ drives the trade-winds, while frictionally induced convergence in the trade-wind boundary layer feeds the cumulus convection in the ITCZ.

The task, then, is to study the genesis, growth, structure, size, organization and life cycle of the deep convective cloud systems, their interaction with the meso-scale circulation patterns in the rain areas, to determine the magnitudes of the energy-conversion processes and the associated fluxes of heat, moisture and momentum, all in relation to such factors as convergence/divergence, vertical motion, lapse rate and humidity distribution of the immediate environment, the sea-surface temperature, and the properties of the synoptic and large scale flows.

This will be the chief objective of the GARP tropical experiment planned for 1974 in the eastern Atlantic, where the structure of cloud clusters will be investigated by soundings from an array of twenty to thirty research ships in a 1,000 × 1,000 km square, by several fully instrumented research aircraft and observed by a geostationary satellite over the area, all in relation to the large scale flow as determined by wind soundings over an area stretching from the west coast of South America to Ethiopia. The whole operation, in which the United States, USSR, United Kingdom, Germany, France and Canada are expected to be the principal participants, will be planned and executed as a fully integrated international experiment under the leadership of an international team of scientists recruited specially for the task and which will work together for several years at the Meteorological Office in Bracknell.

Transport Processes in Boundary Layer

Examples of energy transfer between the ocean and the atmosphere occur when cold continental air flows over a warm ocean and during the formation of trade-wind cumuli over large areas of the tropical oceans. Energy in the form of sensible and latent heat, and moisture, are transported across the interface. These fluxes, which may be relatively uniform at the surface, become strongly concentrated higher up in cumulus towers which, in turn, may emit sufficient radiation to have appreciable influence on the large scale dynamics. Mechanical processes transport momentum into the sea surface at a rate dependent on the lapse rate of temperature and on the sea-surface roughness, but in turn affecting both of these. These processes are all much smaller in scale than the resolution of the grids of current numerical models, but it is evident that in altering the lapse rate and adding moisture and so on they influence the large scale motions in a way that cannot be determined explicitly by the prediction scheme but must nevertheless be represented in a manner that makes physical sense. The land surface exerts a drag on the atmosphere and therefore acts as an energy sink. Again the dynamics of the motions in the boundary layer is very different from that expressed by the model equations for the large scale flow.

Thus, to evaluate the role of turbulent transfer processes in the planetary boundary layer, it will be necessary to establish the size and magnitude of the fluxes of sensible and latent heat, momentum and moisture, in relation to measurable parameters of the temperature, wind and humidity fields and the characteristics of the underlying surface. Again this is difficult, not only because of the obvious problem of logistics, instrumentation and representativeness of the measurements over complex terrain but because we have yet to discover unique relationships between the fluxes, the turbulent kinetic energy balance and measurable properties of the large scale flow that apply throughout the whole depth of the boundary layer and hold in conditions ranging from the stably stratified to the strongly convective.

The difficulties of observing and understanding these meso-scale and small scale processes in sufficient detail to permit their satisfactory parameterization and incorporation in numerical models are likely to present the largest obstacle to understanding and predicting the evolution of major weather systems during the next two or three decades. The properties of the large scale flow are both easier to observe and to represent in numerical models. Accordingly, GARP should give priority to detailed studies of the meso-scale phenomena which are likely to prove intellectually and logistically more intractable than the synoptic and planetary scale systems.

Computer Requirements

If we learn to incorporate these various sub-grid scale phenomena into the numerical models without destroying their stability, we may hope to represent and predict the important synoptic and larger scale developments with a global model based on a horizontal grid length of 1° (110 km at the equator), having, say, twenty levels in the vertical and eight dependent variables (for example, winds, temperature, humidity, precipitation, radiative flux). For an integration carried out in 150 s time steps, the model would require the calculation of 4×10^9 variables or about 2×10^{12} computer operations per simulated day. Thus completion of the calculation in 0.5 h would require a computer capable of handling about 10^9 operations s^{-1}, that is, about 100 times as powerful as the IBM 360/195 or the CDC 7600. Speeds of this magnitude are likely to be achieved only by an array or matrix of central processors operating in parallel mode as envisaged in the ILLIAC IV computer, and which may become available within the next five years.

First Global Observing Year

Of crucial importance will be the acquisition of global observations adequate to define the physical state of the atmosphere at particular instants of time and so provide initial conditions for the start of the numerical integrations. At this stage it is not possible to specify precisely the minimum and optimum standards for the coverage, spatial resolution, frequency and accuracy of the observations. This will be one of the main tasks of GARP which proposes to undertake intensive observations of the global atmosphere over a period of one year—the First Global Observing Year in 1976, with a view to determining the minimum observational, data collection, and data processing facilities that will be necessary to meet the objectives listed above and to fulfil the requirements of the fully operational phases of the World Weather Watch.

To represent and predict the atmospheric processes that will determine the essential features of the weather everywhere for a week or more ahead, it seems likely that the following observations will be necessary.

In extra-tropical latitudes there is need for vertical soundings of temperature, pressure and wind up to heights of 30 km (10 mbar) once and perhaps twice daily, with horizontal spacing of 400 km and similar soundings of humidity up to 10 km with corresponding surface parameters including sea-surface temperature.

In tropical regions there is need to measure speed of winds at the 900, 700, 400, 200 and 50 mbar levels at least once a day, temperature and humidity soundings with a horizontal spacing of 500 km with corresponding surface parameters including sea-surface temperatures and air–sea temperature differences.

As to the required accuracy of the observations, air temperatures to within 1 K, atmospheric pressures to 0.3 per cent (3 mbar at the surface), winds to within ±3 m s^{-1}, vapour pressures to within ±10 per cent, and sea-surface temperatures to within 0.25° C may prove adequate. For verification of predictions, the cloud cover should be known within ±20 per cent and precipitation intensity to within ±10 per cent. All these assumptions, however, will need to be tested, first in long term numerical simulation experiments on the computer and ultimately in predictions using real initial data.

Even these apparently modest requirements cannot be met at present, except in limited areas of the populated part of the northern hemisphere. There are large deficiencies in coverage over the oceanic and tropical regions and in most of the southern hemisphere. Moreover, it is neither economically nor logistically feasible to fill the gaps by extension of existing types of facility such as radiosonde stations, and we must look hopefully to satellites to provide global measurements of meteorological parameters by measuring the intensity, polarization, angular and spectral variation of radiation emitted and reflected by the Earth and the atmosphere. In polar orbit they have the great advantage of being able to survey the whole globe every 12 h and, if placed in Sun-synchronous orbit, stay at a set local time with respect to the Earth and so greatly facilitate the ground system for receiving and using the data on a regular schedule. A geosynchronous satellite, that is, one in equatorial orbit synchronized in period with the rotation of the Earth, remains stationary over a particular point on the equator and therefore allows a particular area to be viewed continuously. Current US satellites of this type carry cameras which scan laterally while the satellite spins about its axis and so cover about one-quarter of the Earth's surface every 20 min. They therefore provide a time lapse film showing the evolution and movement of cloud systems from which valuable information on the winds at cloud level may be deduced. Operational meteorological geostationary satellites planned by the United States for 1975 will have much improved cameras capable of producing pictures with a horizontal resolution of 1 km in the visible and 7 km in the infrared from a height of 36,000 km.

Current American and Russian polar orbiting satellites provide television pictures of cloud, snow and ice cover with a horizontal resolution of about 1 km. Scanning radiometers working in the 11 μm window take pictures by day and night with a resolution of 5–10 km from a height of about 1,000 km and determine the equivalent black-body temperatures of the surfaces to within an accuracy of perhaps 2 K. In the future, television cameras in US satellites will be replaced by high resolution scanning radiometers to give improved resolution in both the visible and infrared parts of the spectrum.

Detailed analysis and interpretation of satellite pictures have provided valuable information on the location, structure and evolution of large cloud systems and on such meso-scale features as hurricanes, thunderstorms, squall lines, jet streams and mountain waves, often from oceanic and other remote areas where the observing networks are too sparse to make their detection likely by conventional methods. A complete global daily coverage of cloud pictures will be required for GARP and might be achieved by four geosynchronous satellites equally spaced round the equator and two polar orbiting satellites both in Sun-synchronous orbits but phased 6 h apart.

Although the cloud pictures and radiation data from relatively simple radiometers currently provide a great deal of valuable information, it is mainly only qualitative in character and difficult to incorporate directly into numerical dynamical models which require data on atmosphere temperature, pressure, composition and winds. We shall now examine the possibilities of obtaining such data on a global basis for GARP by remote sensing of the atmosphere from satellites.

Remote Sensing

In contrast to the simple radiometers required for the determination of total fluxes and surface temperatures, a number of very sophisticated and ingenious spectrometers and radiometers are being developed to obtain the vertical distribution of atmospheric temperature from measurements of the spectral distribution of radiation received from constant constituents such as carbon dioxide and molecular oxygen.

Various techniques are being developed for selecting the narrow frequency intervals and measuring the radiation received in them. The NIMBUS III satellite launched by the United States in April 1969 carries an Ebert infrared spectrometer (SIRS) which uses a fixed grating to select seven narrow spectral intervals of width about 5 cm^{-1} in the 15 μm carbon dioxide band, and one interval in the 11 μm window. The satellite also carries an infrared interferometer spectrometer (IRIS), in essence a Michelson interferometer, to accomplish the same task by scanning the entire spectrum from 6 to 20 μm with a resolution of about 5 cm^{-1}.

A simpler device developed at Oxford and Reading universities and described in detail by Houghton *et al.*[6] is operating on the NIMBUS IV satellite launched in April 1970. It uses narrow-band (3.5 cm^{-1}) interference filters to select six channels in the 15 μm band and absorption cells containing carbon dioxide to filter and further select the required radiation. The equipment weighs only 10 kg and consumes only 5 W of power.

The SIRS instrument on NIMBUS III produced some excellent vertical temperature profiles, especially over the northern hemisphere in the absence of clouds. Fig. 3 shows one of these and, for comparison, the radiosonde sounding taken from Kingston, Jamaica, about 400 km to the north-west and 4 h earlier in time.

Close agreement between the two is evident, the chief differences being in the middle troposphere, where the SIRS sounding is warmer by 2 or 3 K. Most such soundings, how-

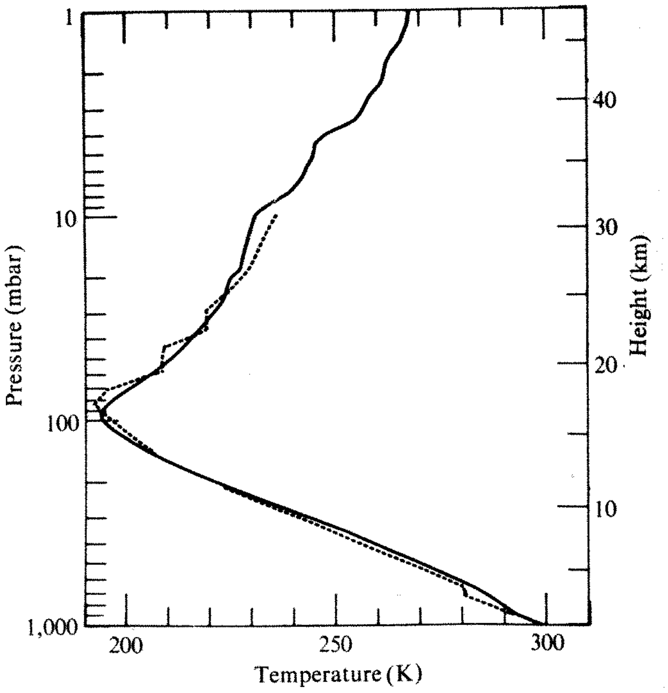

Fig. 3 Comparison of SIRS sounding with radiosonde ascent at Kingston, Jamaica, April 14, 1969. ....., Kingston, 1200 GMT ; ——, SIRS, 16° N, 73° W, 1612 GMT in clear sky conditions.

ever, require adjustment because of the presence of clouds and this is the most important hurdle to be overcome. Future sounding instruments will have a much smaller field of view, about 30 km square, and this will greatly increase the number of soundings obtained in clear air regions between cloud masses. Meanwhile the experiments on NIMBUS III and IV have demonstrated convincingly that atmospheric soundings from satellites are feasible. With further improvements in instrumentation and analysis techniques, it should be possible to produce for the first Global Observing Experiment, a global coverage of temperature data at least as good as that now being provided over only limited areas by conventional methods. In the stratosphere the satellite data are probably already more reliable than the radiosonde measurements which are subject to large instrumental errors at these levels. The cloud problem could, in principle, be solved by using microwave instead of infrared sounders but no such instruments are likely to be flown before 1976.

In principle, the methods developed for obtaining the temperature profile from measurements of radiation emitted by CO_2 (the concentration of which is known) can also be used to obtain the (unknown) vertical distribution of water vapour if the temperature profile is known and corrections are made for the radiation from underlying cloud or land surfaces. With these provisos, it should be possible to obtain the weighted average of the relative humidity of the upper troposphere from measurements of emitted radiation in the 6.3 μm band and in a window between 8 and 12 μm; and by making additional measurements in the broad band between 19.5 and 24 μm it should be possible to deduce the mean humidity in the lower and middle troposphere as well. The SIRS instrument on the NIMBUS IV satellite includes six additional channels for this purpose.

Measurement of Pressure and Winds

Accurate determination of the vertical temperature distribution would allow the pressure profile to be calculated from the hydrostatic equation,

$$\frac{1}{p}\frac{dp}{dZ} = \frac{-g}{RT}$$

provided that the surface pressure p_0 is known. Accurate measurement of the surface pressure on land is readily achieved by modern automatically recording aneroid barometers. The problem is much more difficult over the oceans where it would be possible, but very expensive, to mount aneroid barometers on floating buoys that could be located and interrogated by satellites. This may, however, be rendered unnecessary by the recent development in the United States of a simple, lightweight radar altimeter which, when mounted on a constant level balloon (see next section) floating at, say, 100 mbar (~16 km), can measure the height z of the balloon above the sea surface to within an accuracy of ±10 m. Hence, if the balloon carries instruments to measure the ambient pressure and temperature, the parameters p, T and z in the hydrostatic equation are known, and p_0 may be calculated. Given now the surface pressure, and T as a function of z from satellite infrared spectrometer data, the pressure may be determined as a function of height z from the hydrostatic equation. It seems that about 300 balloons would be required to establish the pressure reference level (at, say, 100 mbar) over the southern hemisphere, but many fewer may be required in the northern hemisphere where there are many more ships that can measure surface pressure directly.

Determination of the pressure and temperature fields as just described would allow the winds to be calculated in middle and high latitudes where the winds are closely related to the pressure field through the controlling action of the Coriolis force due to the Earth's rotation. This would not be the case in the tropics where the horizontal gradients of pressure and temperature and the Coriolis force are all weak, so that determination of winds in the tropics is one of the most important problems of GARP. American meteorologists are devoting considerable effort to the extraction of winds from the movements of clouds on the pictures transmitted on successive frames from the spin-scan cameras carried on geostationary satellites but this tech-

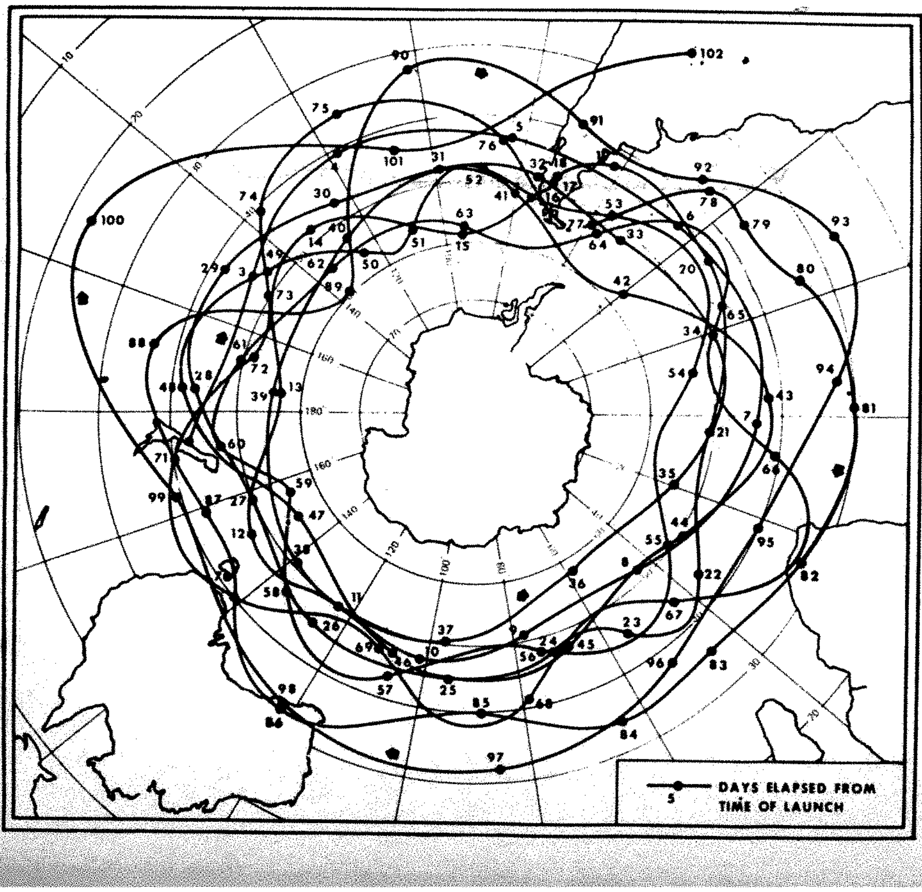

Fig. 4 Trajectories of a balloon released from Christchurch, New Zealand, making 8 circuits at 200 mbar (~40,000 feet) during 102 days.

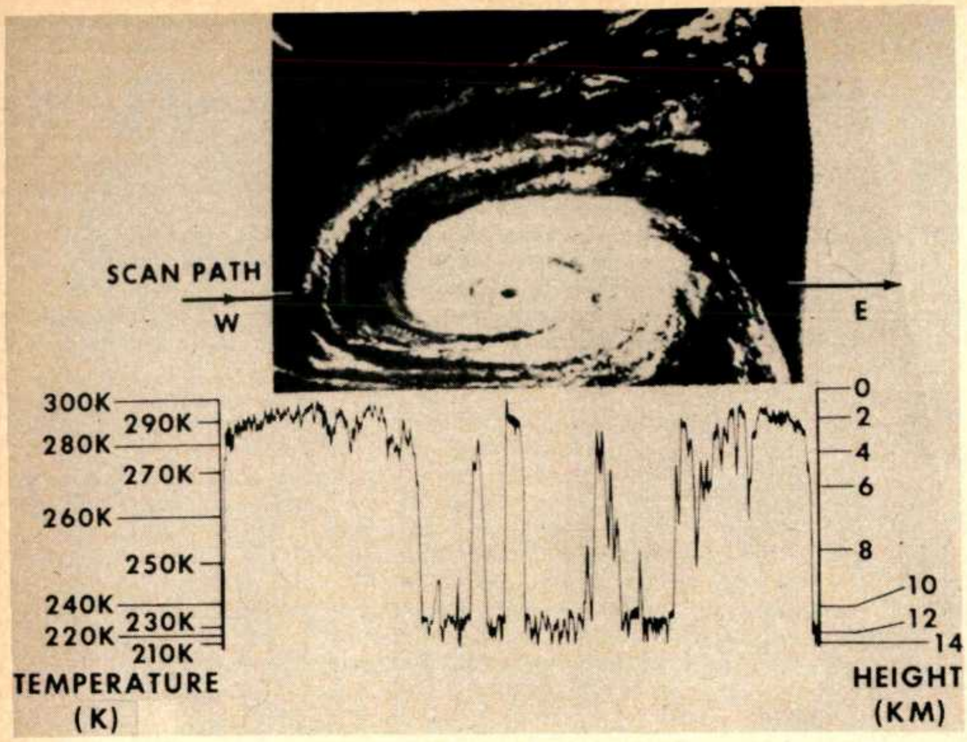

Fig. 5 An infrared photograph of a hurricane taken from a NIMBUS satellite. The temperatures of the ocean or cloud surfaces are determined from measurements of emitted radiation as shown by the record below the photograph.

nique can provide only a limited horizontal coverage of winds and information at only about two levels.

Considerable attention has therefore been paid to the measurement of winds by tracking inextensible constant volume, super-pressurized balloons that drift with the winds along surfaces of constant atmospheric density. In the United States GHOST (Global Horizontal Sounding Technique) Project, more than 200 such balloons have been released from Christchurch, New Zealand, and tracked by the signals from a simple telemetering photoresistor device that measures the elevation of the Sun. Balloons flying at 100 mbar higher are able to remain aloft for many months and make many circuits of the globe. One has flown for more than 450 days circling the southern hemisphere more than 25 times at the 100 mbar level. Balloons flying at the 200 mbar level (40,000 feet) have an average life of about 100 days, Fig. 4 showing the trajectories followed by one such balloon in making eight circuits of the southern hemisphere over 102 days. Unfortunately, balloons drifting at lower levels suffer with varying severity from the accumulation of frost, ice and snow, which limits their duration to weeks or even a few days, and so balloons can be flown economically only above 200 mbar, and below 850 mbar in the tropics, the most vital part of the troposphere being barred. Thus, unless the icing problem is solved, it seems that the constant level balloon will play a much less prominent role in GARP than once seemed likely, and this leaves the difficult problem of obtaining adequate wind data in the tropics unsolved. It has been suggested, however, that a large constant level balloon flying at, say, 100 mbar might release very lightweight dropsondes carrying transponders and fitted with parachutes that would drift with the wind, and that these could be located and tracked by a navigational system such as LORAN or OMEGA. Such a system may be tested within the next year or so.

There is little doubt that the developments described in this article will, during the next decade or two, lead to major changes in the methods and techniques of meteorological observation and measurement and that the direct measurement of some of the basic atmospheric parameters will be gradually supplemented and perhaps ultimately replaced by indirect methods involving the remote sensing of electromagnetic radiation from atmospheric constituents by satellites. For the next ten years or so, the global observing system will probably consist of a mixture of satellites, conventional radiosondes, dropsondes, balloons released from ground stations and ships and tracked by navigational aids such as LORAN and OMEGA, constant level balloons carrying accurate radar altimeters, and so on. Satellite methods, however, are likely to become more and more dominant and, although it may be necessary to retain some ground based sounding stations for the calibration and checking of the satellite system, it will probably be possible to dispense with many of the radiosonde stations in the northern hemisphere and the weather ships well before the end of the century.

Satellites will also play an important role in locating and interrogating automatic instruments on remote land stations, ocean buoys and drifting balloons and in rapidly transmitting the great quantities of data to a few major centres for processing and analysis by giant computers. An adequate global system would consist of four geostationary satellites equally spaced around the equator and two polar orbiting vehicles. On present expectations, it is likely that the system in 1976 will be deficient by one, and probably two, geostationary satellites; this and the lack of adequate wind data in the tropics are likely to be the most serious gaps in the requirements of the first global experiment planned for that year.

Progress in understanding and predicting the behaviour of the global atmosphere, however, is likely to be limited not so much by deficiencies of observational data or computer power, but by the difficulty of adequately simulating in numerical models, however complex, the wide variety of strongly interacting processes and motions encountered in the real atmosphere in such a way that the models remain realistic and stable within the limits set by random disturbances.

Succession of Cainozoic Vertebrate Assemblages from the Northern Kenya Rift Valley

W. W. BISHOP, G. R. CHAPMAN & A. HILL
Department of Geology, Bedford College, University of London, Regents Park, London NW1
J. A. MILLER
Department of Geodesy and Geophysics, University of Cambridge, Cambridge CB3 OE2

A succession of twelve different fossiliferous units in the Baringo area ranges in time from about 14 m.y. to the Holocene. The early part of the sequence provides for the first time faunal and stratigraphic evidence for the period between 5 m.y. and the Fort Ternan sediments dated about 14 m.y.

In Africa south of the Sahara very little is known of the late Miocene and Pliocene vertebrate fossil assemblages. Until recently a gap in the fossil record extended for more than 12 m.y. from the well documented earlier Miocene assemblages older than 17 to 18 m.y.[1,2] to those faunas, sometimes including australopithecines, which range in time from about 5 m.y. to 1 m.y. Only the Fort Ternan fossiliferous sediments, dated about 14 m.y.[3–5] and first described in 1962, were known with certainty to fall within this period. The investigations described here have been carried out since 1965 in the vicinity of Lake Baringo and the Tugen Hills (or Kamasia Range) in the northern Kenya Rift Valley (Fig. 1). The stratigraphic succession includes twelve different sedimentary units which contain vertebrate fossils. The early part of the sequence spans the former large faunal gap.

Between northern Tanzania and the Ethiopian border, the floor of the rift is generally covered by either Pleistocene volcanic rocks or epiclastic sediments which infill fault-bounded basins. Together these obscure the record of earlier rift history. Very little of the Kenya Rift has at its surface rocks older than 3.0 m.y., and thus the Tertiary succession in the Baringo area is particularly interesting. West of Lake Baringo, between latitudes 0° 15′ N and 1° 00′ N, a major tilted block, which forms the Tugen Hills, occurs within the rift graben; exposed in its eastern fault scarp, and in foot hills to the east, is a succession of lavas and sediments totalling 3,000 m in thickness that represents a sequence from mid-Miocene to Holocene. Basement gneisses outcrop beneath the Tertiary succession in the lowest 300 m of the main escarpment[6–8].

The first geological observations in this area were made by Gregory[9,10] who identified the principal lithological units and inferred the former existence of a "Lake Kamasia" to account for some of the sedimentary formations. The area was later accepted as the type locality for a "Kamasian Pluvial"[11,12], in spite of opposition from Shackleton[13]. The term Kamasian has no stratigraphic or climatic significance, and to avoid confusion the topographic feature is called here the Tugen Hills. Fuchs first recorded[14] vertebrate fossils in the area; these and other vertebrates found recently in the same formation[15] have been shown to be of later Pleistocene age. Officers of the Kenya Geological Survey[16] began systematic mapping in the south of the area in the early 1960s. The research reported here was initiated after discoveries made during mapping by members of the East African Geological Research Unit (EAGRU) based at Bedford College, University of London, and under the direction of Professor B. C. King. Stratigraphic and palaeontological investigations have been undertaken in more detail and some preliminary results have

been published[17-19]. On completion of the study the whole palaeontological collection will be lodged in the Kenya National Museum, Nairobi.

Stratigraphy

Provisional lithostratigraphic names have been assigned to all the principal stratigraphic units; most of these are unpublished, although recorded in PhD theses[20]. Names in Fig. 2 are of rock units (formation, member) and not of localities or sites.

The succession in the northern Kenya Rift has been divided into five groups of formations[8]. Group I, the earliest, basaltic, group is absent from the Tugen Hills succession (Fig. 2) where the lowest group present (II) is dominated by phonolite flood-lavas and rests directly on the basement. The oldest phonolite formation is almost certainly older than the Uasin Gishu and other so called plateau phonolites in Kenya. Undersaturated basaltic lavas in the middle of group II may be equivalent to the Elgeyo Basalts of Walsh[21], and from the evidence of stratigraphic correlation and isotopic dates the group II phonolites above the basaltic unit seem to be the equivalents of the Uasin Gishu phonolites[22], and range in age from 12.0 to 13.6 m.y.[1]. Rocks equivalent in age to the Ngorora Formation[18] and the highest group II phonolite unit have not been located elsewhere in the rift area.

A distinct unconformity, representing a major rift faulting episode, separates the rocks of group II from those of the younger groups. The lavas of groups III, IV and V are only rarely of undersaturated types[8]. In the Tugen Hills the lowest lavas of group III are the Kabarnet Trachytes[21], a very extensive formation of holocrystalline flood-trachytes from which several isotopic dates close to 7.0 m.y. have been obtained. The dominant lavas of group III, however, are alkali basalts. Group IV, which is composed of large complex trachyte volcanoes, is absent in the Tugen Hills-Lake Baringo area but is strongly developed farther north (Figs. 3 and 4). The petrologically varied lavas of group V above the Chemeron formations are, at least in part, the same age as the Dispei-Lake Hannington Phonolites (largely phonolitic trachytes) of McCall[23]. The stratigraphy of the Chemeron and Kapthurin formations was established by McCall *et al.*[16] and elaborated by Martyn[17,20].

Figs. 3 and 4 show the upper part of the succession on the Baringo-Turkana border where the dominant features are the large trachyte volcanoes of group IV. Rock units above these in the sequence are essentially local developments and cannot be directly traced by mapping into the Tugen Hills succession farther south.

Although the stratigraphy shown in Figs. 2-4 was established entirely by mapping, a large number of isotopic (^{40}K/^{40}Ar) dates has been obtained from the lavas and from feldspar crystals in tuffs. Some of these have already been mentioned and will be reported in detail elsewhere. The dates available at present, although sometimes showing disparate results in single rock units, enable an approximate time curve for accumulation to be related to the succession illustrated in Figs. 2-4. This effects an approximate dating of the fossil assemblages and assists in correlation with other areas.

The fossiliferous sediments to the east of Lake Baringo can be related approximately to the succession shown in Fig. 2: the Alengerr beds outcrop in the eastern rift escarpment in the area of the Amaya river within a succession, chiefly of phonolite lavas, which is the equivalent of group II in the Tugen Hills. Potassium-argon dates on the lavas indicate that the age of the fossiliferous Alengerr beds is between 12.0 and 14.0 m.y.

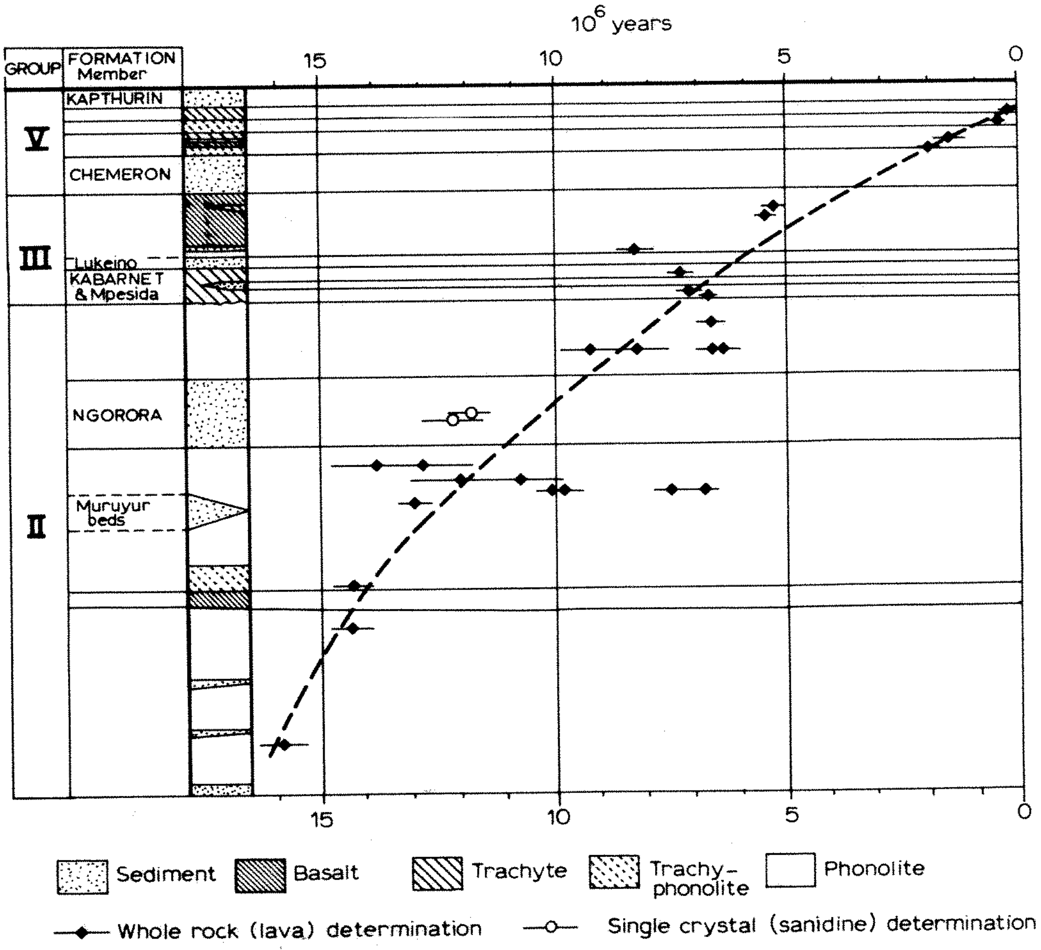

Fig. 2 Stratigraphy and isotopic (^{40}K/^{40}Ar) dates in the Tugen Hills (Kamasia Range). Dotted line: approximate accumulation curve for the sequence.

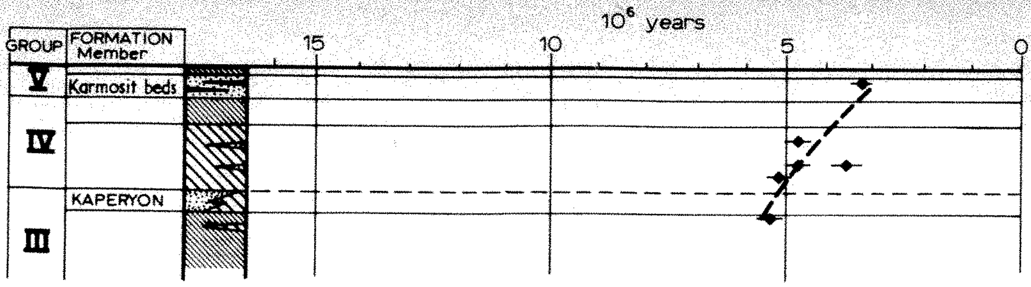

Fig. 3 Stratigraphy and isotopic ($^{40}K/^{40}Ar$) dates in the Ribkwo area.

The Chesowanja sediments[19] were deposited in part of the Chemoigut sedimentary basin immediately to the east of Lake Baringo. Potassium–argon determinations on trachyte lavas which possibly ponded the former Chemoigut lake gave results of 1.1 and 1.2 m.y.

Caprinae/Alcelaphini	

The geological situation, sediments and fauna of the Ngorora Formation, which consists of deposits older than 9 m.y. and younger than 12 m.y., have been described by two of us (W. W. B. and G. R. C.)[18]. In a note in this article[18] L. S. B. Leakey described the hominoid tooth as hominid, having some affinities with "*Kenyapithecus*" and some with both *Homo* and *Australopithecus*. From the teeth, the *Deinotherium hobleyi* material seems more advanced than that from Gebel Zelten[24] and the known East African Miocene localities. An age of 12.5 m.y. has been suggested for the arrival of *Hipparion* in Europe[25]. Consequently its apparent absence from the Ngorora Formation is interesting, because there seem to be neither palaeoecological nor taphonomical features of the formation that would preclude *Hipparion* being represented in the assemblage had it been in sub-Saharan Africa at that time. If *Hipparion* is indeed absent it emphasizes that care should be taken when attempting to date the faunas of one continent by the date of appearance of *Hipparion* on another[26]. The *Brachypotherium* represents the new species recently described from Lothagam I[27]. The *Chilotherium* is also a new species. The hippo remains, which include primitive premolars, are the oldest dental evidence of the family. The small giraffoid may be comparable to one at Fort Ternan; and the *Protragocerus* sp. is similar dentally to a Fort Ternan form, *P. labidotus*, but the horn cores resemble more closely a *Protragocerus* from Langebaanweg, South Africa[28].

Rhinocerotidae	
Artiodactyla	
Hippopotamidae	*Hippopotamus* sp.
Bovidae	

There are three fossiliferous localities, in three separate outcrops of the Mpesida beds, probably with the same age of about 7 m.y. List (*d*) given here is that for the chief locality, but no additional taxa have been recorded from either of the two subsidiary localities. Maglio has mentioned[29] the unit and its possible correlatives, in connexion with the Elephantidae. *Stegotetrabelodon orbus* is found elsewhere only from Lothagam I[29–31] and from the Kaperyon formation. The "*Hipparion*" is the earliest recorded equid in Africa south of the Sahara. The hippopotamus is similar to a new species from Lothagam I.

Hippopotamidae	*Hippopotamus* sp.
Bovidae	Reduncini sp. Antilopini sp.

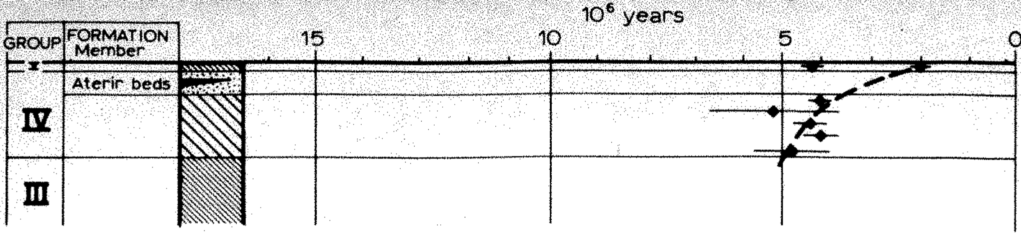

Fig. 4 Stratigraphy and isotopic ($^{40}K/^{40}Ar$) dates in the area north of Kapedo.

There are three fossiliferous localities in the Lukeino member at the same horizon along a continuous outcrop. The fauna is younger than 6.7 m.y., but possibly older than 6 m.y. The *Nyanzachoerus* sp. seems to be more primitive than sp. nov. "C" from Lothagam I, but also has some resemblances to sp. nov. "B" from Kanapoi[32]. The hippopotamus resembles a new species from Lothagam I and from the Mpesida beds. There is a similarity between the Reduncini sp. and a species from the Dhok Pathan and Tatrot levels of the Siwalik sequence.

(*f*) Kaperyon formation

Hystricidae	

The Kaperyon formation contains two fossiliferous localities, the fauna from which is about 5 m.y. old. The formation is referred to by Maglio[29]. The specimen of *Stegotetrabelodon orbus* seems to be closer to that from Lothagam I than does the Mpesida beds form. This is also the case with the *Hippopotamus*, which is like a Lothagam I species, and is more advanced than that from the Mpesida beds.

The sediments in the Chemeron formation have been described by Martyn[17,20] and by McCall, Baker and Walsh[16]. There are several fossil localities in two principal areas of outcrop. These areas were interpreted by Martyn as representing two separate basins of deposition, the Chemeron basin and the Kipcherere basin, in which the successions were broadly equated stratigraphically and lithologically. In list (*g*) taxa marked * are from JM91(90), a locality in the basal member (member 1) in the Chemeron basin. Because of the anomalous presence in the JM91 assemblage of teeth assigned to *Elephas recki* stage 2 it has been suggested that the fauna from this locality is younger than the basal faunas elsewhere in both depositional basins[32]. The geological evidence available at present does not support this view.

Fossils also come from localities higher in the succession. Taxa marked † in the faunal list are found in the lower fish beds (member 2) as well as in the basal beds, and the hominid (marked ‡) comes from a low level in the upper fish beds (member 4). An isotopic age of 2.0 m.y. has been obtained for a lava conformably overlying the formation in the Chemeron basin. L. S. B. Leakey has provided a preliminary note on the fauna[17]; the hominid fragment has been described and discussed by Tobias[33]; R. E. F. Leakey has described the cercopithecoids[34]; Maglio[29-31] has mentioned the Elephantidae; and Hooijer has described[35] the rhinocerotidae—the *Ceratotherium simum* is a primitive form comparable to the *C.s. germanoafricanum* from Laetolil. Upper third molars from Olduvai Bed II are intermediate between those from JM91 and those from Olduvai Bed IV and the recent forms. The new species of *Hippopotamus* resembles the one to be described from Kanapoi.

(*h*) Aterir beds

REPTILIA	
Chelonia	
Pelomedusidae	
Crocodilia

Rhinocerotidae	*Ceratotherium* sp.
Artiodactyla	
Suidae	c.f. *Sus* sp.
	Nyanzachoerus c.f. sp. "B"
Hippopotamidae	*Hippopotamus* sp.
Bovidae	

Several fossiliferous areas occur at the same horizon in the Aterir beds in a sedimentary basin about 4.5 × 1.5 km in extent. The unit is a little younger than 4 m.y. in age. Maglio has referred[29] to the locality as "Atirir" (*sic*) in connexion with the Elephantidae. The *Anancus* sp. is not *A. osiris*, but is comparable to an undescribed species from Kanapoi[27] and to one from Langebaanweg. The *Ceratotherium* is probably a new species to be described from Lothagam.

(*i*) Karmosit beds

MAMMALIA

	? *Connochaetes* sp.
	small sp.
	smaller sp.
Antilopini	? *Antidorcas* sp.

Descriptions of the geology of the Chemoigut beds and of a hominid partial cranium, together with a faunal list, have already been published[19]. The specimen of *Deinotherium bozasi* is the latest occurrence of the genus so far known. The *Kobus* sp. is as large as the largest *K. sigmoidalis* from the Omo and Olduvai deposits, and the extant *K. ellipsiprymnus*. The middle size group of the Alcelaphini is about the size of *Damaliscus niro* or *Parmularius angusticornis*.

(*k*) Kapthurin formation

MAMMALIA	
Primates	
Cercopithecidae	*Colobus* sp.
Hominidae	*Homo* sp.
Carnivora	indet.
Hyracoidea	
Procaviidae	*Heterohyrax* sp.
Artiodactyla	
Suidae	*Potamochoerus* sp.
	Tapinochoerus sp.
	Phacochoerus sp.
Hippopotamidae	*Hippopotamus amphibius* (Linn.)
Bovidae	
Tragelaphini	*Tragelaphus* c.f. *scriptus* (Pallas)
Reduncini	*Redunca* sp.
Alcelaphini	indet.

Orycteropodidae	*Orycteropus* sp.
Rodentia	
Muridae	*Oenomys* sp.
	Rattus c.f. *rattus* (Linn.)
Thryonomyidae	*Thryonomys* sp.

The Kapthurin formation includes two fossiliferous localities and it is younger than a single unconfirmed potassium-argon age of 230,000 yr. The sediments have been described by Fuchs[14] and later by Martyn[15,17,20] and by McCall, Baker and Walsh[16]. Margaret Leakey has discussed the archaeology[15] and the same reference has contributions from Martyn on the sediments, Tobias on the hominid which he believes is probably *Homo erectus*, and R. E. F. Leakey on the rest of the fauna. The identifications and list above were kindly provided by Dr J. Harris.

(*l*) Kokwob beds

The fauna of the Kokwob beds consists of abundant mollusca and fragments of fish and mammalia in beach and shallow water deposits at various levels up to 20 m above the present level of Lake Baringo. The age of the deposits is probably Holocene.

Fossiliferous horizons recently investigated at Omo, East Rudolf, Kanapoi and Lothagam have extended knowledge of the East African Pliocene/Pleistocene mammalian faunas back from about 1.8 m.y., the age of the base of the sequence at Olduvai Gorge, to about 5 m.y. As well as representing this time span, the Baringo succession provides the first faunal and stratigraphic evidence between about 5 m.y. and the Fort Ternan faunal assemblage at 14 m.y. Further detailed work on the Baringo faunal assemblages together with more isotopic dates will facilitate more confident comparisons with other African localities and should produce valuable information on the still little known earlier Pliocene and late Miocene record in Africa.

This work was financed by the Kenya Government, the Natural Environment Research Council, the Royal Society, the Wenner-Gren Foundation for Anthropological Research and the Boise Fund of the University of Oxford. We thank the EAGRU members, J. N. Carney, Dr M. P. McClenaghan, Dr J. E. Martyn, J. S. C. Sceal and Dr P. K. Webb, whose work has led to the elucidation of the succession and who discovered many of the fossil localities; and Professor B. C. King, Dr L. S. B. Leakey, R. E. F. Leakey, Dr G. J. H. McCall, Dr A. C. Walker, Dr J. Walsh and Dr L. A. J. Williams for their help. Dr N. J. Snelling of the Institute of Geological Sciences allowed us to use the results of several isotopic age determinations on the lavas. For identification and preliminary comments on the fauna we thank Mrs S. C. Savage (Hippopotamidae), Professor H. B. S. Cooke (Suidae), Dr A. Gentry (Bovidae), Dr J. Harris (Deinotheriidae), Dr D. A. Hooijer (Rhinocerotidae), Dr V. J. Maglio (Elephantidae) and Dr R. Wood (Chelonia).

Antigens of Developing *Drosophila melanogaster*

DAVID B. ROBERTS
Genetics Laboratory, Department of Biochemistry, South Parks Road, Oxford OX1 3QU

The changes in the antigenic complements of extracts of soluble proteins of *Drosophila* have been followed through development.

THE genetic control of development in eukaryotes can be investigated in terms of the control of synthesis of one or a few proteins. Thus many people[1-4] have studied the relationship of enzymes to development in *Drosophila*. I have studied simultaneously many proteins detected immunologically in *Drosophila* at all stages from the unfertilized egg to the eclosed adult, and a study is in progress (Gouveia and myself, unpublished results) of the spatial distribution during development of these proteins. Some of the proteins have been identified as known enzymes, but the function of most of them is unknown. The apparent concentrations of the antigens, however, suggest that the proteins are enzyme or structural proteins rather than being concerned exclusively with control. Development has already been studied in terms of changes in the antigens in extracts of soluble proteins of amphibia[5-10], echinoderms[11,12] and insects[13,14], but usually for a limited period of development or for one tissue. The presence or absence of an antigen is taken to reflect the state, active or inactive, of the gene or genes responsible for the synthesis of that antigen. But this concept overlooks genes with reduced activity, which may be below the resolution of the techniques used. It also overlooks control at the level of translation, although this has been investigated with one protein. Because of the complexity of the problem, however, such a simple approach is necessary. Although the simultaneous appearance of many antigens seems to correlate with phases of sensitivity to the action of lethal mutations, no attempt has yet been made to associate the appearance or disappearance of these proteins with specific morphological events.

To obtain different developmental stages, about 10,000 flies, Oregon-R, were placed in a 'Perspex' population box with Petri dishes containing medium for egg laying (4% agar, 10% glucose, 10% live yeast dissolved in 100 ml. water, and autoclaved at 15 pounds/inch^2 for 15 min, and with the addition of nipagin just before the agar set). The Petri dishes were changed at hourly intervals, the samples when harvested were $X \pm 0.5$ h from the mid-laying time. All times are given from this mid-laying time. Because eggs may be retained by the female after fertilization, no eggs collected in the first hour of any working day were used, so that each stage contained few individuals significantly older than the stated age. The mean hatching time was 22 h, the mean time of puparium formation 128 h and the mean time of eclosion 215 h.

Rabbits were immunized with extracts of eggs (laid over 4 h), embryos (eggs laid over 22 h), first instar larvae (eggs laid over 4 h and collected at 40 h), second instar larvae (eggs laid over 4 h and collected at 60 h); third instar larvae (eggs laid over 4 h and collected at 96 h); adult flies. All immunized rabbits produced antibodies which reacted with the extracts used for immunization. Differences in the antigenic complement of different developmental stages were obvious on double diffusion plates (Fig. 1). Because of the many precipitin bands formed the results were more readily interpreted on immunoelectrophoresis plates (Fig. 2). Using the antibody preparations described above, thirty-three different protein antigens were identified which appeared at some time during the development of *Drosophila* (Fig. 3). Ten of these proteins are detected in newly fertilized eggs and, of these ten, eight are found in unfertilized eggs (Fig. 4) and probably represent the products of genes active in the egg during oogenesis or the products of genes active in adjacent nurse cells.

The other two proteins may represent the products of mRNA transcribed from the maternal genome and masked in the unfertilized egg but released by fertilization. This suggestion is supported by the observations of Lockshin[15] that no RNA synthesis could be detected in the eggs of two species of Coleoptera until the nuclei appeared in the cortex of the egg, which is at about 1.5 h in *Drosophila*[16]. The suggestion is also supported by the observations of Gross[17] and others on masked mRNA and early protein synthesis in sea urchins. Five new proteins appear in 3 h old extracts, probably translated from mRNA transcribed from the zygote genome after the nuclei have migrated to the cortex and which therefore represent the earliest paternal proteins in this organism. New proteins are observed in extracts of late embryos and of young larvae. At these times, studies using electrophoretic variants of enzymes have shown that many enzymes, which must be translated from mRNA transcribed from the zygote genome, are synthesized[3]. This is also the first sensitive phase for lethal point mutations[18]. New proteins are again detected in extracts from the other developmental periods, from mid second instar to mid third instar and late in pupal life. The first of these coincides with the two lethal phases, early and late third instar detected by Hadorn and Chen[19], with the death of the larvae occurring some time after the normal appearance of the essential protein. The second of these periods may reflect the pupal lethal period of Hadorn and Chen.

No new proteins were detected at the time of puparium formation although extracts were made of larvae/puparia-pupae at 3 h intervals from 115 h to 145 h. The absence of new proteins at this period was surprising in view of the consider-

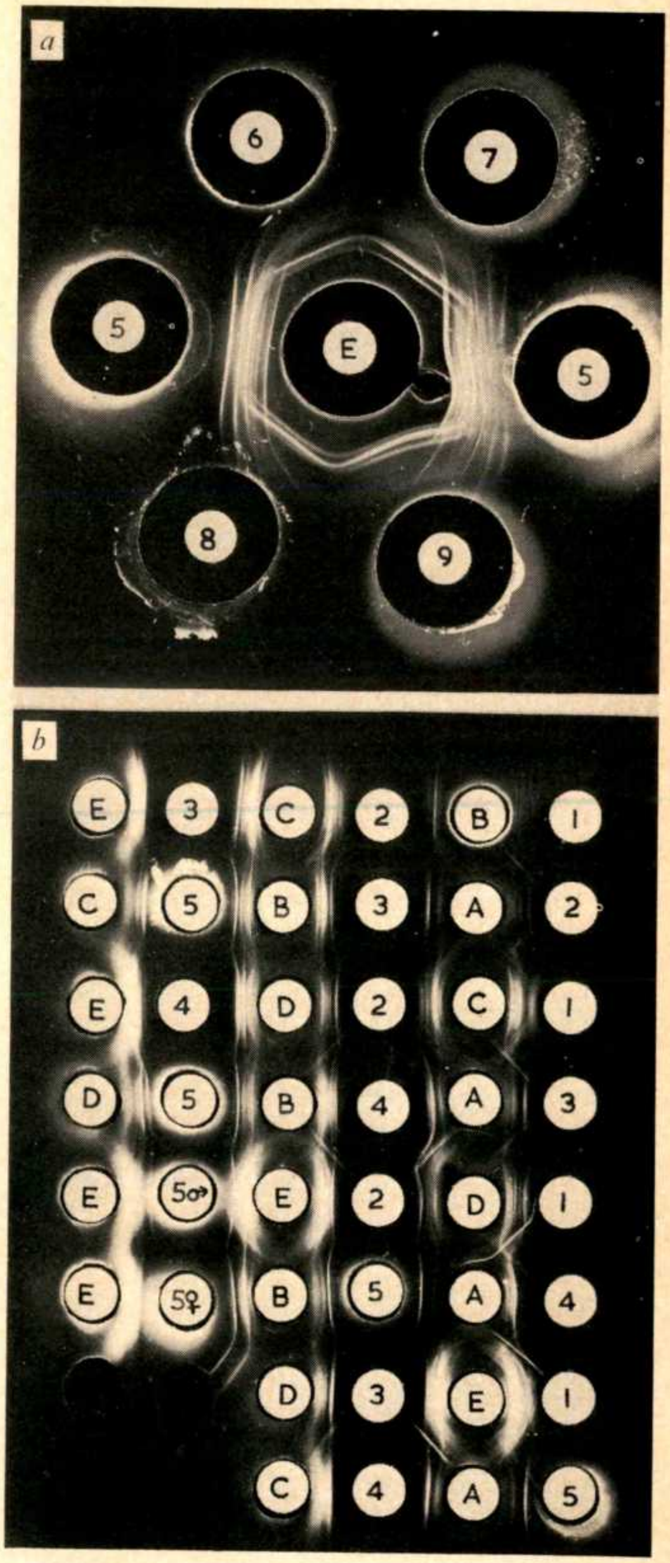

Fig. 1 Double diffusion plates of extracts from different developmental stages. *a*, The double diffusion plates were set up as indicated in the text. *b*, Horizontal precipitin band represents a heterologous interaction, that is, an antigen reacting with antibodies prepared against another antigen; a diagonal precipitin band represents a homologous interaction. 1, Egg; 2, first instar larvae; 3, second instar larvae; 4, third instar larvae; 5, whole fly; 6, 3 h old eggs; 7, 6 h old eggs; 8, 9 h old eggs; 9, 12 h old eggs; A, anti-egg; B, anti-first instar larvae; C, anti-second instar larvae; D, anti-third instar larvae; E, anti-fly.

able changes in puffing pattern that occur at this time[20]. One protein (No. 28) precipitated by antibodies against extracts of third instar larvae was subjected to a more detailed study than the others. Its molecular weight was determined on a sucrose density gradient[21] with reference to catalase as 420,000 daltons. The protein was detected on the gradient by analysing alternate drops on double diffusion plates with antibodies. This antigen is found at a high concentration in haemolymph and at a very low concentration in salivary gland/fat body extracts. The protein is first detected at about 60 h and cannot be detected in extracts of mature adults.

Molecular weight studies, time course studies and location studies suggest that this protein is similar to protein No. 1 found by Laufer[22] in *Hylophora crecopia* which has a molecular weight of about 450,000 daltons and is located in the haemo-

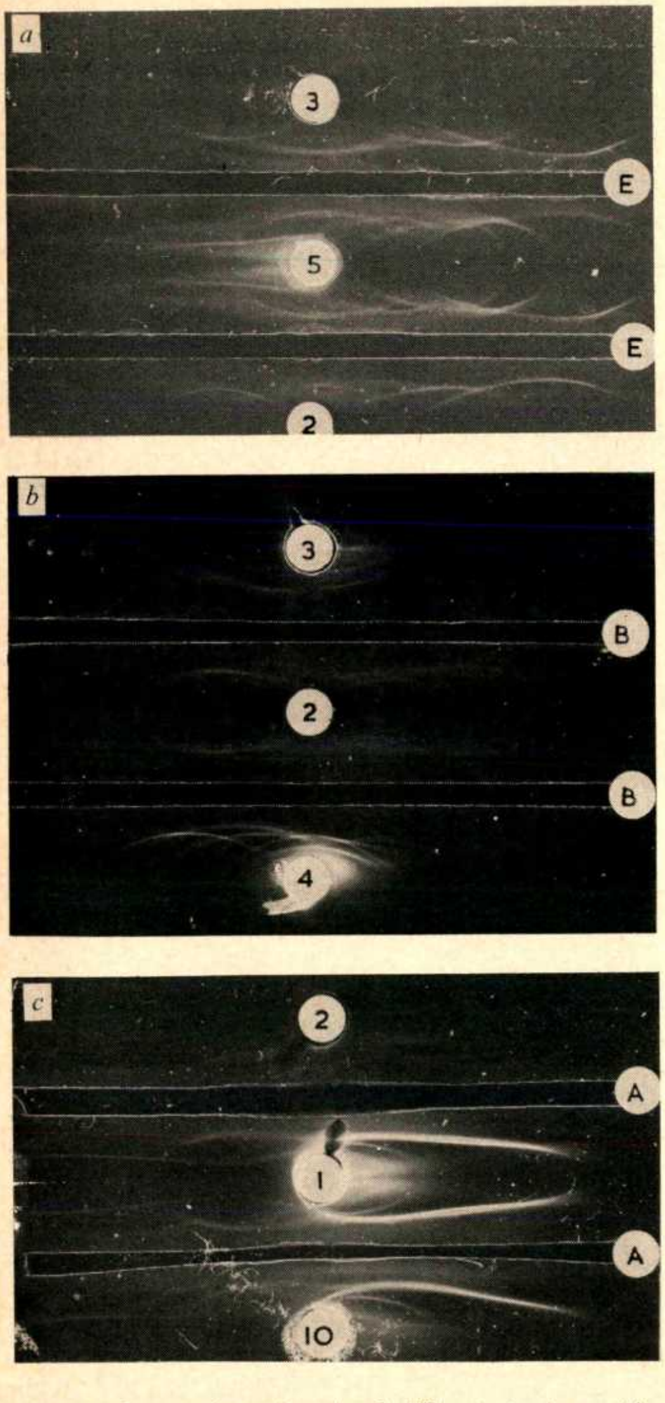

Fig. 2 Immunoelectrophoresis of different developmental stages. The plates were set up as indicated in the text. Ten embryos were used.

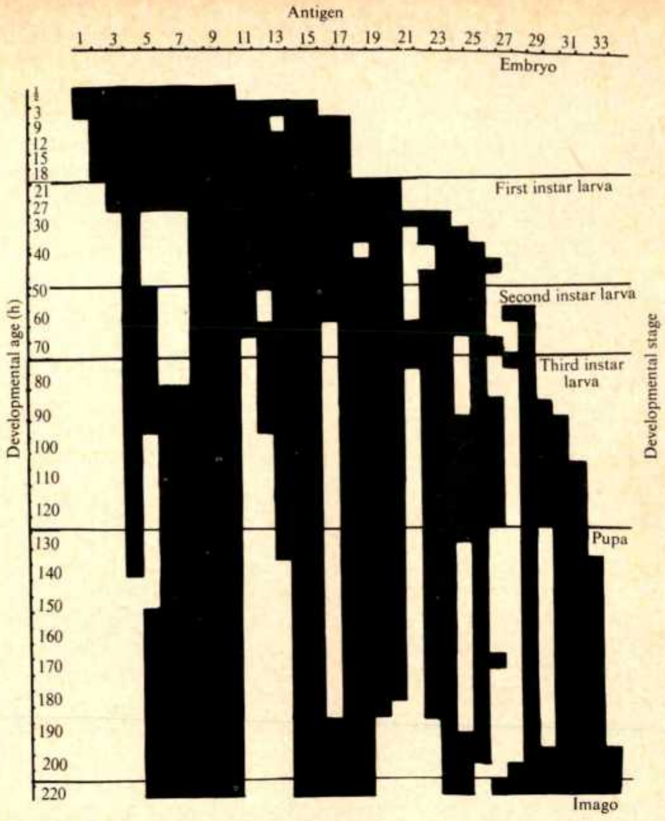

Fig. 3 Antigens appearing during the development of *Drosophila melanogaster*. Flies laid eggs for 1 h periods, the eggs, larvae, pupae or flies were harvested at the times indicated and extracts of soluble proteins were prepared from these by sonicating for 30 s in 0.05 M phosphate buffer (*p*H 7.2) containing 0.8% NaCl, using an MSE sonicator. Third instar larvae, pupae and flies were homogenized with a tissue grinder before being sonicated. Extracts were kept cold at all times. The extracts were centrifuged at 30,000*g* for 20 min and the protein concentration of the supernatant was estimated by the micro-Biuret method[24]. All extracts were adjusted to the same protein concentration and were analysed by immunoelectrophoresis using the antibody solutions described above. The table shows the presence of the antigens at different developmental ages tested.

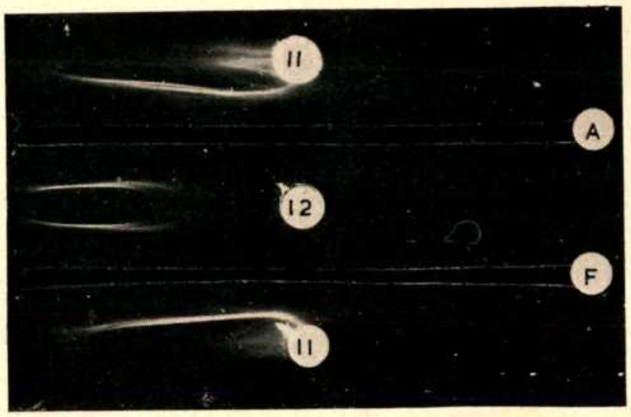

Fig. 4 Immunoelectrophoresis plate of fertilized and unfertilized eggs. The unfertilized eggs were collected from virgin female flies which laid eggs for 1 h periods. The eggs from many collections were stored at −20° C until a sufficient quantity for making an extract had been collected. The fertilized eggs were collected after flies had laid for 0.5 h periods and again stored at −20° C until sufficient eggs had been collected. Both extracts were adjusted to the same protein concentration. 11, Newly fertilized eggs; 12, unfertilized; F, anti-embryo.

lymph at all stages of development excepting egg, embryo and mature adult and to calliphorin described by Munn and Greville[23] in *Calliphora erythrocephala* and other insects. Calliphorin shows a similar distribution but has a higher molecular weight.

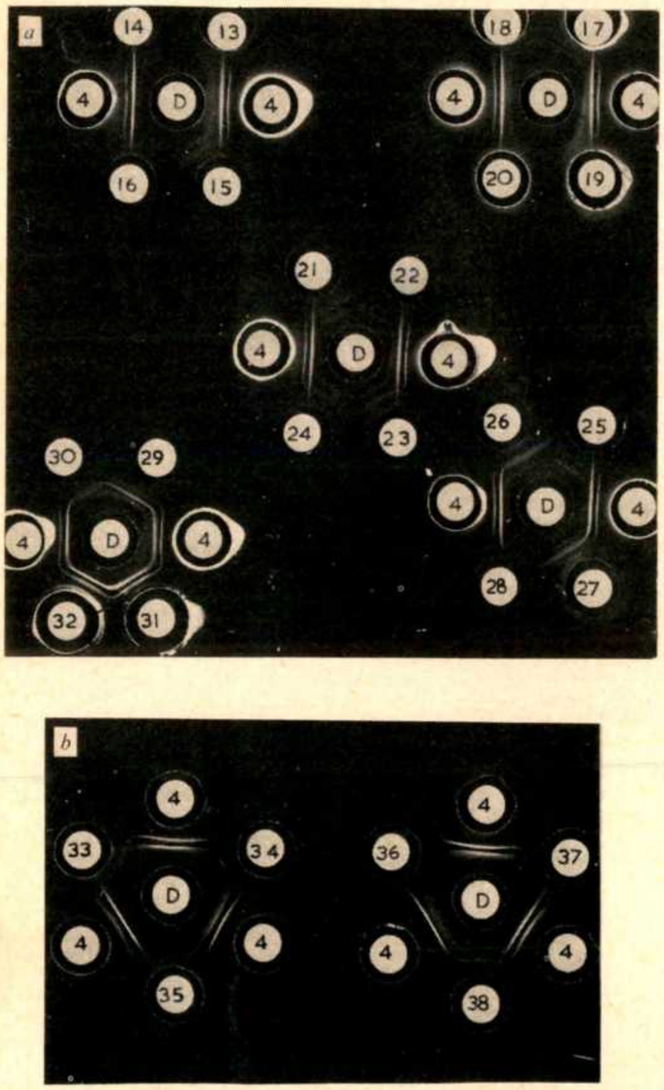

Fig. 5 Analysis of the control of the synthesis of protein No. 28. *a*, Double diffusion plate showing the time of appearance of two antigens during development. No. 28 at 60 h and No. 29 at 75 h. *b*, Double diffusion plate of larvae grown on normal medium and on medium-containing actinomycin D. The larvae were either harvested at the time shown (ii) or transferred to actinomycin D at the time shown and harvested at 85 h (i). 13, 1 h old egg; 14, 4 h old egg; 15, 8 h old egg; 16, 12 h old egg; 17, 16 h old egg; 18, 20 h old egg; 19, 25 h old larvae; 20, 30 h old larvae; 21, 35 h old larvae; 22, 40 h old larvae; 23, 45 h old larvae; 24, 50 h old larvae; 25, 55 h old larvae; 26, 60 h old larvae; 27, 65 h old larvae; 28, 70 h old larvae; 29, 75 h old larvae; 30, 80 h old larvae; 31, 85 h old larvae; 32, 90 h old larvae; 33, 54 h old transfer; 34, 57 h old transfer; 35, 60 h old transfer; 36, 54 h old larvae; 37, 57 h old larvae; 38, 60 h old larvae. All extracts adjusted to the same protein concentration.

The control of the appearance of antigens could be mediated at the level of transcription or at the level of translation. To test this a detailed study was carried out on protein No. 28. This protein was detected in extracts of 60 h old larvae grown on normal medium but not in extracts of 57 h old larvae. Larvae transferred to medium containing actinomycin D had not synthesized this protein 30 h later if transferred at 54 h but had synthesized the protein at this time if transferred at 57 h (Fig. 5). This suggests that the structural gene for this protein is transcribed between 54 h and 57 h and the protein first appears between 57 h and 60 h. Thus there is little delay in the translation of the mRNA so that the control of the synthesis of this protein is at the level of transcription. Actinomycin D had no effect on embryogenesis nor on proteins appearing during that time, probably because of permeability factors; in contrast actinomycin D seriously disturbed larval development and proteins appearing during larval life.

Antibodies against extracts of egg and of whole flies showed a significant difference in the antigenic complement of male and female flies. Two extra antigens were present in the female. Fractionation of the adults into head, thorax and abdomen showed that this difference was confined to the abdomen. These two antigens were also present in extracts of eggs and seem to be proteins either synthesized in the egg during oogenesis or in the nurse cells and transported to the eggs. No other differences could be detected between adult male and female flies.

These results show which proteins should be studied further and what questions such studies can hope to answer. The preparation of antibodies against different organs and the use of fluorescent antibodies will decide which proteins characterize an organ and which are found generally. A study of wild type strains for electrophoretic variants of the antigens will reveal the formal genetics of these proteins, and indicate the earliest time of mRNA synthesis from the paternal genome in the zygote. The role played by these proteins in development could be elucidated by the study of the disturbed antigenic complement of developmental lethal mutations.

I thank Mr J. Hewitt and Miss Susan Moffitt for technical assistance. This work was assisted by a grant from the SRC. Actinomycin D was a gift from Merck Sharp and Dohme Ltd.

Bacterial Virus Gene Expression in Human Cells

CARL R. MERRIL & MARK R. GEIER
Laboratory of General and Comparative Biochemistry, National Institute of Mental Health, Bethesda, Maryland 20014

JOHN C. PETRICCIANI
Laboratory of Pathology, Division of Biologics Standards, National Institutes of Health, Bethesda, Maryland 20014

Human fibroblasts, from a patient with congenital lack of α-D-galactose-1-phosphate uridyl transferase activity, have been infected with transducing bacteriophage that harbours either wild type or defective transferase gene. Infection only by the former phage initiates transferase synthesis.

IF the genetic code is truly universal it might be possible to make genetic changes in mammalian cells by introducing a specific gene by bacteriophage transduction[1,2]. Human fibroblasts from a patient with galactosemia served as a model system to test for such a possibility. Galactosemia is the result of an autosomal recessive inborn error of metabolism in which there is a congenital absence of the enzyme α-D-galactose-1-phosphate uridyl (GPU) transferase activity[3,4].

The viruses which were tested in this system were lambda ($\lambda_{\mathrm{CI}}857$, $\lambda_{\mathrm{CI}}857S_7$)[5-7] and two transducing viruses derived from λ: the first, $\lambda pgal_8C_I857(K^+T^+E^+)$, contains the complete galactose operon (ref. 8, and personal communication from D. Court and S. Adhya), and the second, $\lambda pgal_8C_I857(K^+T^-E^+)$, contains the galactose operon with a mutation that renders the transferase gene inactive (made for us by M. E. Gottesman).

To obtain a functional enzyme from a bacterial virus, a mammalian cell would have to transcribe at least part of the phage genome into mRNA and then translate this into protein. Transcription was demonstrated in this study by the discovery of λ-specific RNA in cells exposed to either λ virus or λ DNA. GPU-transferase activity was also detected after exposure of the cells to λpgal T^+ virus or its DNA.

Transcription was studied by using galactosemic human fibroblasts (CCL-72 obtained in the sixteenth passage from the American Type Culture Collection). In each experiment, flasks infected with λ virus and control flasks were labelled with radioactive uridine 24 h before the cells were collected. When RNA was extracted and hybridized with denatured λ DNA on cellulose nitrate filters, the production of λ-specific RNA reached a maximum of 0.2% of labelled total RNA within 4.5 days after infection (Fig. 1). Cultures exposed to λ have remained at this level through two 3 : 1 subcultures for longer than 40 days. A similar result was obtained when the cells were exposed to λ DNA. Less than 0.005% of the labelled RNA extracted from the control cells was bound to the λ DNA filters. As a control for any contaminant which might be homologous with *E. coli*, the labelled RNA from both the λ infected and non-infected cells was hybridized with *E. coli* DNA filters. The binding was less than 0.005%.

Transferase activity in fibroblasts was assayed by a modification of the method of Russell[12-14]. In this assay, galactose-1-phosphate (Gal-1-P) is converted to UDP-galactose (UDP-Gal) by the transferase enzyme and by using ^{14}C labelled Gal-1-P it is possible to follow this reaction (Fig. 2). This activity was linear with time in the conditions used and proportional to the amount of cell lysate used (Fig. 3). All activity was lost by boiling the cell lysate. Uninfected galactosemic cells had an activity ≤0.2 nmol of UDP-Gal/60 min/mg of protein (Table 1). No difference in enzyme activity could be detected between uninfected galactosemic fibroblasts and fibroblasts infected with λ virus or λpgal $T(^-)$, with a mutation in transferase structural gene. The λpgal T^+ DNA-infected cells had enzyme levels which were generally greater than the λpgal T^+ whole virus-infected cells. Infected cell cultures have

Table 1 Assays for Transferase Activity

Cell strain	Exposure	Multiplicity of infection	Time after exposure	Transferase* activity
Normal fibroblasts				
Rat embryo fibroblasts	None	—	—	46.0
VMK	None	—	—	23.2
WI–38	None	—	—	6.3
Galactosemic fibroblasts (CCL-72)				
(*a*) Uninfected	None	—	—	<0.2
(*b*) Infections with transferase negative virus or DNA				
	λ virus	4×10^5	96 h	<0.2
	λpgal $(K^+T^-E^+)$ virus	4×10^5	96 h	<0.2
	λpgal $(K^+T^-E^+)$ DNA	6×10^4 phage p.f.u. equivalents†	96 h	<0.2
(*c*) Infections with transferase positive virus or DNA				
	λpgal $(K^+T^+E^+)$ virus	4×10^5	96 h	2.0
	λpgal $(K^+T^+E^+)$ virus	4×10^5	52 days	10.1
	λpgal $(K^+T^+E^+)$ DNA	6×10^4 phage p.f.u. equivalents†	96 h	15.6

* Galactose-1-phosphate uridyl transferase activity is expressed in terms of nmol of UDP-Gal formed in 60 min/mg of protein at 37° C.

† 1 μg of λDNA = 2×10^{10} p.f.u. equivalents.

Rat embryo fibroblasts were prepared as a primary culture from Holtzman rat embryos (donated by V. Huebner), VMK is a primary cell strain from African green monkey kidney cells (prepared by the cell biology section of the Division of Biologics Standards) and WI-38 is a normal human diploid cell line (CCL-75, passage 16, from the American Type Culture Collection). The cells were grown, infected and assayed for transferase activity as described in Figs. 2 and 3. $\lambda_{\mathrm{CI}}857$[5] virus was grown vegetatively on *E. coli* N205 (a spontaneous gal$^+$ revertant of strain W3102 gal K^2 and carries recA allele from strain 152 gal$^+$ of Meselson)[17]. λpgal$(K^+T^-E^+)$ was also grown on N205. λpgal$(K^+T^+E^+)$ was grown vegetatively on N205 and also on N580 (a transferase negative strain, W3104)[18]. These viruses were purified and banded in CsCl prior to use[9]. Virus DNA was prepared as described in Fig. 3.

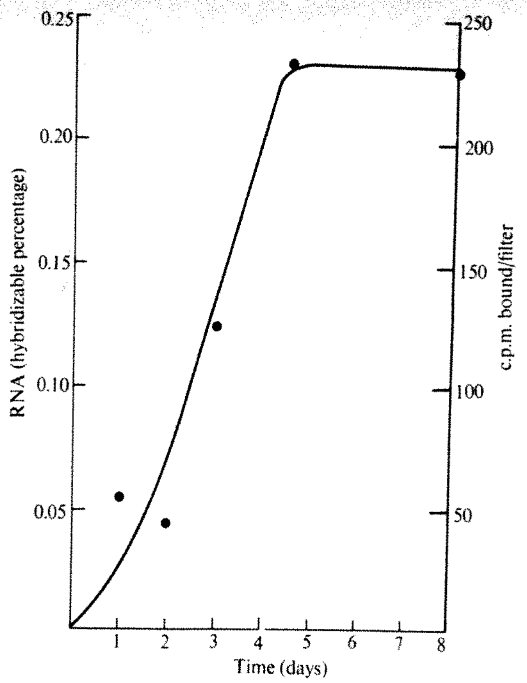

Fig. 1 Appearance of λ-specific RNA after infection of CCL-72 human galactosemic fibroblasts with $\lambda_{CI}857S_7$ virus at a multiplicity of infection (m.o.i.) of 1×10^5 λ plaque forming units (p.f.u.)/cell. The data presented are in c.p.m. above background as well as hybridizable percentage which is defined as c.p.m. bound to filter-scintillation system background (20 c.p.m.)/total c.p.m. input. Hybridization with RNA extracted from uninfected cells gave ≤ 5 c.p.m. above background. Cells were cultured in Eagle's minimal essential media (EMEM) containing sodium bicarbonate (1 g/l.), foetal calf serum (10%), penicillin (100 U/ml.), streptomycin (50 μg/ml.), and glutamine (0.17%) in 10 cm Petri dishes. This mixture was used for all tissue culture unless otherwise indicated. $\lambda_{CI}857S_7$ was heat-induced from *E. coli* M5107 (given by E. Signer)[6,7], precipitated with polyethylene glycol, and banded in a gradient of CsCl[9]. The virus was dialysed in 0.015 M Tris-HCl, *p*H 7.6 buffer containing 0.01 M $MgSO_4$, and before use it was diluted into 1 ml. of Earle's balanced salt solution without bicarbonate (Earle's BSS) and passed through 'Millipore' filters (0.45 μm pore size). The filters were rinsed with an additional 1 ml. of Earle's BSS. The cells were infected by the addition of 2 ml. of λ virus (5×10^{10} p.f.u.) in Earle's BSS. The virus was allowed to adsorb for 1 h with gentle rocking at 37° C, followed by the addition of 10 ml. of tissue culture media. Incubation was conducted at 37° C in an atmosphere of 5% CO_2 in air. The cellular RNA was labelled by removing the media and adding 10 ml. of fresh media plus 100 μCi of ^3H-5-uridine (Lot No. 1745–40 from ICN, 21.7 mCi/mmol). The cells were incubated a further 24 h, rinsed twice with phosphate buffer saline (calcium and magnesium-free), and trypsinized. The RNA was extracted using SDS to break the cells followed by phenol, chloroform–isoamyl alcohol extractions and DNAase digestions using the method of Biswal and Benyesh-Melnick[10]. The extracted RNA was precipitated with ethyl alcohol and resuspended in a solution containing 0.003 M EDTA (adjusted to *p*H 7.4 with HCl). Hybridization was carried out in 6 × 50 mm test tubes in a total volume of 0.480 ml. containing a final concentration of 2 × SSC and 50% formamide. Cellulose nitrate filters (Schleicher and Schuell, B-6) containing 50 μg of denatured DNA each (the DNA is in excess at this concentration) were placed in the tubes and the ^3H RNA was added. The tubes were sealed and incubated at 37° C for 24 h (hybridization was complete within 24 h). These filters were then extensively washed with 2 × SSC, treated with 20 μg of RNAase A (Worthington) and 10 units of RNAase T_1 (Sankyo) at 37° C for 10 min. They were again washed with 2 × SSC and incubated in 2 ml. of 1 × SSC containing 70% formamide for 10 min at 37° C. The filters were again washed with 2 × SSC, dried, and counted in a Nuclear Chicago refrigerated scintillation counter (model 8914). The scintillation system contained 12 g of BBOT (Packard)/gallon of toluene. This hybridization technique was developed as a modification of the Gillespie and Spiegelman[11] method by M. Das and S. Spiegelman (personal communication). All spent medium was tested for bacterial contamination by inoculating 0.5 ml. of medium on to tryptone plates and into 10 ml. of fresh tissue culture media without antibiotics. These were been assayed through repeated subcultures and enzyme activity has remained relatively constant at the level achieved 4 days after infection. All eight λpgal virus preparations give similar results. Cells were grown in the presence of strepto- cultured for 5 days at 37° C and at room temperature. Cells were also periodically monitored for mycoplasma contamination. All such tests were negative.

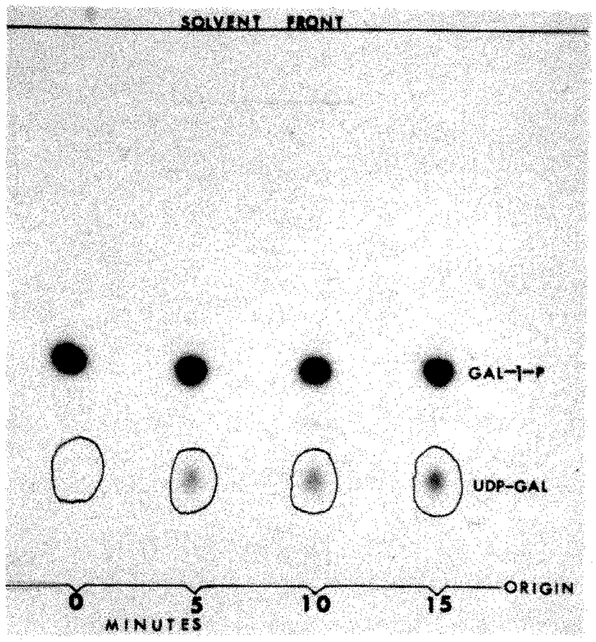

Fig. 2 Chromatography of 5 μl. aliquots at 5 min intervals from an assay for α-D-galactose-1-phosphate uridyl transferase activity. The ^{14}C-Gal-1-P reactant is clearly visible in the autoradiogram, while the product UDP-Gal becomes more visible as its concentration increases. The circles represent a UDP-Gal marker (non-radioactive). Cells (5×10^5, normal rat fibroblasts) were grown as described in Fig. 1, and scraped off the wall, centrifuged (1,400*g* for 5 min), rinsed in PBS (calcium and magnesium-free) and resuspended in 20 μl. of glycine buffer (0.08 M, *p*H 8.7). Sodium dilauryl sulphate (2 μl. of 0.2% solution) was added and the cells were freeze–thawed three times and centrifuged at 12,000*g* for 2 min. The supernatant was then assayed for transferase activity and protein concentration was determined by the Lowry method[15]. The reaction mix contained 5 μl. of D-galactose-^{14}C-1-phosphate (4.5×10^{-4} M, New England Nuclear Corp., 227 mCi/mmol)*, 5 μl. H_2O, 5 μl. of glycine buffer (1 M, *p*H 8.7), 10 μl. of UDP-glucose (4×10^{-4} M) and 10 μl. of crude cell lysate. The reaction was performed at 37° C and 5 μl. aliquots were removed and applied to the thin-layer chromatography plates PEI (Brinkman). Unlabelled UDP-Gal (2 μl. 10 μmol/ml.) was spotted at the origin as a marker. The chromatogram was run for 4 cm in 1 N formic acid and 17 cm in 2 N sodium formate, *p*H 3.6. The position of the UDP-Gal could be determined by the ultraviolet absorption of the unlabelled marker. Similar results were obtained by using DEAE paper ('Whatman DE81') with 0.015 M $Na_2HPO_4 \cdot 7H_2O$ and 0.15 M citric acid, *p*H 3.8; however, this system gave a higher background. Autoradiography of the chromatogram was performed with X-ray film ('Kodak NS-2T') and the UDP-Gal spots were cut out and placed in a toluene-TLA (Beckman) scintillation system for quantitative counting. A Beckman LS250 scintillation counter was used.

* Commercial Gal-1-P gives a relatively high background in this system (1,000 c.p.m.); however, it is possible to purify this material by utilizing the PEI thin layer chromatography system described above. The Gal-1-P is located by autoradiography and the spots cut out. These are washed twice with 1 litre of distilled H_2O and then placed in 100 ml. of 0.5 M LiCl for 20 min. The LiCl solution is then decanted off and passed through a 'Dowex 50' column, 5 mm × 20 mm (which was previously washed with 0.5 M LiCl). The column effluent was diluted fifty times and pumped through a 'Dowex 1' column (which was previously washed with 2 M ammonium formate and then with distilled H_2O). The column was eluted with 1 M formic acid and the Gal-1-P collected. The sample was freeze dried and brought to the desired concentration with distilled water. This purified Gal-1-P gives a background of about 100 c.p.m.

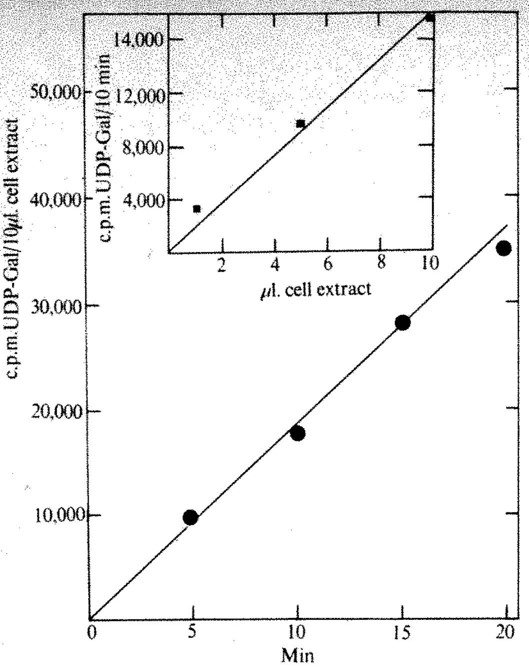

Fig. 3 Linearity of the α-D-galactose-1-phosphate uridyl transferase assay as a function of time. Inset demonstrates the linearity of the assay as a function of protein concentration. The cells used in this assay were galactosemic human fibroblasts infected with a multiplicity of infection of 6×10^4 phage plaque forming unit equivalents of λpgal T$^+$ DNA*. The DNA was added to three flasks, each containing 5×10^5 cells, in 2 ml. of Earle's BSS with 75 µg/ml. of DEAE-D (MW$=10^6$, Pharmacia)[16]. This DNA was allowed to adsorb for 1 h with gentle rocking at 37° C, followed by the addition of 10 ml. of tissue culture medium and incubated for an additional 95 h at 37° C in an atmosphere of 5% CO_2 in air. The cells were harvested and the assay performed as described in Fig. 2.

* 1 µg of λDNA $=2\times10^{10}$ p.f.u. equivalents, based on a molecular weight of $\lambda=3\times10^7$. Phage DNA was obtained by phenol extraction of 3 ml. of phage with an equal volume of freshly distilled phenol equilibrated with 2×SSC followed by an extraction with isoamyl alcohol and chloroform (1 : 100), and a second phenol extraction. The DNA was treated with 1 mg of pronase in 1 ml. of Tris-HCl (0.1 M, *p*H 7.5) buffer containing EDTA (0.003 M) for 5 min followed by three more phenol extractions and two ethyl ether extractions. It was then exhaustively dialysed against 2×SSC at 4° C.

mycin (50 µg/ml.) and penicillin (100 U/ml.). Mycostatin (50 U/ml.) was tested in cultures with no effect on enzyme production or λ-specific RNA levels. Cycloheximide (1 mg/ml.) which blocks protein synthesis in mammalian cells[19] but not in bacteria[20] prevented enzyme production in cultures infected with λpgal T$^+$. These cultures were monitored for bacterial and mycoplasma contamination in the same manner as in the hybridization study.

We determined whether λpgal T$^+$ enhances intracellular galactose metabolism. Morphological evidence of metabolic stress (granular cytoplasm, rounding up and detachment from the surface of the flask) could be detected in galactosemic cells after 72 h incubation with galactose as sole hexose source. Cells infected with λpgal, however, have survived from 1 to 3 weeks longer than control cells when both were grown in media containing 1 mg/ml. galactose and dialysed foetal calf serum. Normal human fibroblasts have survived in this medium for at least 1 week longer than any galactosemic cells infected with λpgal T$^+$ virus. Furthermore, galactosemic fibroblasts exposed to λpgal T$^+$ produce more $^{14}CO_2$ from galactose-1-^{14}C than uninfected fibroblasts (our unpublished observations).

The possibility of contaminating organisms giving rise to the data is remote as subcultures of the spent medium in thioglycollate and trypticase soy broths showed no growth, nor did cultures on tryptone plates and tissue culture media without antibiotics, and the cells were periodically shown to be free of mycoplasma. The presence of organisms in numbers sufficient to yield the transferase data (5×10^5 *E. coli*, N205) should have been detected easily and, furthermore, no *E. coli* specific RNA was detected in the hybridization experiments. As the cells were cultured in penicillin and streptomycin, the contaminant would be insensitive to these antibiotics as well as mycostatin, but inhibited by cycloheximide. As a further control 10^6 λ lysogens (*E. coli* M5107), were added to a culture of galactosemic fibroblasts and labelled for 24 h with ^{3}H-uridine. These cells were then washed in the normal manner, leaving only the fibroblasts bound to the flask surface. No λ-specific RNA could be found by hybridization, indicating that the λ-specific RNA is not produced by an *E. coli*-like organism. The possibility that the λpgal T$^+$ virus is merely transporting enzyme into the cells can be discounted as the enzyme is produced by cells infected with pronase-treated λpgal T$^+$ DNA.

The detection of λ-specific RNA supports the occurrence of transcription, while the lack of enzyme production in the presence of cycloheximide indicates that translation is necessary for transferase activity.

The experimental conditions used by us do not permit a differentiation between the various models of phage gene preservation within mammalian cells. The detection of both λ-specific RNA and transferase enzyme activity 41 days after infection with no decrease in levels indicates that the genome is not being segregated out in these conditions of growth. The phage DNA may be preserved by any of the following mechanisms: integration into the host genome, plasmid-like existence in the cytoplasm, interaction with the mitochondria (known to have some bacteria-like properties), or perhaps in some totally unknown manner.

Our results suggest that it might be possible to introduce a selected bacterial gene into human cells *in vivo*, using phage as a vehicle, and significantly to alter a specific metabolic pathway. Our results also agree with recent evidence[21,22] that there are much greater biochemical similarities between far ranging living species than had been appreciated previously[23].

We thank Dr M. Gottesman, S. Spiegelman, R. L. Kirschstein, G. L. Cantoni and R. S. Krooth for their support and encouragement.

PHYSICAL SCIENCES

Further Data on the Optical Variable PKS 1514-24

Biraud[1] and Bond[2] have drawn attention to the close agreement in position between the variable star AP Lib and the radio source PKS 1514–24. The optical object, which was originally classified by Ashbrook[3] as an irregular variable, exhibits chaotic variations[1] in brightness over time scales of hours and days. Although the optical position given by Ashbrook[3] is not precise, there seems to be little doubt that this object is associated with the radio source. However, it is important for further investigations that the radio-optical association be more firmly established by the measurement of accurate radio and optical positions.

Radio observations of PKS 1514–24 were carried out in 1971, July 31 and August 1–2, using the pencil beam response of the cross-type telescope at the Molonglo Radio Observatory. The operating frequency is 408 MHz and the antenna beamwidth is 2′.6 EW × 2′.9 NS at this declination. Six nearby sources with accurately known positions and flux densities were also observed on each day to calibrate the telescope pointing and gain.

The optical position of AP Lib was measured on the glass copies of the Palomar Sky Survey. The techniques used for these measurements have been described in detail before[4]. The position was determined with respect to nine reference stars from the Smithsonian Astrophysical Observatory star catalogue. Measurements were made on both the E ("red") and O ("blue") plates; the two estimates agreed to within 0″.2 arc.

Table 1 Radio and Optical Data for PKS 1514-24 and AP Lib

	R.A. (1950.0)	Declination (1950.0)
AP Lib	15 h 14 m 45.28 s ±0.03 s	−24° 11′ 22″.9±0″.4
PKS 1514–24	15 h 14 m 45.64 s ±0.09 s	−24° 11′ 20″.6±1″.6
Peak flux density at 408 MHz	1.75±0.05 flux units *	

* 1 flux unit = 10^{-26} W m^{-2} Hz^{-1}.

The radio and optical positions with their standard errors are shown in Table 1. The errors in the 408 MHz radio position and peak flux density were obtained by combining the calibration uncertainty and the internal scatter among the three scans. The flux density is based on the absolute scale of Wyllie[5]. Following the procedure outlined earlier[4], the errors in the optical position represent the mean of the r.m.s. residuals for the two plate solutions. A comparison of the radio and optical positions shows that they do not in fact coincide within the errors. The difference of 4″.9 arc in right ascension corresponds to 3.8 combined standard errors and certainly appears significant, although the declination difference of 2″.3 (1.4 σ) may not be real. The radio position in Table 1 is supported by the 1,425 MHz position of Fomalont and Moffet[6] as well as by an earlier but less precise R.A. measurement by Hoskins and Murdoch[7]. There is evidence in the pencil beam scans for a weak confusing source ~0.2 flux units lying 2–3′ E and ~1′ N of the main source. A possible bias in the fitting process caused by the presence of this additional source may partly explain the observed radio-optical discrepancy. However, the narrower Molonglo fan beam is not affected by this weak source and a more accurate determination based on further scans in 1966 (D. G. Hoskins, private communication) gives the fan beam R.A. as 15 h 14 m 45.61 s ± 0.18 s (1950), in excellent agreement with the present value. It will therefore be important to carry out observations at higher resolution to search for possible small scale structure.

Table 2 Flux Densities (Flux Units) of PKS 1514-24 Measured by Different Observers and Arranged in Chronological Order

Observatory	Approx. epoch	Ref.	Frequency (MHz) 408	1,410	2,650	5,000
Parkes	1963	8	5.3±0.9	2.7±0.2	2.1±0.2	
Parkes	1964	9			1.8±0.15	
Owens Valley	1965	6		2.32±0.10 *		
Parkes	1966	10	2.6±0.4 †			
Molonglo	1966.32	7	1.9±0.3			
Parkes	1968	11				1.94±0.05
Molonglo	1971.58	Here	1.75±0.05			

Errors have been obtained directly from the references cited.
* Flux density at 1,425 MHz.
† Flux density measured at 468 MHz with the Parkes interferometer.

The published spectral data for PKS 1514–24 are given in Table 2 and the more recent measurements indicate an extremely flat spectrum. The apparent discrepancy between the two low frequency flux densities measured at Parkes[8,10] is only partly resolved by the detection[10] of a 1.4 flux units confusing source in the Parkes beam. Additional scans with the Molonglo pencil beams confirm the existence of an extended source lying 12′ E and 17′ N of PKS 1514–24. This source has an integrated 408 MHz flux density of 1.6±0.1 flux units and no further sources >0.3 flux units were found within ±30′ in R.A. or ±20′ in declination. Therefore, although there is no convincing evidence for variability, it seems possible that a secular decrease in 408 MHz flux density has occurred. Some support for this conclusion is given by the marginally significant decrease at 21 cm. A more definite indication of radio variability, however, must await further observations at all wavelengths.

When proposing the identification of PKS 1514–24, Bolton, Clarke and Ekers[12] classified the optical object as a 16 m elliptical galaxy. The object is reclassified by Westerlund and Wall[13] as an N-type galaxy, which is more consistent with its appearance and UBV colours. AP Lib lies very close to the centre of the Sky Survey plates (epoch 1955.3; seeing 3) and the image on the E plate is clearly non-stellar with an irregular nebulous envelope of small extent. The total diameter is $\sim 10''$ arc and there appears to be a small prominence or "jet" on the eastern limb; this feature lies very close to the 408 MHz radio position. There is further evidence for faint extensions to the north.

On the Palomar O plate the image is most unusual. The halo is of smaller extent and there seems to be a number of narrow radial filaments distributed around the disk and extending about $5''$–$10''$ arc from the nucleus. A close comparison of the E and O plates shows that the position angles for several of these filaments are correlated on the two plates. While recognizing that there are problems involved in correctly identifying weak features which are of the same order as the grain size of the emulsion, a careful examination shows no similar peculiarities in any of the nearby stellar or non-stellar images. Large scale photographs taken in good seeing will obviously be necessary to confirm the existence of these nebulous filaments.

It is worth considering further the possible similarity[1] between AP Lib and the peculiar variable object BL Lac (=VRO 42.22.01)[14,15]. Macleod and Andrew[14] have reported a faint envelope around BL Lac, although an examination of the Sky Survey prints shows it to be much less obvious than the nebulosity surrounding AP Lib. Photometric observations of the two objects[13,16,17] place them close together on the two colour diagram and more towards the domain of the N galaxies than the region occupied by the quasi-stellar objects. Neither object shows the presence of emission lines in the optical spectrum[16,18,19]. If the conventional interpretation of radio spectra applies, then the inverted spectrum of BL Lac suggests it is a much younger source than AP Lib. A final point of interest concerns the recent discovery that two further radio sources ON 231 and B2 1215+30 are also associated with bright variable objects[1,20,21] of neutral colour and unusual appearance. It is therefore tempting to speculate that these four objects may belong to a new class of highly active discrete sources.

I thank Dr A. J. Turtle for assistance with the radio observations and for helpful discussions. This work was supported by grants from the Australian Research Grants Committee, the Sydney University Research Grants Committee, and the Science Foundation for Physics within the University of Sydney.

Cosmological Evolution in Radio Galaxies

ROWAN-ROBINSON has presented evidence that radio galaxies exhibit remarkably strong evolutionary effects with cosmological epoch[1]. Examination of his evidence, however, indicates that, although an evolutionary effect may indeed be present, no reliable estimate of the time scale involved can yet be made in the way he proposes. This is because (i) the mean value of $V/V_{\rm max}$ (defined by Rowan-Robinson) is very sensitive to changes in the limiting magnitude assumed for the sample, and (ii) the redshift corrections (*K*-corrections) which have to be applied to the apparent magnitudes of the fainter radio galaxies (for which the evolutionary effects appear to be strongest) are not sufficiently well known. These effects will now be considered in turn.

(i) In this section I shall follow the procedure of Rowan-Robinson but make use of a slightly smaller yet more complete body of data (199 out of the 220 sources used by Rowan-Robinson). These sources are all those in a statistically complete sample of 199 extragalactic radio sources from the revised 3C survey which have been mapped with high resolution at declinations $\delta > +10^\circ$ and more than 10° from the galactic plane. It is only within this area of sky that all the sources in the revised 3C catalogue have been mapped with high resolution and for which identifications have been established with a fair degree of reliability[2-4]. Following Rowan-Robinson, I have estimated $x = V/V_{\rm max}$ in an Einstein–de Sitter cosmological model for each source in the complete sample known to be a radio galaxy. In making these calculations I have used the radio spectral data of Kellermann, Pauliny-Toth and Williams[5], and the optical spectral data (*K*-corrections) of Oke and Sandage[6]. The latter are only available for redshifts $z < 0.28$ (at which redshift a galaxy would have an apparent visual magnitude $m_v = 19.0$ if its absolute magnitude $M_v = -21.60$, the mean for all the galaxies in the sample with a measured redshift) and it has therefore been necessary to extrapolate the data of Oke and Sandage to give $K_v{}^6 = 1.05$ and 1.25 at redshifts of 0.32 and 0.37 respectively. Although it will be shown later that the *K*-corrections of Oke and Sandage may not be appropriate for distant radio galaxies, they probably give a good description of the spectral properties of nearer, less luminous radio galaxies and have been used here, in the absence of any alternative data. The procedure was to fix the radio flux density limit 9×10^{-26} W Hz^{-1} sr^{-1} at 178 MHz (the limiting flux density of the 3C(Rev) catalogue), to vary the limiting apparent visual magnitude m_v in 0.1 magnitude steps between 17.75 mag and 20.35 mag and estimate the mean value $\bar{x}$ for each limiting magnitude. The results are shown in Fig. 1; the error bars represent the standard deviation in the mean expected for n values of x uniformly distributed between 0 and 1, equal to $(12\,n)^{-0.5}$. The number of sources which have contributed to $\bar{x}$ is shown above each point. As the limiting magnitude is increased, progressively more objects are included in the sample which determines $\bar{x}$. In most cases the apparent magnitudes used have been estimated from the plates and prints of the Palomar Sky Survey since very few photoelectric V magnitudes have been measured for faint radio galaxies. Because of the consequent uncertainty most are quoted[7] only to the nearest half magnitude and the number of sources which contribute to $\bar{x}$ correspondingly increases in jumps every half magnitude. If the apparent magnitude limit is chosen just to include galaxies with m_v equal to one of these discrete values, then each will contribute a value of $x \sim 1$ to $\bar{x}$ and produce the

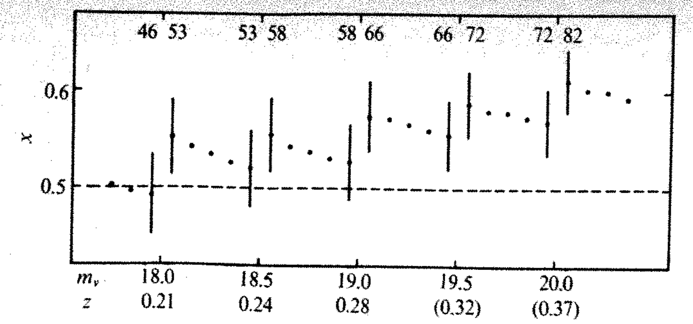

Fig. 1 The value of $\bar{x}$ (defined by Rowan-Robinson[1] and in the text) determined for samples of radio galaxies brighter than magnitude m_v. The number of sources which contribute to each value of $\bar{x}$ is shown above the point, and the expected standard errors in the mean (see text) are shown by the vertical bars. The mean absolute visual magnitude for all the radio galaxies in the present sample (excluding 3C231) with a measured redshift is $M_v = -21.60$. The redshifts at which a galaxy of this absolute magnitude would have the apparent magnitudes in the diagram are shown below each number. The values for $m_v > 19.0$ are based on an arbitrary extrapolation from the available data and are likely to be particularly unreliable.

jumps found in Fig. 1. As the magnitude limit is again increased, no further sources contribute to $\bar{x}$, so that the contribution of the faintest galaxies decreases from $x \sim 1$ and $\bar{x}$ slowly decreases. Eventually the next discrete value of m_v is reached when another jump in $\bar{x}$ occurs. The values quoted by Rowan-Robinson are found to agree well with the peak values in each saw-toothed cycle of $\bar{x}$ but it is obvious that they give an exaggerated measure of the variation of $\bar{x}$ with m_v. Rowan-Robinson has attempted to reduce this effect when estimating the rate of evolution of sources, but the rest of his discussion concentrates on the values of $\bar{x}$ and not the weighted $\bar{x}^*$. Both his results and the present results, taken at face value, still suggest that $\bar{x}$ becomes increasingly different from 0.5 as fainter limiting magnitudes are approached and that this difference is greater than the expected error in the mean for every point fainter than 19.0 mag. Unfortunately they cannot be taken at their face value because of the uncertainty of the *K*-corrections.

(ii) It is found that the sources with $v/v_{\max}$ determined by the optical limit of the sample contribute systematically larger values of x to the mean $\bar{x}$ than do those for which $v/v_{\max}$ is set by the radio limit. For example, the twelve sources which are optically limited contribute an average value of 0.679 to the point with the faintest limiting magnitude, while the seventy which are radio flux density limited contribute an average of 0.574 to $\bar{x}$. This difference becomes progressively less marked as brighter limiting magnitudes are approached and is due partly to the effect of the *K*-corrections. If appropriate *K*-corrections had been used this difference would in no way invalidate the volume-luminosity test or the evolutionary conclusions that may be drawn from it. But there is reason to believe that the *K*-correction given by Oke and Sandage may be substantially different from those appropriate when correcting the apparent magnitudes of distant radio galaxies with strong emission line spectra.

The values given by Oke and Sandage[6] are based on observations of the spectra of the nuclei of several nearby giant *E* and *SO* galaxies and *M*31. The composite spectrum from which the *K*-corrections were determined decreases very sharply for wavelengths shorter than 5000 Å, so that galaxies of this type which are at redshifts large enough for this part of their spectrum to be displaced into the visual band (centred on λ 5500 Å) will appear relatively faint. For redshifts $z > 0.2$, the *K*-corrections are therefore large and strongly redshift-dependent. A small increase in the redshift of such a galaxy will make it relatively much fainter, so that a source with $v/v_{\max}$ determined optically will tend to have $x > 0.5$. In addition *K*-corrections have not been determined[6] for redshifts $z > 0.28$ (corresponding to $m_v = 19.0$ for a typical radio galaxy) where the greatest differences between $\bar{x}$ and 0.5 are found, and it has been necessary to extrapolate from the available data at lower redshifts. The composite spectrum used by Oke and Sandage was obtained from galaxies which are almost entirely free from emission lines, whereas all but 4 of the 24 radio galaxies with $z > 0.1$ listed recently by Burbidge[8] have strong emission lines, which must obviously affect the *K*-correction. The spectrum of 3C405 (Cygnus A) is entirely dominated by the strong emission lines[8], nearly all of which have wavelengths shorter than 5000 Å. The optical spectra of distant radio galaxies are not well established but in many respects they appear to be intermediate between those of elliptical galaxies and quasars[8,9].

Sandage has estimated *K*-corrections for quasars[10] and, for the red-shift range $z = 0.1$ to 0.4, although they are much less reliably determined they are probably of similar magnitude but of opposite sign to those for elliptical galaxies. A lower limit to $\bar{x}$ of 0.53 ± 0.035 at a limiting visual magnitude of 19.5 is set if all the sources were limited by their radio flux density. Any *K*-corrections can only increase this value, but plausible values for the *K*-corrections could give values of $\bar{x}$ different from 0.5 by more than one standard deviation only for the faintest radio galaxies. The uncertainties in the magnitudes of these galaxies of between 0.5 mag and 1 mag[2-4,7] are such as to make any interpretation of this difference in terms of an evolutionary effect rather unreliable. The present results suggest, however, that Rowan-Robinson has substantially over-estimated the rate of evolution in radio galaxies. It is clear that, until accurate spectrophotometric data are available for a sample of distant radio galaxies, it will not be possible to determine the cosmological evolutionary properties of these objects with any confidence by the method used by Rowan-Robinson.

I thank Drs J. R. Shakeshaft and M. S. Longair for discussions on this subject, and the Science Research Council for a research fellowship.

Reply to Mackay

FIRSTLY, Mackay raises the issue of the completeness of the sample I used. The restriction to sources with declination greater than 10° and further than 10° from the galactic plane which he suggests does not materially affect the results I obtained (6 of the sources I used would have to be omitted).

The discontinuous dependence of the mean value of $x = v/v_{\max}$, $\bar{x}$, on the chosen limiting optical magnitude is dealt with by using the quantity $\bar{x}^*$, explained in my article[1]. The quantity $\bar{x}^*$ is by definition a continuous function of limiting optical magnitude and in fact, by taking the values given on line 6 of my Table 1, Mackay would have noted that it runs smoothly through the middle of the points plotted in his Fig. 1.

On the question of *K*-corrections for galaxies, I should explain that Oke and Sandage's[2] *K*-corrections for the "standard giant elliptical" played no part at all in my argument about 3C radio galaxies, so that Mackay's polemic seems rather misdirected. What I actually did was to determine a mean relation between estimated visual magnitude and redshift empirically, and then used this to estimate redshift in the cases where it is not yet known. Now it is true that below 19th magnitude this relation is essentially an extrapolation, since only one radio galaxy fainter than this has had its redshift measured. But on the one hand the result is still significant if attention is confined to galaxies with $V \leqslant 19$: and on the other the result is very insensitive to what extrapolation is used.

Over the redshift range $0 < z \leqslant 0.4$, Oke and Sandage's *K*-correction for the standard giant elliptical can be approximated by $K_\nu \sim 2.2\, z$, whereas Sandage's[3] composite spectrum for quasars gives, over the same redshift range, roughly $K_\nu \sim -2.0\, z$. *N*-galaxies, which have colours intermediate between ellipticals and quasars[4], may then be presumed to have *K*-corrections in the range $K_\nu \sim (0 \pm 2)\, z$. For $V \geq 17$, *N*-galaxies already constitute half the data from which my mean empirical V-*z* relation was determined. Thus our ignorance of the appropriate *K*-correction for radio galaxies can be expressed by saying that the quantity *B* in my equation (1) is uncertain by ±2 from this cause (there may well be other systematic errors).

In fact I find that $\bar{x}^*$ is hardly changed if *B* is changed by ±5, and the corresponding values of the evolutionary parameters given in my Table 2 remain within the uncertainties quoted there. From the fact that a luminosity evolution of strength $(1+z)^6$ is needed to reduce $\bar{x}^*$, corrected for this evolution, to 0.5, I would infer that the optical spectra of galaxies would have to behave like $P(\nu) \propto \nu^5$ to be the sole cause of the effect reported. Such objects would hardly have been overlooked by those making the identifications.

It is, incidentally, absurd to say, as Mackay does, that the difference between $\bar{x}$ for sources with $\nu_{\max}$ determined by the optical and radio limits respectively "is due to the effect of the *K*-corrections". A difference is entirely to be expected, since a galaxy near the optical limit must be one of the most distant in the sample, whereas one near the radio limit may be either near or far, due to the vast range of radio luminosities found in galaxies. Thus the effects of evolution will be greater for the optically limited sources. A detailed calculation, including the effects of the dispersions in optical and radio luminosity, shows that the evolutionary rates quoted in my Table 2 give practically the same ratio of $(\bar{x}-0.5)$ for optically limited sources to $(\bar{x}-0.5)$ for radio limited sources as that given by Mackay, whether quasar or elliptical galaxy colours are assumed.

Two effects, neither of them discussed by Mackay, could explain part, or possibly all, of the results I obtained.

(i) The radio galaxies that have had their redshifts measured are totally unrepresentative of the remainder. In other words, an entirely new class of objects is going to be discovered when spectra are taken of the remaining 3C radio galaxies (for example nearby dwarf radio galaxies). Fortunately a number of observers are now taking spectra of these galaxies, so that this hypothesis will shortly be tested.

(ii) A large proportion of the identifications of radio sources with faint galaxies could be mistaken. Although I gave a simple argument in my paper which suggested that the number of chance identifications should be small, it is impossible to be totally confident about this. It has to be borne in mind that the number of faint galaxies per square degree is not well known. If it were substantially more than is generally assumed (implying, incidentally, a strong evolutionary effect in the distribution of galaxies!), many of the associations of radio sources with 19–20th magnitude galaxies could be mistaken.

I thank Dr Mackay for showing me his paper in advance of publication, and Professor F. Hoyle for the hospitality of the Institute of Theoretical Astronomy, Cambridge where the additional calculations in this note were done.

Interaction of Gravitational and Electromagnetic Fields or Another Effect?

THERE have been many articles recently on the interpretation of certain anomalous effects observed in frequency and interplanetary time delay measurements in terms of the interaction of gravitational and electromagnetic fields[1-6]. Usually the proposed explanations are inconsistent with the general theory of relativity[2,5,7,8], and often the predicted effects do not match the measurements. We show here that in the interpretation of the anomalous phenomena there is no need to contradict general relativity and the different measurements can be reconciled[4,9,10].

The anomalous phenomena can be quite satisfactorily explained by attributing them to the interaction of the electromagnetic field and the moving, inhomogeneous media traversed by the signal. Model computations show that in the time delay and light deflexion measurements the magnitude of this effect is about the same as or less than the measurement errors, but in the frequency measurements the effect exceeds the noise level[11].

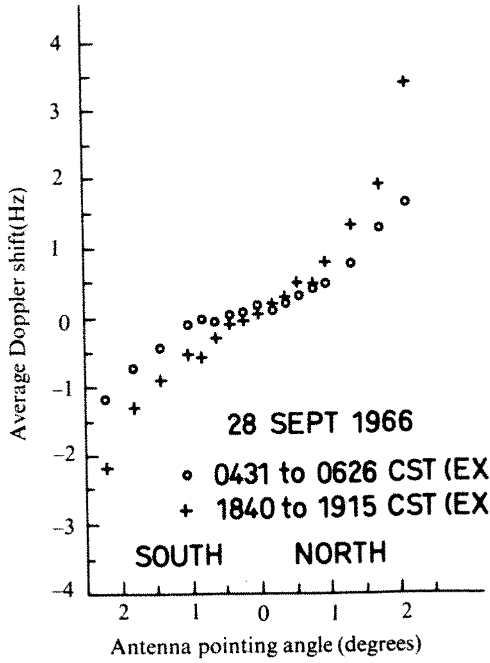

Fig. 1 Average Doppler shifts against azimuthal antenna pointing angle measured at 960 and 810 MHz using a 230 km closed loop circuit. The crosspath component of wind speed was from the north-west at all altitudes above approximately 400 m and its magnitude averaged at several m s^{-1} (after Birkemeier *et al.*[15]).

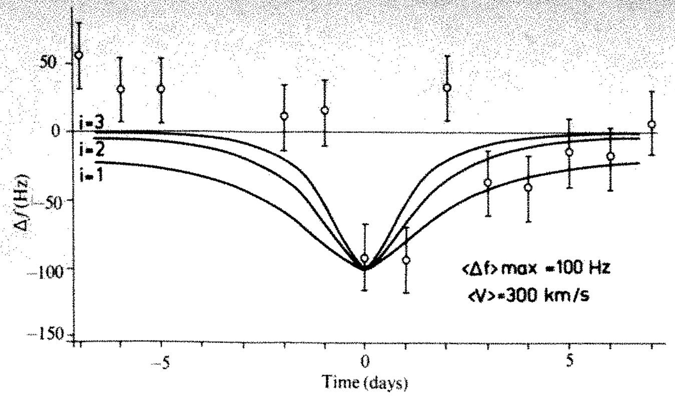

Fig. 2 Frequency decrease of the 21 cm radiation of Taurus A when it passed near to the Sun. Comparison of theoretical curves[11] resulting from the secondary effect of high velocity streams in the solar corona and combined result of 1967–68 measurements[2]. Zero time corresponds to the closest approach of the Sun.

The crux of the phenomenon is the simple physical fact that an electromagnetic wave propagating in matter inevitably interacts with the particles of the matter. This effect is usually described by the "material parameters"—the refractive index, permeability, permittivity and so on. In the case of moving media, however, one must not forget that the velocity of the signal source (and hence the location of emission, the "particle" which took part in the preceding interaction and so on) and that of the "particle" just interacting with the signal are generally not equal. Thus the "particle" observes and reradiates an electromagnetic wave, the characteristics (field intensity, frequency and so on) of which are changed according to the theory of relativity. Because the existence of an absolute system of coordinates is precluded by the theory of relativity, the phenomenon can be investigated only by tracing stepwise the path of the signal[12–14]. This is the method of relativistic ray-tracing—a search for a solution in a closed form is being made. The interaction, of course, depends on the frequency of the signal.

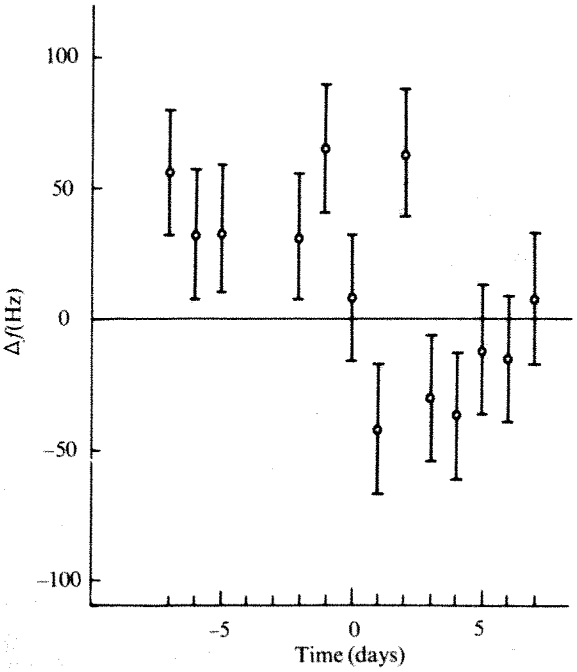

Fig. 3 Residuals of the frequency decrease of Taurus A 21 cm radiation after rejecting the theoretical value of the secondary effect. The resulting pattern can be attributed to the axial rotation of the Sun[11].

For computation purposes the moving medium is decomposed into constant velocity layers, which are also generally inhomogeneous: at the individual layer boundaries the coupling of the solutions is obtained from rigorous computations of the Doppler effect, aberration and so on. In this way the changes in the signal parameters can be studied adequately. In this communication only the frequency changes, which can be measured more reliably, will be discussed.

The frequency change due to moving inhomogeneous media was first observed by Birkemeier *et al.*[15] in terrestrial troposcatter measurements. The results were originally interpreted in terms of a mechanical model involving a "moving mirror"[15] (an optical method), but a more exact method was subsequently developed[12]. The influence of wind on the frequency of the wave propagating between two fixed stations can be seen in Fig. 1.

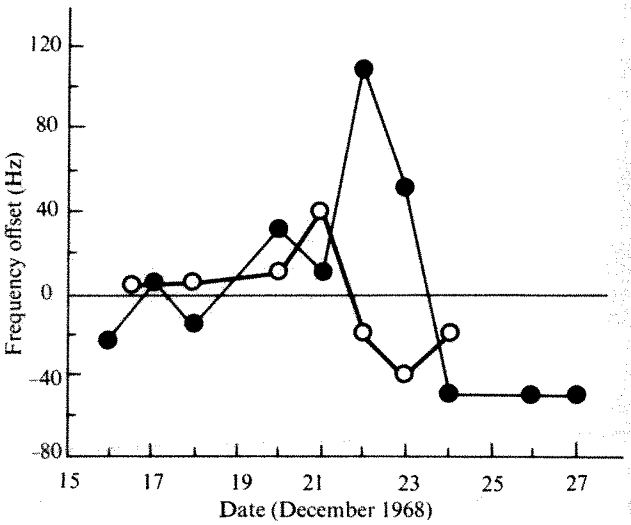

Fig. 4 Apparent frequency shift of the 1,612 MHz OH emission feature from W28S. The closest approach of the Sun occurred on December 21, 1968. ●, Agassiz data; ○, Haystack data (after Ball *et al.*[10]).

An active discussion on the frequency decrease of the 21 cm radiation when the source passed near to the Sun was initiated by the experiments of Sadeh *et al.*[1–3]. The measurements were not very reliable and their interpretation met serious difficulties[11]. According to our model computations, the redshift of the order of 10^{-7} observed near the occultation of Taurus A by the Sun is produced by high velocity streams in the solar corona. The magnitude of this effect may amount to several parts in 10^{10} to 10^{7} (Fig. 2). The residuals can be attributed to the average motion of the solar corona due to the axial rotation of the Sun (Fig. 3), which is in good agreement with the measurements carried out later by Ball *et al.*[10] (Fig. 4). Because of the strongly varying solar streaming pattern, the overall effect measured may exhibit significant variations but the effect of axial rotation is always present.

The problem of the so-called solar limb effect has remained unsolved for nearly half a century. This phenomenon is evident at the extreme of the solar limb (at radial distances greater than about 95% of the radius of the disk) where the Fraunhofer lines exhibit a redshift substantially exceeding the gravitational shift—0.636 km s^{-1} (refs. 16–23). In the inner parts of the Sun (at distances greater than about 0.5′ to 1′ from the limb) the variation of wavelengths has been successfully described in terms of source (transmitter) motions or motions of the location of absorption (receiver) due to the solar currents[24]. The interaction we proposed at that time was still not considered. Based on the streaming patterns adopted for the Sun we carried out accurate model computations

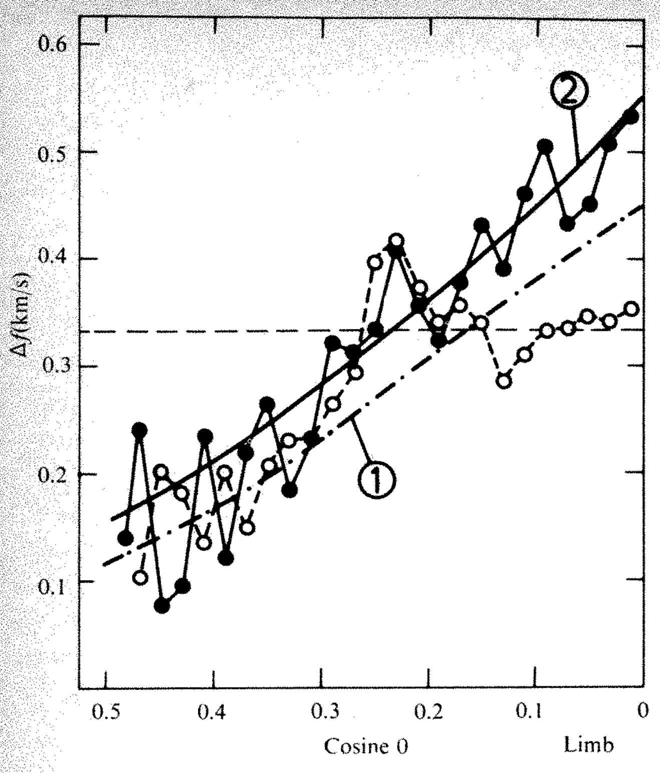

Fig. 5 Comparison of the limb effect determined by Adam[21] and theoretical curves[25]. Δf is the frequency difference from the centre value, θ is the angle between the line of sight and the radius connecting the observed point with the centre of the Sun. ●, East limb observations; ○, west limb observations; - - -, gravity shift; 1, corresponds to Schröter's radial current model[24] ($v=0$, 3 km s^{-1}); 2, a similar fit to the east limb data ($v=0.57$ km s^{-1}).

which resulted in a good interpretation of the anomalous redshift measured at the limb[25] (Fig. 5) because of the radial expanding character of the currents.

It follows that the development of new theories to explain the measured "anomalous" phenomena do not seem to be justified. Such theories will only be required if reliable measurements show anomalous effects differing from the effects of moving media. As far as we know such effects have not yet been observed. The high redshift values observed for quasars will probably be partly explained in terms of high velocity material motions (expansion and so on) associated with them. Finally it must be pointed out that the evaluation of interplanetary occultational experiments (Mariner, for example) requires great care, because motions in the medium of propagation may introduce additional terms. Similarly, in the very accurate measurements of satellite geodesy the ionospheric motions must be taken into account.

Age Determinations of Recent Hawaiian Lavas using Measurements of Weathering Changes

HAWAII has many recent lava flows in the age range of 200 to 1,000 years BP but carbon-14 dating of these flows is usually not possible because adequate carbonaceous material is difficult to find. Other isotopic methods, such as potassium–argon and thorium–lead ratios, and the technique of fission-track dating[1], are not applicable to this time range. Thermoluminescence dating of geologically recent lavas seems possible[2,3] although not yet widely tested. We investigated the possibility of dating late prehistoric flows by measuring weathering changes of surface rocks.

The study area was the eastern slopes of Mauna Loa and Kilauea volcanoes from 40 to 4,000 feet (10–1,200 metres) altitude with a range in mean annual temperature of 22.8°–15.5° C, and mean annual rainfall of 90 to 150 inches (2,300–3,700 mm). The area includes both aa and pahoehoe lava flows which are olivine basalt, basalt, or oceanite in composition[4]. Five dated aa flows, ranging in age from 13 to 218 years, and three undated aa flows were sampled. Sampling sites were selected by taking areas at which rainfall isohyets, suitable for comparative purposes, intersected flows of convenient age.

Small surface rocks (1–2.5 cm in diameter) were taken as representative of the weathered condition while small cubes of rock within large surface boulders (>30 cm diameter) were used as unweathered samples. Using a randomized sampling procedure, either five or ten samples of both weathered and unweathered rocks were collected at each site. The samples were ground to 100 mesh size before analysis and measurements of weathering changes made from the differences found between weathered and unweathered samples.

The principal weathering changes investigated were pH, hydration, oxidation, mineralogical and elemental changes. Many parameters were found to be unsuitable as age indices either because the amount of change in the historic rocks (≤ 218 yr) was too small or because there was no consistent relationship between age and the magnitude of the change measured. The most useful parameters were found to be: ΔpH ($p\mathrm{H}_{\mathrm{KCl}} - p\mathrm{H}_{\mathrm{H_2O}}$ of weathered rocks only), pH difference between unweathered and weathered rocks, percentage losses of total sodium and calcium, percentage gain of titanium, and a 110°–350° C weight-loss measurement of the amount of hydration and adsorbed water.

Table 1 Representative Measurements of Weathered Rock Parameters from Five Hawaiian Lava Flows

Parameter	Mauna Loa 1942 flow	Mauna Loa 1852 flow	Kilauea 1750 flow	Late prehistoric flows of Mauna Loa Lower Stainback	Upper Stainback
No. of samples	10	10	10	5	4
ΔpH* (pH_{KCl}-pH_{H_2O})	−0.22	−0.37	−0.61	−0.67	−0.84
*p*H difference (between unweathered and weathered rocks)	1.28	2.07	2.92	3.52	3.41
% loss of Na	7.2	15.0	13.0	23.5	48.3
% loss of Ca	Not significant	4.8	4.7	9.6	14.3
% gain of Ti	Not significant	2.2	2.3	25.8	30.5
110°–350° C weight loss*	0.78	0.94	2.03	2.87	3.28

* Measurements of weathered rocks only.

Table 1 shows representative results from five flows: historic flows of ages 13, 116 and 218 yr, and two late prehistoric flows whose ages were subsequently estimated at about 360 yr. The results are given in full elsewhere. In Table 1, losses and gains of the elements listed are percentages of the amounts originally present in the unweathered rocks.

The two parameters, *p*H difference and 110°–350° C weight loss, had the highest correlation coefficients with time (0.58 and 0.68 respectively). These parameters were regressed on measurements made of site factors on five sampling sites from the five dated flows, a total of fifty groups of measurements. The site factors were age, mean annual rainfall, mean annual temperature, a plant factor (based on the *p*H of the undecomposed plant litter); and four parameters of the unweathered lava: rock porosity and texture (both rated semi-quantitatively), and titanium and combined calcium and sodium content. The equations obtained were examined for confidence limits, multiple R^2 value and statistically significant regression coefficients, and checked to ensure that the residuals did not show a trend when plotted against time. Three equations were selected which met the above criteria most adequately:

$$(1)\quad (p\text{H difference})^2 = -0.54 - 0.08\ (\text{Na loss}) + 0.27\ (\text{Ca loss}) + 0.03\ (\text{age}) - 0.29\ (\text{porosity}) + 1.21\ (\text{Ti})$$

$$R^2 = 80\% \qquad \text{confidence limits: } \pm 87 \text{ yr}$$

$$(2)\quad 110°\text{–}350° \text{ C weight loss} = 0.66 + 0.008\ (\text{age}) + 0.00005\ (\text{temperature} \times \text{rainfall})$$

$$R^2 = 55\% \qquad \text{confidence limits: } \pm\ 108 \text{ yr}$$

$$(3)\quad p\text{H difference} = -0.55 + 0.008\ (\text{age}) + 0.004\ (\text{rainfall}) + 0.461\ (\text{Ti content})$$

$$R^2 = 65\% \qquad \text{confidence limits: } \pm 108 \text{ yr}$$

Using measurements of weathering changes and site factors from two of the undated flows sampled, the regression equations were solved for age with the following results:

Upper Stainback flow:	359 ± 87 yr	(1)
	383 ± 108 yr	(2)
	310 ± 108 yr	(3)
Lower Stainback flow:	362 ± 87 yr	(1)
	341 ± 108 yr	(2)
	343 ± 108 yr	(3)

Both groups of equations show some measure of internal agreement and, in particular, equations (1) and (2) which utilize different rock parameters and site factors. It is assumed that errors arising from curvilinear change in weathering parameters and from climatic change are small for the comparatively limited time span studied.

Results using these methods need to be tested against alternative dating methods so that their value in measuring absolute ages can be assessed. This approach, however, may have value as a comparatively inexpensive method of assigning relative ages to lavas. Information on relative ages can provide a time axis for many studies where such questions as rates of rock weathering and clay formation, or rates of vegetation succession, are being examined. With further refinement it seems likely that weathering changes could be used to assign relative ages to both aa and pahoehoe lavas of greater age than and differing climate from the flows included in the present study.

Experimental Study of Channel Patterns

RIVER channel patterns are described as being braided, meandering, or straight[1] with braided rivers having steeper gradients than meandering rivers at the same discharge[2]. Recent experimental studies also suggest that straight channels have gentler gradients than meandering channels for the same discharge[3]. The difference in slope has at times been assumed to be the cause of the difference between braided and meandering channels, although braided channels have also been attributed to rapid variations in discharge, high sediment load, or erodible banks[4]. All of these explanations are plausible, and the last two can be related to the higher velocity and greater tractive force associated with steep gradients.

As part of a programme of research on river morphology, experiments were undertaken to investigate further the effect of slope on channel pattern and especially to determine if at certain ranges of slope marked changes of channel pattern occur. The experiments were performed in a 30.5 m long, 7.3 m wide, and 1 m deep flume at the Engineering Research Center, Colorado State University (Fig. 1). The flume was filled with poorly sorted sand (median grain size 0.7 mm),

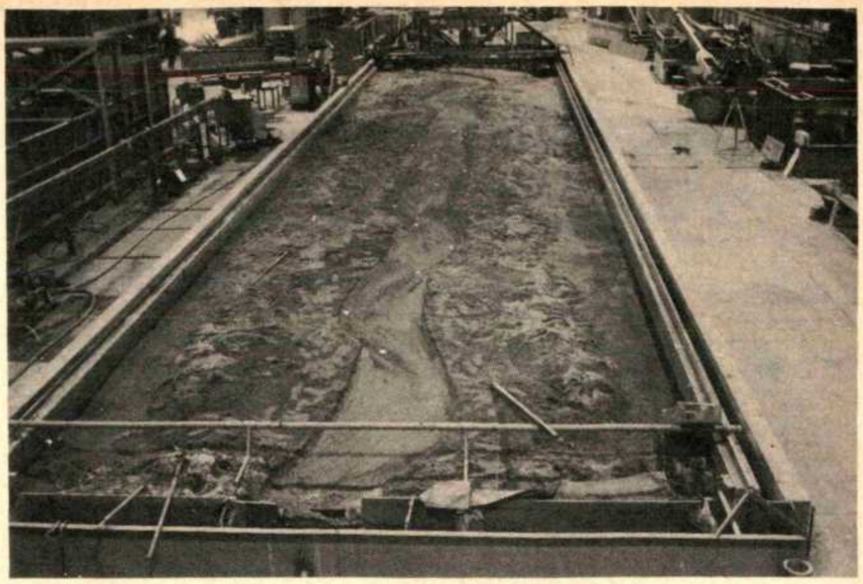

Fig. 1 Experimental facility used to study development of diverse thalweg patterns. Model channel has meandering thalweg, as identified by white spots in channel. Note that although thalweg sinuosity is about 1.2 and the banks are irregular, the channel itself is straight.

which contained particles representative of the complete range of sand sizes. The slope of the sand surface was graded to the desired inclination, and a channel 0.3 m wide and 7.6 cm deep was then cut into its surface. At the beginning of each experiment, water was introduced into the channel at a constant discharge of 0.15 cubic feet per second (0.004 m^3 s^{-1}) and sand was fed into the flow from a vibrating sand-feed device. During fifteen experiments the slope was changed from a minimum of 0.1% to a maximum of 2%. The rate of sand feed was regulated so that scour did not occur at the head of the channel, and the experiments were continued until the model channel had developed a stable configuration.

As anticipated, the rate at which sand was fed into the channel (sediment load) was closely related to slope (Fig. 2). There are three segments to a line drawn through the points. A lower segment for slopes less than about 0.2% for which there is a relatively slow increase of sediment load with slope; an intermediate segment between slopes of about 0.2% and 1.3% and, finally, an upper segment where a doubling of slope causes an approximate doubling of sediment load. Similar changes in the rates of increase of flow velocity and of tractive force occur at these slopes. Thus, there seem to be two threshold values of slope at which significant changes in hydraulics of flow and sediment transport occur, and these changes are also reflected in alterations of channel morphology (Fig. 3). At slopes less than about 0.2% the channel is straight (sinuosity equal to 1.0); at slopes in excess of 0.2%, however, the channel pattern changed as alternate bars formed, and a sinuous thalweg developed. Thalweg sinuosity increased with increased slope and sediment load to a maximum of 1.25 at slopes between 1% and 1.3%.

As the slope was increased beyond 1.3%, another change in channel morphology occurred. The alternate bars began to erode, and for slopes of 1.6% and greater a braided channel pattern developed (Fig. 3). The change from meandering thalweg to braided channel was not as abrupt as the change from a straight to a meandering thalweg channel. Nevertheless, within a narrow range of slope (1.4% to 1.6%) the channel was completely transformed, as was the sediment transport rate.

Water was introduced into the model channel at an angle in order to initiate meanders; nevertheless, at slopes less than 0.2% the channel remained straight. Thus, as Ackers and Charlton suggested[3], there is a threshold value of slope below which a meandering thalweg will not develop, although our experiments were designed to force development of a sinuous pattern. Furthermore, our experiments confirm the existence of an upper slope threshold between meandering thalweg and braided channels, as suggested by others[1,2].

Our meandering thalweg channels were similar to those developed during earlier attempts to study model meandering channels[5–8]. Fig. 1 shows, however, that, although the thalweg meandered, a truly meandering channel did not form, for the alternate bars were always submerged and did not form point bars. Freidkin[7] notes, in fact, that in order to obtain photographs of his "meandering channels", the discharge was reduced until the water level had decreased sufficiently to expose the alternate bars.

In summary, in the conditions imposed during experimentation (one type of sediment and constant water discharge) the complete range of previously described thalweg patterns formed as slope and sediment load increased. From the geological point of view the experiments can be considered to represent a fluvial system that at constant discharge is receiving a progressively larger sediment load. As the sediment load increases, the gradient is increased by aggradation. Depending on the initial pattern, a channel may change from straight to meandering thalweg or from meandering to braided as the threshold sediment loads are exceeded. We conclude therefore that two threshold values of sediment load exist at a given discharge. When these values are exceeded, channel patterns change and the rate at which slope increases with sediment load decreases (Fig. 2).

Considerably more remains to be done, but the results of

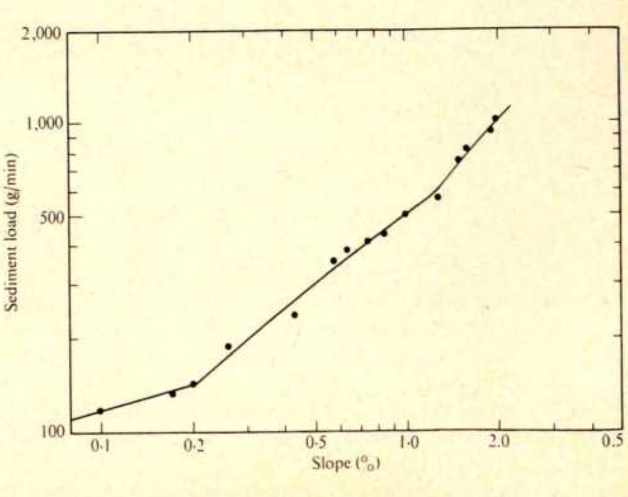

Fig. 2 Relation between rate at which sand was fed into experimental channels and slope of surface on which channels were formed. Breaks in slope of line indicate threshold values of sediment load and/or slope at which channel pattern changed.

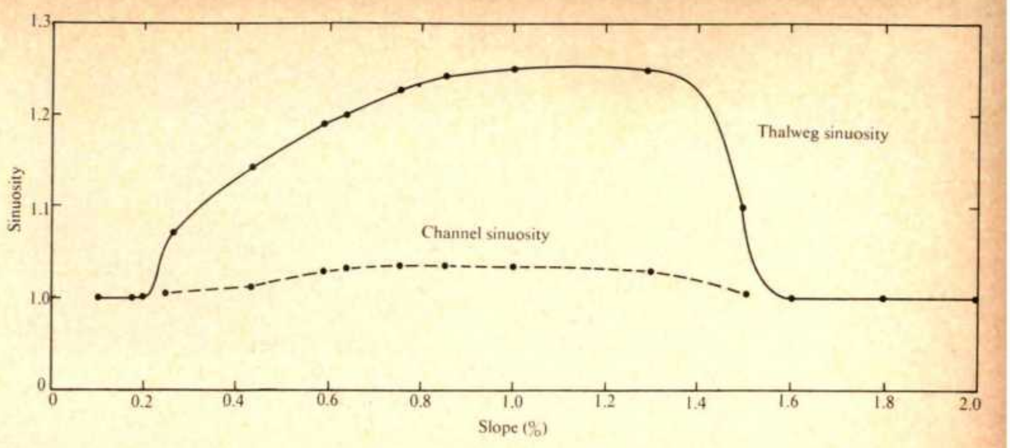

Fig. 3 Relation between thalweg sinuosity (distance along deepest parts of channel divided by length of flume), channel sinuosity (distance along midline of channel divided by length of flume) and slope.

these experiments raise questions concerning some previous explanations of diverse channel patterns. For example, a deflexion or perturbation of flow is not always sufficient to induce meandering because a meandering thalweg would not develop at low sediment loads and slopes, although the water was introduced into the flume through an initiating bend. Further, although the water was introduced directly into the channel during other experiments, a meandering thalweg always developed at moderate sediment loads and slopes.

In addition, high sediment loads do indeed appear necessary for the development of a braided channel, but bank erodibility is not in itself a sufficient reason. The banks of the model channel eroded during every experiment. That is, at low slopes the width of the channel almost doubled, but the channel remained straight. Therefore although the banks must be erodible for a channel to adjust to altered conditions, bank erodibility in itself is not the cause of meandering or braiding. Rather we consider bank erosion in these experiments as simply the response of the channel to altered slopes and sediment loads.

Except within the ranges of sediment loads and/or slopes where thalweg sinuosity increases rapidly (0.2% to 0.4%) and where the change from a meandering thalweg to a braided pattern occurs (1.4% to 1.6%), a considerable increase of sediment load and/or slope may have a minor effect on the thalweg pattern and on the nature of sediment transport and deposition within a channel. If a river falls near one of the threshold zones on Fig. 3, however, a minor change in sediment load and/or slope could completely alter the channel morphology as well as the character of the sedimentary deposit produced by the river.

We thank the NSF for support, and R. B. Johnson and J. A. Campbell for reviewing the manuscript.

Aerodynamic Noise produced by a Gliding Owl

THE flight of owls has been reported by ornithologists to be unusually quiet[1]. This conclusion is generally based on the success of the owl's hunting technique and on the relative inability of the observer to distinguish the owl aurally from other birds.

As part of an investigation of aerodynamic noise and

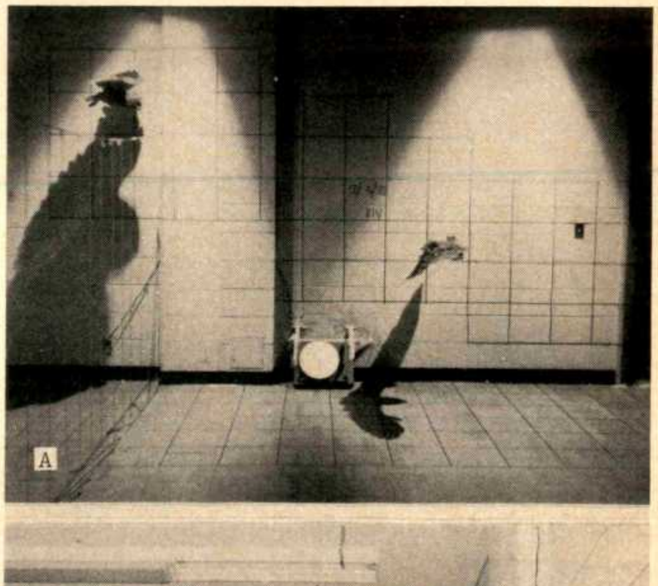

Fig. 1 Reverberation chamber. *A*, Double exposure of the owl during a gliding flight, showing a typical flight path of the bird. The bird glides from the string barrier down to the lower perch which is in the right-hand corner of the room (not shown). The patterns on the wall and the ground were used to determine the gliding velocity of the owl. The average gliding velocity was 24 foot s^{-1}.

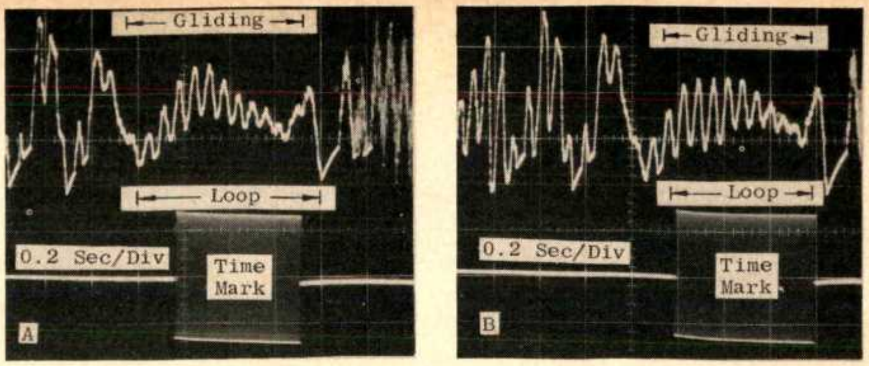

Fig. 2 *A* and *B*, Noise signals of two different test flights. The upper trace on the oscilloscope photograph shows the unmodified noise signal as sensed by the microphone, the lower trace indicates the gliding phase as judged by the observer in triggering a "time mark". The noise produced during the "gliding" of the owl is thereby identified. "Loop" indicates the noise signal which was frequency analysed.

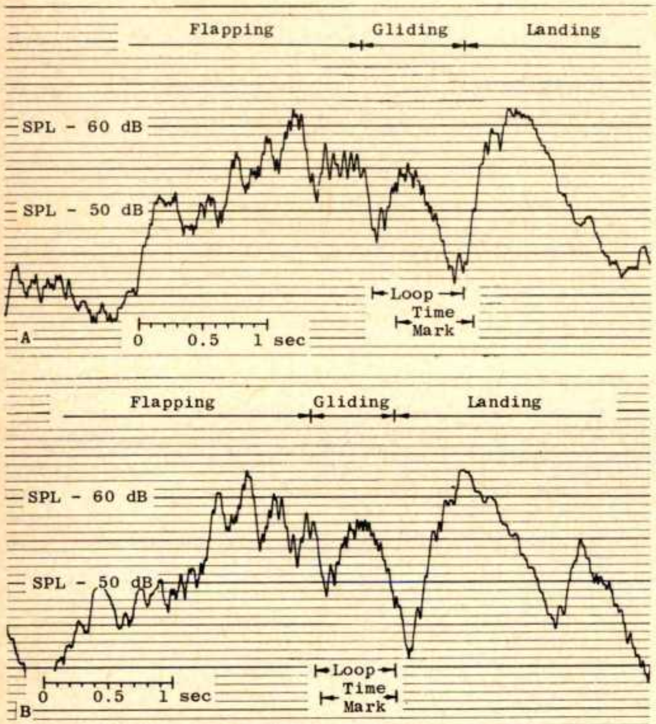

Fig. 3 *A* and *B*, Time history of the overall sound pressure level (OSPL) in dB, ref. 2×10^{-4} μbar, of the noise produced by the owl during the two test flights mentioned in Fig. 2. The recordings were made directly with a sound level recorder during the tests. The notation of the different flight phases is the same as in Fig. 2. The peak of the OSPL during the "gliding" is obviously due to the relatively high level of the low frequency components (fundamental frequency 15 Hz).

noise reduction methods, we conducted a series of tests at the University of Tennessee Space Institute, Aeroacoustic Laboratory, to determine the level and the characteristics of the noise produced by owls during flight, especially during gliding approaches. The owl used in these tests was the Florida barred owl (*Strix varia alleni*). (See Table 1 for measurements.)

We used a reverberation chamber[2] to measure the total sound produced by the flying owl and the spectral distribution of the overall noise signal. The chamber (see Fig. 1) is a room of 240 m^3 volume with reverberation times varying between approximately 0.8 s and 0.4 s in the frequency range 100 Hz to 10 kHz. The general procedure involved the recording of the unmodified noise signal and simultaneously the overall sound pressure level (OSPL) in dB, ref. 2×10^4 μbar, of the noise produced by the flying owl. The noise signal was then frequency analysed in terms of one-third octave frequency bands.

It was particularly important that we obtained noise samples from only the gliding phase of the observed flights. In all tests, the owl flew from an upper perch in one corner of the room to a lower perch in the diagonal opposite corner (see Fig. 1). A flight generally consisted of an initial flapping phase followed by a gliding phase and a short flapping during touch down. Because of the size of the test room the duration of the gliding phase of all flights was relatively short, usually in the order of 0.6 to 0.8 s. By introducing a light string barrier mounted near the middle of the room, the test flight configuration, however, became very reproducible. The owl was forced to flap up to the string barrier and to a gliding descent with nearly constant speed down to the lower perch. The average value of all measured gliding velocities was 24 foot s^{-1}.

We report here acoustic data for two representative flights. The measurements were made with a single condenser micro-

Table 1 Data of the Florida Barred Owl

Weight	1.52 pounds
Wing area *	344.8 $inch^2$
Wing span	38.1 inches
Wing sweep angle	32.7 deg. forward
Chord at half span	11.0 inches
Wing loading	4.41×10^{-3} pounds/$inch^2$ = 0.635 pounds/$foot^2$
Wing aspect ratio	4.21

* Wing area includes the body area intercepted by the wing.

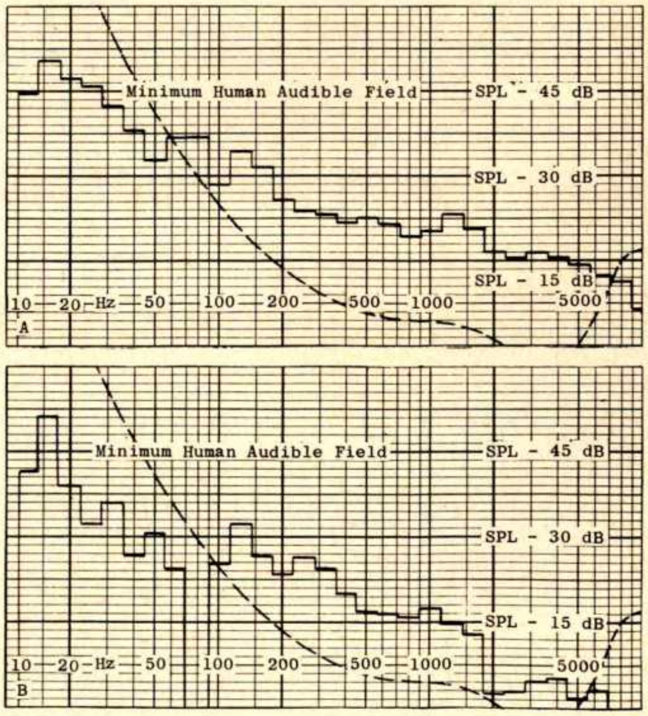

Fig. 4 *A* and *B*, Spectral distribution of the sound pressure level of a gliding owl. The one-third-octave band frequency analysis was made by using a magnetic tape reproduction of the gliding noise signal which is indicated in Fig. 2 by "Loop". The spectral distribution is compared with the normal human minimum audible field.

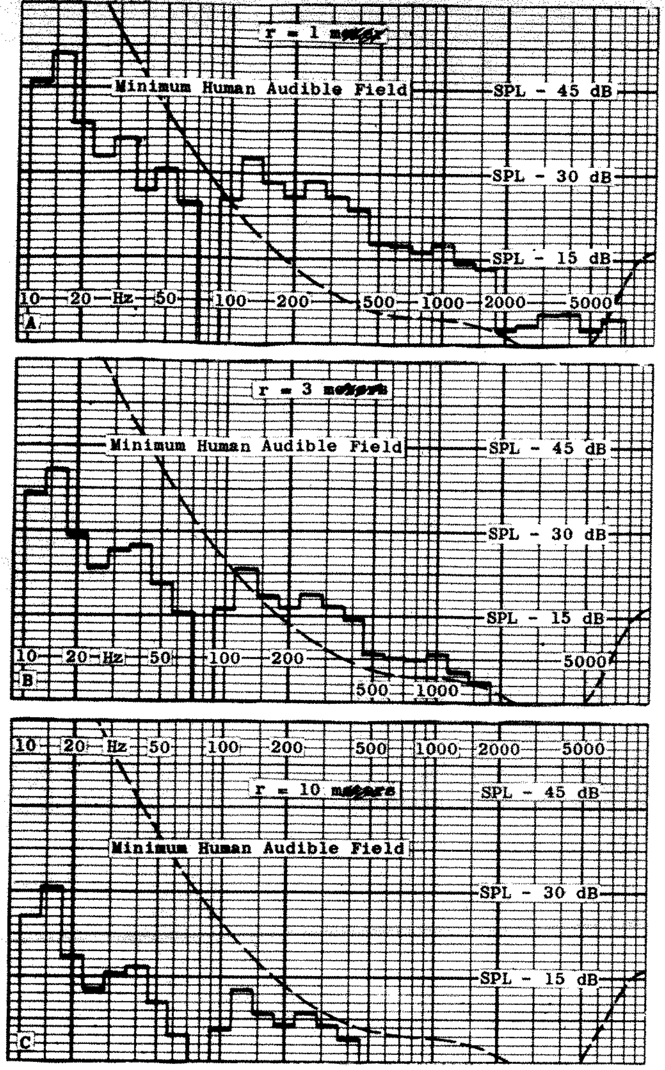

Fig. 5 *A*, *B* and *C*, Spectra of the sound pressure level of a gliding owl for distances of (*A*) 1 m, (*B*) 3 m and (*C*) 10 m. The data results from the second test flight (Figs. 2*B*, 3*B* and 4*B*). The calculation of the spectra shown is based on the assumption that the OSPL measured in the test room equals the free field sound pressure level at the reverberation radius. From the comparison with the normal human minimum audible field it becomes evident that the gliding owl is inaudible for a human observer beyond a distance of approximately 3 m.

phone with a sensitivity of 5 mV/μbar and a flat frequency response within the range 2 Hz to 10 kHz. The microphone was positioned slightly above the floor and at a lateral distance from the flight path larger than the reverberation radius of the moving noise source. During a flight test two recordings were obtained, a direct recording of the unmodified noise signal as sensed by the microphone made with an FM magnetic tape recorder (Fig. 2), and a graphical recording of the time history of the overall sound pressure level made with a sound level recorder (Fig. 3). The oscilloscope photographs show the unmodified noise signal in the upper trace and a "time mark" on the lower trace indicating the gliding phase of the flight as judged by the observer in the test room. In identifying the noise produced only during the gliding of the owl the observer's reaction time in triggering the time mark has to be taken into account. This leads to a corrected "gliding" as indicated in Figs. 2 and 3.

A one-third-octave band frequency analysis was also made by using only a reproduction of the gliding noise signal on a magnetic tape loop. The measured spectra were corrected for the ambient noise level observed during the tests. In Fig. 4 the resulting spectral distribution of the sound pressure level is shown and is compared with the normal human minimum audible field. Below about 150 Hz, the sound field in the chamber may no longer be considered as perfectly uniform because the relative magnitudes of the measured sound levels at lower frequencies are influenced to a certain degree by discrete room resonances.

In order to arrive at an estimate of the sound pressure levels which would occur at various distances in an acoustic free field, the data obtained in the reverberation chamber were used to calculate the sound field radiated by a spherical source of the same intensity. This is based on the assumption that the OSPL measured in the reverberation chamber equals the free field sound pressure level at the reverberation radius given by

$$r = \sqrt{\frac{0.163\ V}{16\,\pi\ T}}\,[\mathrm{m}]$$

where V is the volume of the chamber measured in m^3, and T is the reverberation time in seconds. For the chamber used in the test, r was approximately 1 m. The calculated spectra for distances of 1, 2 and 3 m are shown in Fig. 5; absorption effects in humid air of 50% relative humidity at 20° C are taken into account based on the results obtained by Harris[3]. It becomes evident from these results that a gliding owl would be inaudible for a human observer beyond a distance of approximately 3 m.

The source of the periodic component with a fundamental frequency of 15 Hz which is apparent in all gliding noise signals (see Fig. 2) could not be clearly identified, but it may be caused by the aeroelastic properties of the owl feathers[4].

This is part of a research work which has been supported by the US Air Force. We thank Dr B. H. Goethert, director of the Space Institute, for his interest in this work and for many helpful discussions; Dr R. A. Kroeger and Dr T. C. Helvey, who conducted the aerodynamics and bionics studies of the project; Mr G. O. Schrecker and Mr J. Goodman for technical assistance.

BIOLOGICAL SCIENCES

Is the Local Orientation of Anadromous Fishes determined by Pheromones?

IN the study of the navigating ability of anadromous fish a distinction is made between long range navigation and navigation in local waters[1]: here I am concerned with the latter ability. My results support White's[2,3] suggestion that the standing fish population in a river conditions the water in such a way that individuals on their way back from the sea recognize the stream in which their relatives are living. The attractant may be substances in the mucus excreted.

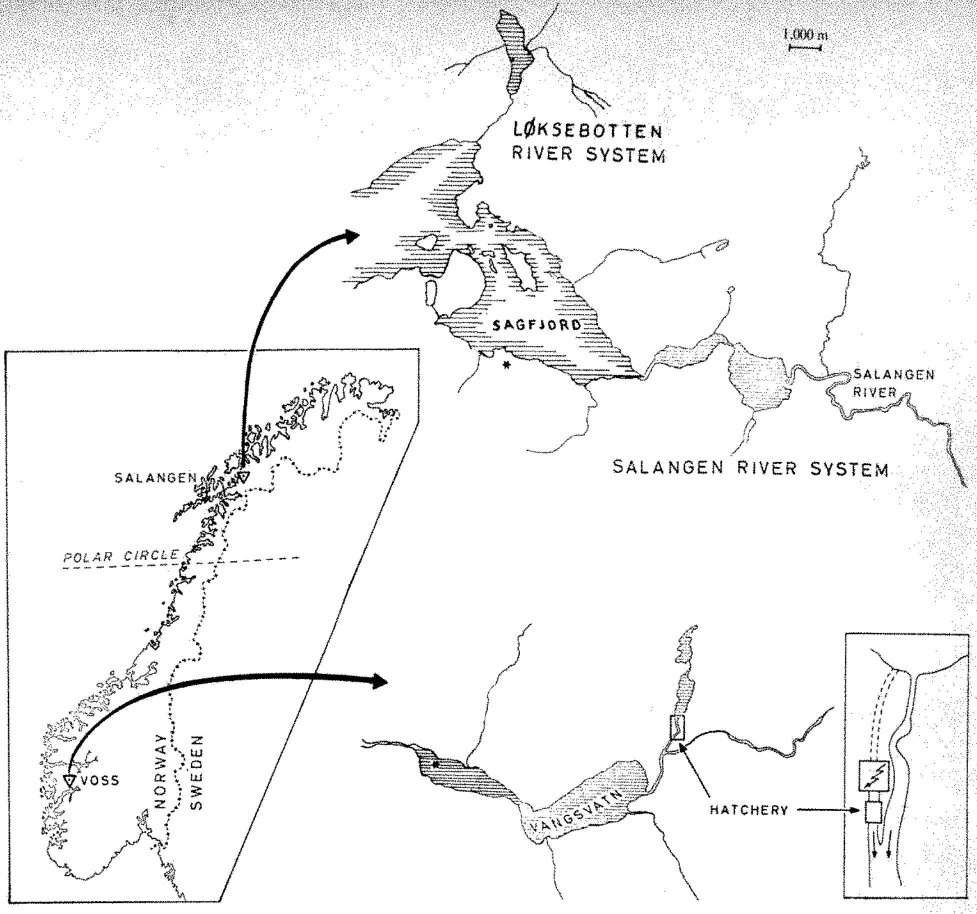

Fig. 1 Map of investigation areas.

The char (*Salmo alpinus* L. = *Salvelinus alpinus* (L.)) in the Salangen river system in North Norway is divided into a stationary and a migratory population[4]. The stationary population stays in fresh water during the whole life span and reproduces every year (up to thirteen times) after reaching maturity at an age of 2–8 yr. Smolt of the migratory population descend to the sea, when 3–4 yr old, and return to their native river after about 1 month in coastal waters. From then on, each individual migrates to the sea once every summer during the rest of its life. Most of the char of the migratory population become mature after their second or third sojourn in the sea and will then reproduce up to seven times in successive autumns.

The Salangen fjord with its inner bay, Sagfjord, receives two river systems—the Salangen river system and the Løksebotn river system (Fig. 1). Char were tagged in the Salangen river system and at a station in Sagfjord marked on the map with an asterisk. Table 1 shows that individuals of the migratory population tagged at stations in the Salangen river system return exclusively to this system after their yearly sojourn in the sea. None were recaptured in the Løksebotn river, although large quantities of char descend and ascend both rivers during the same period (May–August). On the other hand, char tagged as smolt from the same catches at the station in Sagfjord were recaptured annually in both the Løksebotn and the Salangen river systems indicating yearly mixing and subsequent separation of the populations in the sea.

In the autumn of 1964, artificially fertilized eggs of the migratory population at Salangen were transported by air to South Norway, and arrived at the hatchery at Voss less than 24 h after fertilization. The embryos were hatched and the young reared in the hatchery until spring 1968 when they had passed their fourth winter. Then 317 individuals were taken back by air and released in the estuaries of the Løksebotn and Salangen river systems. Of the 174 released in the Løksebotn estuary, thirty-one (18%) were recaptured—ten in the Løksebotn river and twenty-one in the Salangen river system, the estuaries of which are about 10 km apart.

Considering the distance, the result indicates that the fish preferentially return to the stream of their parents. This conclusion is supported by the 143 fish released in the Salangen estuary. Of these, twenty-six were recaptured in the Salangen river, and only one in the Løksebotn river. The result could be explained if the eggs were conditioned by the water from Salangen river in which fertilization and transportation took place. A more reasonable hypothesis, however, is that the released fish were attracted to the Salangen river system by an attractant released by their relatives in that system.

The hypothesis is supported by a few casual observations. Offspring of the migratory population from Salangen were reared for three years in the Voss hatchery (see Fig. 1). In the spring of 1962, 200 immature individuals of smolt size were tagged and released, at a station marked with an asterisk, in Vangsvatn (lake) below the hatchery. A fortnight later (late

May) during a period of 1 week, a great number of these fish were observed under the floor of the hatchery, standing at the outlets from the tanks containing the rest of the population (2,000 fish). Individuals from the large population of the local stationary char were not observed. This observation is in agreement with the results of another transfer experiment[5] and can be explained in the same manner provided that the hatchery to which the transferred sockeye returned in mature stage was still populated by relatives.

In 1957 the Russians started to introduce pink salmon (*Oncorhynchus gorbuscha*) into four rivers at the Kola peninsula, and in 1960 thousands of mature individuals were caught along the Norwegian coast and around Iceland and Scotland[6]. Coincident with natural spawning[7] and continued release of pink fry[7,8] in the Kola rivers, the catches of mature pink in Norwegian waters decreased to zero in 1961–62. This development was to be expected if a population had to be built up before the salmon could recognize the area in which they belonged. In this case pink fry distributed in coastal waters may attract the spawners to the estuaries. The attraction of eelings (*Anguilla anguilla*) to fresh water increased when adult eels were present in the water, but no conclusions were drawn from this observation[9].

The experiments of Donaldson and Allen[10] with silver salmon (*Oncorhynchus kisutch*) show clearly that the fish return to the river where they were reared and not to the river where they were born. This seems at first sight contradictory to our results. But both findings can be understood if the fish are conditioned to react to different attractants present in the waters. These attractants are derived partly from their own bodies and partly from the native population. When the fish return from the sea their behaviour will then first be determined by the dominant attractant. In the transfer experiment reported above, the char reared at Voss were exposed to both their own attractant and the attractant of the local stationary race in the lakes above. When released in Salangen their behaviour could be determined only by their own race-specific attractant, for this was the only one present.

Table 2 shows that none of the 313 char of the migratory population tagged as young in the Salangen lakes were recaptured in post-smolt stages in the river above the lakes, whereas 14 of the 112 char tagged in the river were recaptured there. This indicates that char in the river and in the lakes belong to different populations. To test this possibility 599 char in smolt or post-smolt stage, derived from a population in the upper lake and reared at Voss, were released in the river and at the spawning place of the parents (autumn 1967, spring 1968). Of the 396 fish released at the spawning place, forty were recaptured in the lakes and only one in the river when they returned from the sea. Of the 233 fish released in the river, eleven were recaptured there and only three in the lakes. This result does not support the view that there are local races of char in the Salangen river but, on the other hand, does not exclude this possibility. The explanation may be that experimental fish are conditioned to the attractant of the local school of fish into which they are introduced.

Expression of Differentiated Functions in Mouse Neuroblastoma mediated by Dibutyryl-cyclic Adenosine Monophosphate

CELLS derived from the mouse neuroblastoma (C1300) grown in culture are predominantly round and highly refractile. A small number of the cells are flatter and possess one or more extensions ("neurites") which may be as long as 3 mm[1–3]. The proportion of these morphologically differentiated cells increases when the medium lacks serum[4] or when 5-bromodeoxyuridine is added[5]. The cells also contain enzymes of neural function[2,6] and are capable of generating action potentials *in vitro*[7,8]. We now show that differentiated characteristics of neuroblastoma cells can be induced by $N^6,O^{2'}$-dibutyryl adenosine 3′ : 5′-monophosphate (dibutyryl-cyclicAMP).

The C1300 tumour was obtained as a solid implant in strain A/J mice from the Jackson Laboratories, and the cells adapted to growth in Dulbecco's modified Eagle's medium containing 15% calf serum, in 10% CO_2–air at 37° C. Clones were obtained as previously described[9], in the absence of feeder layers, and one, NB60, was used in the experiments below.

Clone NB60 extended neurites when serum was removed from the medium, as reported by others[4] (Fig. 1*A* and 1*B*). Extension was complete within 24 h and was readily reversed on readdition of serum. In medium containing both serum and 1 mM dibutyryl-cyclicAMP, neurite extension was also induced (Table 1, Fig. 1*C*). Higher concentrations of dibutyryl-cyclicAMP were only slightly more stimulatory, while 0.1 mM had only a small effect. Neurite induction by dibutyryl-cyclicAMP was reversed by feeding the cells with fresh, drug-free medium. Adenosine cyclic 3′ : 5′-monophosphate (cyclic-AMP) at 1 mM was not as effective as the dibutyryl derivative in inducing neurite extension; higher concentrations of cyclicAMP did not induce more cells to extend neurites. AMP (and ADP and ATP, data not shown) induced modest degrees of neurite extension and, in the concentrations used (1 mM), inhibited growth and were toxic to the cells. Sodium butyrate induced no increase in cells possessing neurites.

Cycloheximide, added to serum-free medium, was reported as not preventing neurite extension, suggesting that the specific protein components of the microtubules found in neurites are

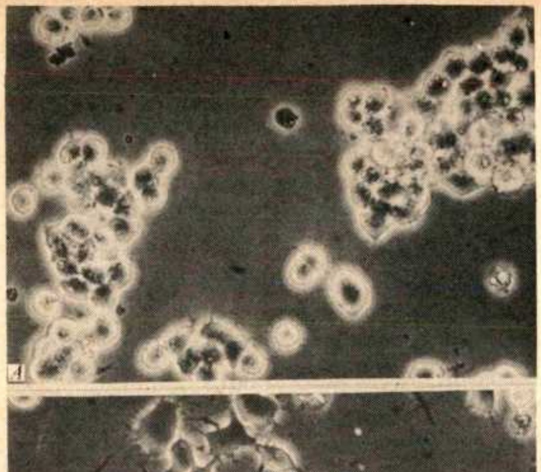

Fig. 1 Morphological differentiation of neuroblastoma clone NB60 *in vitro*: *A*, cells in the presence of serum; *B*, cells in the absence of serum for 48 h; *C*, cells in the presence of serum and 1 mM dibutyryl-cyclicAMP for 48 h.

preformed in uninduced cells[4,10]. In the conditions described here, cycloheximide (10 µg/ml.) consistently caused a moderate decrease in the percentage of cells, in serum-free medium, with visible neurites (Table 1). In contrast, in the presence of serum, 1 mM dibutyryl-cyclicAMP, and 10 µg/ml. cycloheximide, induction of neurite extension was inhibited.

Theophylline, which inhibits cleavage of cyclicAMP by phosphodiesterase (see ref. 11), induced a small percentage of the cells, grown in the presence of serum, to extend neurites, and this effect was additive with induction by dibutyryl-cyclicAMP (Table 1).

Table 1 Induction of Morphological Differentiation in Neuroblastoma Clone NB60 by Dibutyryl-cyclicAMP

Conditions	Cells with neurites (%)
A. +serum	12
−serum	89
+serum+1 mM dibutyryl-cyclicAMP	60
+serum+1 mM cyclicAMP	44
+serum+1 mM sodium butyrate	11
+serum+1 mM AMP	23
+serum+10 µg/ml. cycloheximide	7.7
−serum+10 µg/ml. cycloheximide	54
+serum+1 mM dibutyryl-cyclicAMP +10 µg/ml. cycloheximide	8.5
B. +serum+1 mM dibutyryl-cyclicAMP	57
+serum+1 mM theophylline	25
+serum+1 mM dibutyryl-cyclicAMP +1 mM theophylline	73

Cells were collected from suspension culture by centrifugation, treated with 0.02% EDTA in calcium-magnesium-free phosphate-buffered saline to disaggregate clumps, recentrifuged, and seeded on to 60 mm plastic tissue culture dishes (Falcon) containing 5 ml. of Dulbecco's medium with 15% calf serum. After incubation for 24 h, the medium was replaced with fresh medium containing appropriate additions, in the presence or absence of serum, as indicated in the experiments. Cells were examined under phase optics and scored as positive when at least a single extension of about one cell diameter or greater was seen[5]. More than 500 cells were counted per plate. The results are from typical experiments. Reproducibility among experiments was ±10%.

In the presence of serum and dibutyryl-cyclicAMP, the growth rate of neuroblastoma cells in culture was greatly reduced when compared with cells in serum alone (doubling times of 170 and 22 h, respectively). Because morphological differentiation of neuroblastoma cells has been suggested to be a function of their growth rate[4], neurite extension produced by dibutyryl-cyclicAMP might be attributed to inhibition of growth. The possibility, however, that this inhibition is not the cause of neurite extension but the result of induction of differentiated functions incompatible with rapid growth is supported by the following observations. (1) In the absence of serum, during the period of most active neurite extension, cells divide at a rate equivalent to control cultures, and only subsequently does growth rate decline (see refs. 4 and 10, and unpublished observations); and (2) cyclicAMP, AMP, ADP, ATP, and sodium butyrate inhibited growth substantially but were only poor inducers of neurite extension. Thus, inhibition of cell growth is not a sufficient cause of neurite extension.

Table 2 Acetylcholinesterase Activity of Neuroblastoma Clone NB60 *in vitro*

Conditions	Specific activity of acetylcholinesterase 48 h	96 h
+serum	2.1 (1.0)	7.5 (3.6)
−serum	10.4 (4.9)	23.2 (11.1)
+serum+1 mM dibutyryl-cyclicAMP	6.8 (3.2)	48.3 (23.0)

Cultures were grown as described, the cells removed from the plates with EDTA, washed, sonicated, and assayed by the method of Ellman[12]. Specific activity is expressed as nmol product formed/min/mg protein. Enzyme activity with butyrylthiocholine was subtracted from the rates obtained with acetylthiocholine. The inoculum had a specific activity of 5.4. The values are the average of at least three determinations. The numbers in parentheses represent the increase in activity compared to the value at 48 h in the presence of serum, taken as 1.

The activity of acetylcholinesterase, an indicator of biochemical differentiation, was measured in cells of neuroblastoma clone NB60 in several conditions (Table 2). Both addition of dibutyryl-cyclicAMP and removal of serum increased enzymatic activity. The increase in specific activity in the control plates when the cells reached stationary phase (96 h) agrees with results previously reported for neuroblastoma[6].

As described here, the morphological and biochemical differentiation *in vitro* of a neural cell tumour is induced by dibutyryl-cyclicAMP. It has recently been reported that dibutyryl-cyclicAMP causes the reversal of abnormal morphological and growth characteristics of fibroblastic tumour cell lines *in vitro*[13,14]. The cells become elongated with narrow processes and oriented in parallel arrays; this reversal, as indicated in one report[14], requires protein synthesis. Thus, dibutyryl-cyclicAMP may have a generalized effect on various tumour cells, a manifestation of which is the reversal of abnormal growth, and the induction of differentiation in neuroblastoma. The determinants of expression of differentiation in neuroblastoma are of interest because human malignant neuroblastomas occasionally differentiate *in vivo* and give rise to benign ganglioneuromas[15].

Leukaemia Virus-induced Alteration of Leucocyte Migration *in vitro*

INFECTION of susceptible mice by a leukaemia virus generally suppresses the immune response at both the cellular and humoral levels[1-8]. Although the mechanism of such immunodepression is not fully understood, it is widely recognized that normal functions of the reticulo-endothelial system are affected by the leukaemic process. Earlier studies in this laboratory of the effects of leukaemia virus on cellular immunity included the macrophage migration inhibition assay with lymphoid cells from normal and virus infected mice sensitized to mycobacterial antigens[9]. It was found, however, that spleen cells from leukaemia virus-infected mice failed to migrate normally *in vitro*, even in the absence of antigen. Studies with normal mice showed that cells from lymphoid tissues other than the spleen, such as the thymus, bone marrow and superficial lymph nodes, as well as from the peripheral blood, migrated readily from capillary tube cultures[10]. The effects of leukaemia virus infection on the *in vitro* migration pattern of lymphoid cells from various organs were determined by comparison of infected and non-infected cells.

Young adult Balb/c mice were infected with Friend leukaemia virus (FLV), which induces a rapid leukaemia-like erythroblastic disease. Graded concentrations of the virus preparation were used, ranging from 10 to 1,000 ID_{50} per inoculum[5-7]. At various times after infection the animals, together with an equal number of control mice of the same age, were killed and their spleens and other lymphoid tissues were excised. Dispersed cell suspensions were prepared by "teasing" the tissues in cold Hank's solution. The cells were washed several times at 4° C by serial centrifugation and placed in individual capillary tubes, approximately 1–2 mm in diameter and sealed at one end with melted paraffin wax[10]. The tubes were centrifuged for 5–10 min at 500*g* and then cut with a glass file at the interface between the cells and the medium[9,10]. The bottom portions of the tube, with the packed cells, were placed in Sykes-Moore chambers containing 1 ml. medium 199 containing 20% foetal calf serum[10]. The chambers were incubated at 37° C for 18 to 24 h and the area of migration of cells out of the capillary tubes was determined by planimetry or by projecting the image of the migrating cells on a sheet of paper. The outline of the image was cut and the paper weighed. The area of migration inhibition or enhancement was expressed as a percentage of the migration area of experimental cultures relative to the average migration of cells from control cultures.

Table 1 Migration of Lymphoid Cells from FLV Infected Mice *in vitro* from Capillary Tube Cultures

* Mice were infected intraperitoneally with 500 LD_{50} FLV and the lymphoid cell suspensions were tested on the day indicated for *in vitro* migration.

† The average area of cell migration of 3–5 cultures of cells derived from the lymphoid tissue on day indicated after infection with FLV.

Table 1 shows that the area of migration of spleen cells from infected animals decreased considerably with time after infection. When infection occurred 2–3 days before death, the area of migration was 10 to 20% smaller than that of the controls. After 4–7 days, the area of migration was 70–80% smaller than that of the controls (Fig. 1). This inhibition of *in vitro* migration of spleen cells was directly related to the dose of infecting virus. The decrease of migration activity was less pronounced and occurred more slowly when lower dilutions of virus were used for infection. Smaller doses of FLV produced a slower development of splenomegaly and blood cell dyscrasia.

Migration of cells from the superficial and deep lymph nodes, the thymus and the bone marrow was not depressed during the first 7–10 days after infection (Table 1). After 2–3 weeks, however, the lymph node and bone marrow cells migrated less actively than the same cells from control mice. The thymus cells were affected least; moderate inhibition occurred only when mice were infected 3–4 weeks earlier (Table 1).

The mechanism whereby spleen cells from FLV infected mice rapidly lose their capacity to migrate *in vitro* is not clear. This effect cannot have been due merely to the presence of leukaemia virus in the lymphoid cell suspensions, because addition of spleen cells from 14 day infected mice to spleen cells from control animals gave the expected degree of migration. Furthermore, incubation of concentrated FLV splenic homogenates with normal spleen cell suspensions for 1–8 h at 37° C before culture in capillary tubes did not affect the subsequent cell migration.

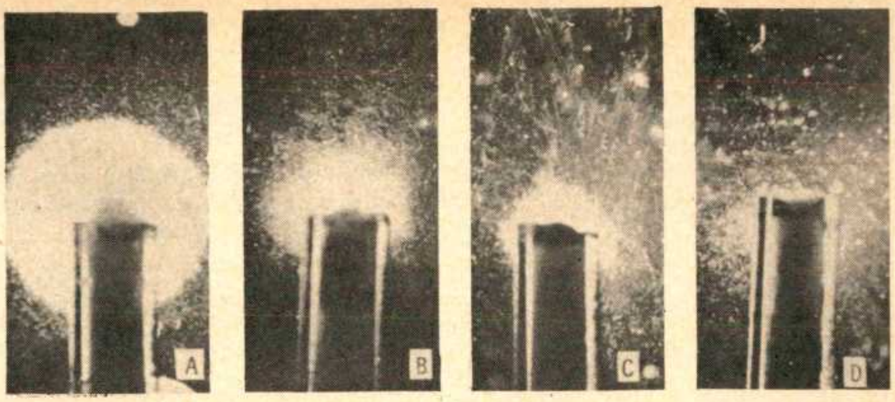

Fig. 1 Typical areas of leucocyte migration from capillary tube cultures containing spleen cells from normal mice (*A*) or mice infected with FLV either 4 (*B*), 6 (*C*) or 9 (*D*) days earlier.

Macrophages are highly motile on glass surfaces and they are thought to be the chief type of cell to migrate rapidly from capillary tubes. Yet other lymphoid cells, including typical lymphocytes, are also highly motile[10]. Histological examination of splenic tissue from infected mice showed a marked increase in the number of leukaemic or undifferentiated cells. Cells morphologically similar to macrophages were also present. The marked infiltration of obvious leukaemic cells did not occur until about 7–10 days after infection. Nevertheless, significant inhibition of leucocyte migration occurred with spleen cells from mice infected 3–5 days earlier, before splenomegaly became apparent. Thus it seems evident that a functional capability of splenic leucocytes, presumably macrophages, was affected by the FLV infection. We therefore attempted to determine whether glass adherent macrophages could be concentrated from the spleens of infected animals by the glass adsorption procedure and shown to migrate *in vitro*. Spleen cell suspensions from normal and 7-day infected mice were passed through glass bead columns and the fraction containing mainly macrophages was eluted with EDTA. There was no significant increase in the migration capacity of cells in the fraction containing the glass-adherent cells when the spleens were derived from the infected mice. A similar fraction from spleen cell suspensions from normal mice had the same migration capacity as the unfractionated cell suspension. Thus, it seems likely that the decrease in motility of spleen cells from infected mice was not due merely to "dilution" of macrophages with non-migrating cells.

It seems from our results that infection of mice with a typical leukaemogenic virus not only causes a rapid diminution of antibody forming capacity but that it also suppresses the *in vitro* migration activity of macrophages which is involved in cellular immunity and antigen handling. Although the significance of this loss of cell motility *in vitro* is not clear, it seems to be related to the leukaemic process.

We thank Mrs Leony Mills and Mrs Vivian Simmons for technical assistance and Dr Maria Sanz for assistance in some experiments. This work was supported in part by research grants from the US National Science Foundation, the American Cancer Society and the Damon Runyon Cancer Fund, Inc.

Cytogenetic Analysis of a Chinese Hamster–Mouse Hybrid Cell

THE usefulness of cell fusion in the genetic analysis of somatic cells stems largely from two observations. First, Harris and Watkins[1] demonstrated that not only like cells, as shown by Okada[2], but also cells of widely different types, for example, man and mouse, could be fused together by inactivated Sendai virus. Second, Weiss and Green[3] found that in man–mouse hybrid cells most of the human chromosomes were rapidly eliminated. While most of the known human linkage relationships have been established by classical pedigree analysis[4], the "segregation" of chromosomes that occurs in man–mouse hybrid cells has enabled two further linkage assignments to be made: assignment of the gene controlling thymidine kinase production to an *E* group chromosome[5,6] and linkage of the genes controlling the production of lactate dehydrogenase B and peptidase B[7,8].

The hybrid cells used most often in genetic analysis have been man–mouse hybrids. Kao and Puck[9], however, have suggested that for optimal results cells with the greatest difference in growth rate should be used, on the assumption that the chromosomes of the slower growing parental cell would be preferentially eliminated. All the hybrid cells so far described seem to confirm the inverse correlation between growth rate and chromosome loss, but I have found an exception to this rule, in which the chromosomes of the more rapidly growing parental cell are preferentially lost from the hybrid. Some mechanism unrelated to the growth rate of the parental cells must therefore be responsible for the preferential loss of chromosomes.

The parental cells used were a Chinese hamster (DON)[10] cell (Wg 3-h) resistant to 3 μg/ml. 8-azaguanine, obtained from Dr A. Westerveld, and having a doubling time of about 12.5 h, and a mouse (3T3)[11] cell, resistant to 30 μg/ml. bromodeoxyuridine (BUDR)[12] and having a doubling time of about 24 h. The generation time of the mouse cell was thus approximately twice that of the Chinese hamster cell. The Chinese hamster cell was pseudodiploid with a sharp mode of twenty-two chromosomes, while the mouse cell had a mode of sixty-six chromosomes all acrocentric or telocentric (Fig. 1). The cells were fused essentially as described by Harris and Watkins[1].

In all, 5×10^5 cells of each type were mixed with 4,000 HAU of ultraviolet-inactivated Sendai virus. After fusion, the cells were incubated in Dulbecco's modification[13] of Eagle's medium[14], containing 10 µg/ml. of hypoxanthine and thymidine and 2 µg/ml. of aminopterin (HAT medium[15,16]). The cells were grown continuously in this selective medium. After 3 months chromosome preparations were made and examined. Two populations of cells were observed (Fig. 2*a*). In one population, consisting of 86% of the cells, the chromosome count ranged between seventy-five and eighty-nine with a mode at eighty-two; in the other, the chromosome count ranged between 124 and 148 without a distinct mode. Two published reports describe the chromosomes of hybrids between Chinese hamster and mouse cells: in one, the results suggest a preferential loss of mouse chromosomes[17], in the other the Chinese hamster chromosomes were preferentially lost[18]. In the second case, however, the Chinese hamster parental cell had a doubling time of 40.4 h compared with 14.5 for the parental mouse cell.

Karyotypic analysis of the hybrid cells reported here (Fig. 2) revealed the following points. (1) The cells with seventy-five to eighty-nine chromosomes contained approximately one mouse and one Chinese hamster chromosome complement. (2) Metaphases with 124–148 chromosomes were apparently derived from one Chinese hamster cell and either two mouse cells or one 2s mouse cell. These hybrid cells resemble those described by Koyama *et al.*[18]. (3) Both populations of hybrid cells showed preferential loss of Chinese hamster chromosomes in all cells examined. The number of identifiable Chinese hamster chromosomes varied between eight and thirteen. (4) There were some cells with eighty-eight chromosomes, this being the number to be expected from the sum of the two parental modes, but these cells nonetheless showed a loss of Chinese hamster chromosomes (Fig. 2*c*). Thus a hybrid cell may have a chromosome number corresponding to the sum of the two parental chromosome sets and have marker chromosomes of both parental cells yet still lack the full chromosome complements of both parental cells. (5) There was much karyotypic variation in the hybrid cells, as in the parental Chinese hamster cell. Of fifteen hybrid cells examined *seriatim*, no two contained the same complement of Chinese hamster

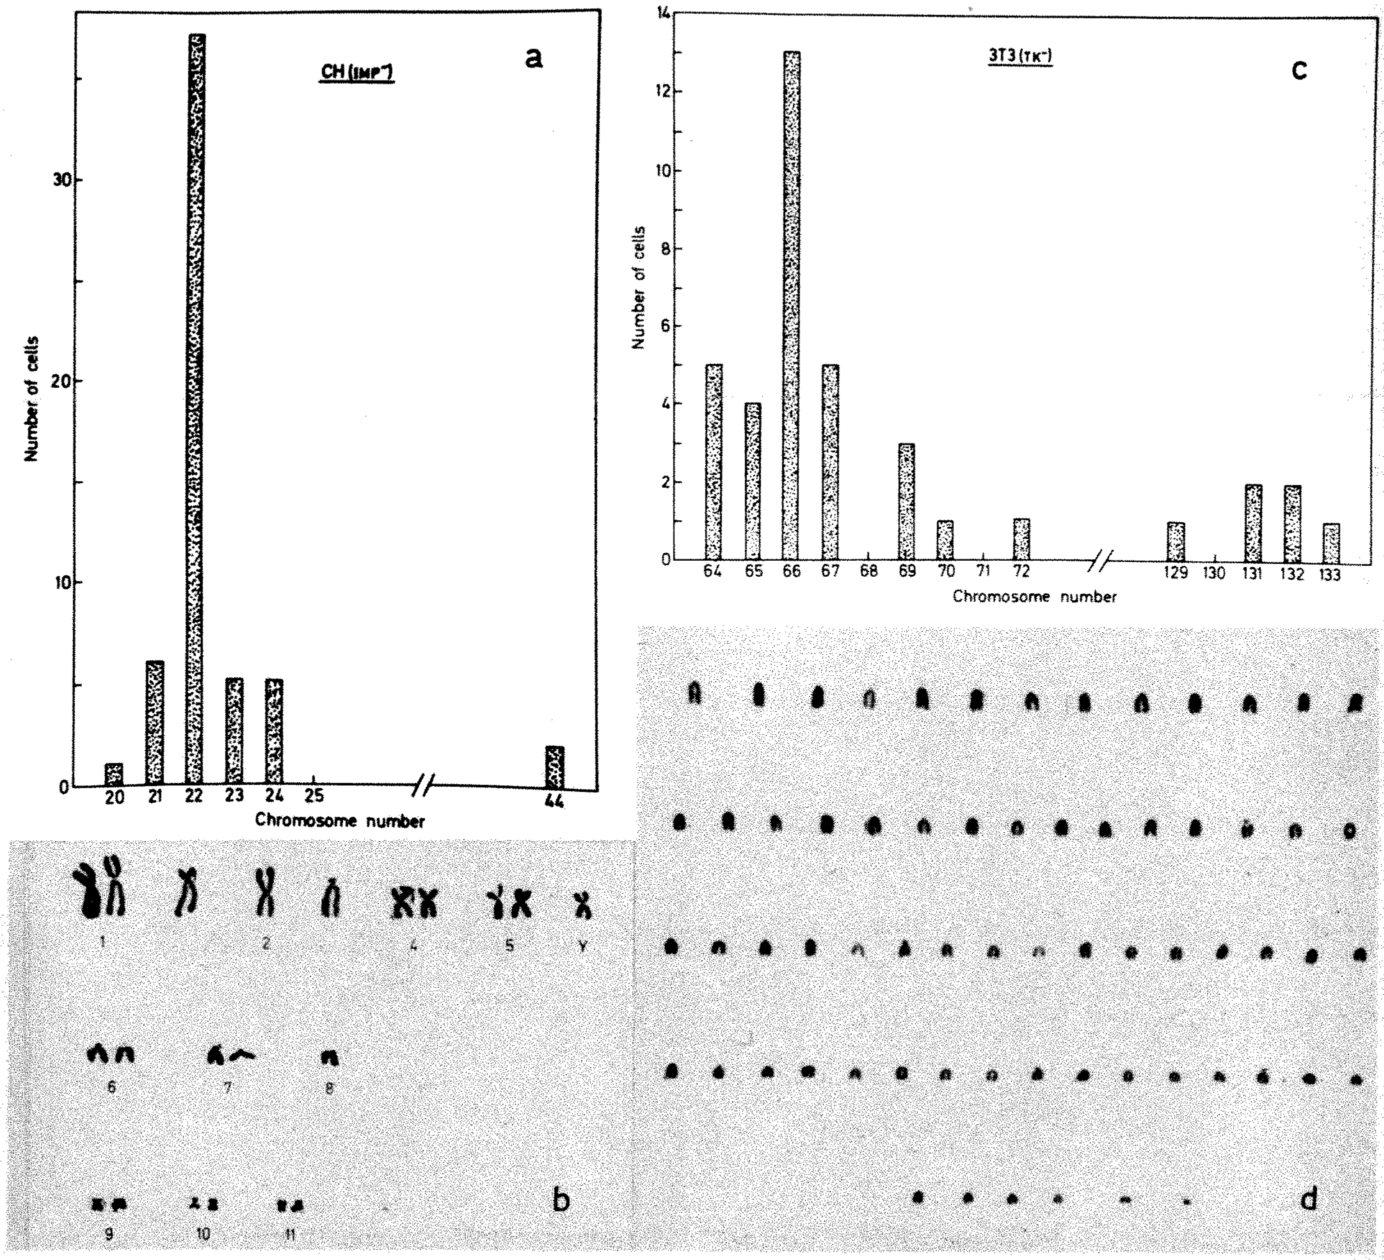

Fig. 1 Chromosome analysis of parental cells. *a*, Distribution of counts of Chinese hamster metaphases. *b*, Karyotype of Chinese hamster cell containing twenty-two chromosomes. *c*, Distribution of counts of mouse metaphases. *d*, Karyotype of mouse cell containing sixty-six chromosomes.

chromosomes (Fig. 2*d* and *e*). (6) Non-disjunction was a feature of both parental cells and was also characteristic of the hybrid cells; this could account for the chromosomal variation observed in the hybrid cell population. One example of this non-disjunction, illustrated in Fig. 2, was seen in the Chinese hamster marker chromosome intermediate in size between numbers 1 and 2: this varied from none (Fig. 2*b*) to four (Fig. 2*d*, line 3) per cell.

A characteristic pattern of chromosome behaviour in hybrids between cells of different species is the preferential loss of the chromosomes of one of the species. This was first shown by Weiss and Ephrussi[19], who observed preferential loss of rat marker chromosomes from rat–mouse hybrid cells. When the preferential loss of human chromosomes from man–mouse hybrid cells was demonstrated[3], it was immediately appreciated that such cells would be particularly suitable for genetic

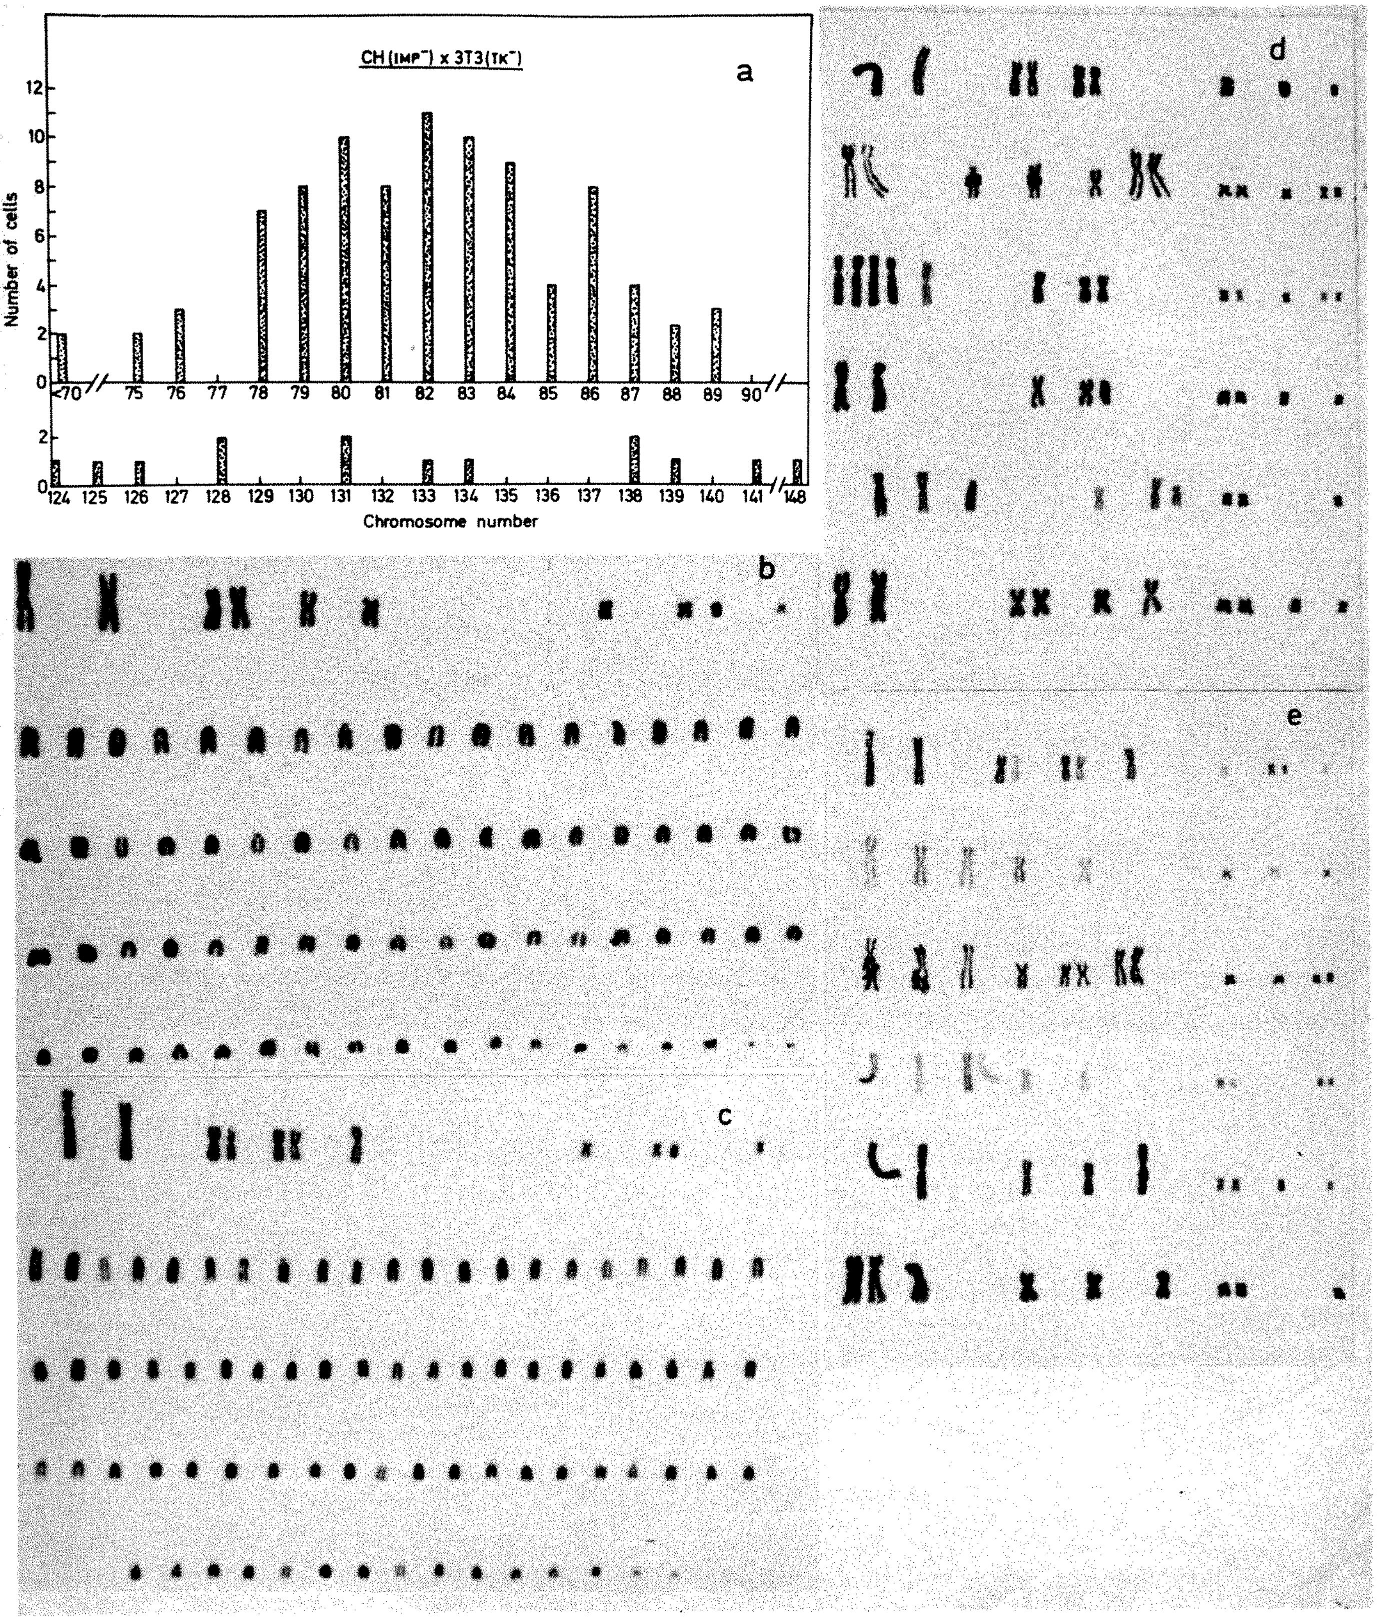

Fig. 2 Chromosome analysis of Chinese hamster–mouse hybrid cells. *a*, Distribution of counts of hybrid metaphases. *b*, Karyotype of Chinese hamster–mouse hybrid cell containing eighty-two chromosomes. *c*, Karyotype of Chinese hamster–mouse hybrid cell containing eighty-eight chromosomes. *d* and *e*, Identifiable Chinese hamster chromosomes in different hybrid cells.

analysis of human somatic cells. The chief limitation of this approach remains the relatively slow and unpredictable loss of chromosomes even in these cells. Kao and Puck[9] suggested that the difference in the growth rates of the parental cells determined the degree and direction of chromosome loss in the hybrid. If this were generally true, the usefulness of cell fusion for genetic analysis might be greatly enhanced. Unfortunately, as can be seen here, some other mechanisms must be sought to explain the pattern of chromosome loss. Perhaps different mechanisms operate in different cells. It is clear that the variation observed in the karyotype of the Chinese hamster–mouse hybrid cells reported here can be explained by non-disjunction, whereas this seems not to be true of man–mouse hybrids (my unpublished results with J. F. Watkins and D. R. Thompson). Similarly, the early losses of chromosomes in man–mouse and in Chinese hamster–mouse cell hybrids may be due to different causes.

I thank Drs A. Westerveld and M. Fried for the Chinese hamster and mouse cells, respectively, Miss L. Rolfe for technical assistance, and Mr S. Buckingham for photography. I am a research fellow of the Helen Hay Whitney Foundation.

Proposed Reaction Mechanism for the (Na^++K^+)-Dependent Adenosine Triphosphatase

ALTHOUGH a definitive description of the reaction mechanism of the ($Na^+ + K^+$)-dependent ATPase[1,2] must await determination of the three dimensional structure of the enzyme, some clues can be gained from studies of the amino-acids that seem to participate in the active site.

Of such amino-acids the participant best documented is glutamate: in the presence of Na^+ and Mg^{2+} the terminal phosphate of ATP is incorporated into the enzyme, and by isolating a derivative the phosphorylated group was identified as the γ-carboxyl of L-glutamic acid[3]. Certain misgivings[4] are based on the failure of hydroxylamine to inactivate the enzyme although it can release the phosphate (but see ref. 5); on the other hand, the possibility of phosphate migration during processing has been minimized by identification of an acyl phosphate after only mild treatment[6].

Cysteines also seem near the active site, and inhibition of the ATPase by N-ethylmaleimide (NEM) may be retarded by ATP[7]. Although there is a class of proteases in which sulphydryl groups are acylated during catalysis[8], such a role seems less attractive for a phosphatase. Perhaps the cysteines function in nucleotide binding, as suggested for a class of sulphydryls at the active site of myosin[9,10].

Mechanistic proposals often invoke a histidine, and in cases where firm data are available histidine frequently fulfils expectations: beyond demonstrations of its presence near the active sites of such enzymes as alkaline phosphatase[11] and myosin[10], histidine is a crucial component of the detailed catalytic mechanisms of several classes of esterases whose structure has been determined[8,12,13]. For this ATPase two lines of evidence suggest a histidine at the active site. (i) Plots of log V_{max} against incubation pH indicate an ionizable group with a pK of about 7.1 (ref. 14) to 6.7 (my unpublished results), consistent with the pK of the histidine imidazole. (ii) Photo-oxidation of a rat brain ATPase preparation in the presence of 5 μM methylene blue (Table 1) rapidly inactivated the enzyme (first order rate constant, $k = 0.41$/min), while 3 mM ATP markedly slowed the loss of enzymatic activity ($k = 0.13$/min). Further additions with ATP influenced inactivation little (Table 1), in contrast to their effect on NEM inactivation, as shown previously[7] and confirmed for this preparation (Table 1). This latter point is of interest because photo-oxidation is not entirely specific for histidine[16], and other amino-acids, notably cysteine, may also be destroyed. Unfortunately, the impurity of the enzyme preparation makes determination of destroyed amino-acids futile; since all reagents that attack histidine also attack cysteine[16] the limitations to this approach are obvious.

Table 1 Inhibition of the ($Na^+ + K^+$)-dependent ATPase by Photo-oxidation and by NEM

Additions	ATPase activity (% of control) After photo-oxidation	After NEM treatment
None	14±3	20±4
$MgCl_2$, 3 mM	11±2	18±3
NaCl, 90 mM	13±2	—
ATP, 3 mM	53±3	58±2
+$MgCl_2$	54±4	49±3
+NaCl	49±2	52±4
+KCl, 10 mM	54±5	40±4
+$MgCl_2$ and NaCl	50±2	39±2
EDTA, 1 mM	22±5	—

In the photo-oxidation experiments a rat brain ATPase preparation[15] was incubated for 5 min in an ice bath with 10 mM Tris-HCl (pH 7.8) and 5 μM methylene blue, plus the additions listed, either illuminated by a 100-watt tungsten bulb (at 8 inches), or kept in the dark (control). The preparations were then diluted 1 : 1 with buffer, homogenized, and incubated under dim illumination for 6 min at 37° in media containing 50 mM Tris-HCl (pH 7.8), 3 mM ATP, 3 mM $MgCl_2$, 90 mM NaCl, and 10 mM KCl (final concentrations). Concurrent incubations were performed in the absence of Na^+ and K^+, and the difference in activity, measured in terms of P_i production[15], was taken to represent the ($Na^+ + K^+$)-dependent ATPase. In the experiments with NEM, the ATPase preparation was incubated for 8 min at 37° with 50 mM Tris-HCl (pH 7.8) plus the additions noted, in the presence and absence of 1 mM NEM. To stop the action of NEM, 2-mercaptoethanol was added to a final concentration of 1 mM, and 4 min later the incubation was initiated by adding the components necessary for the standard incubation media (see above). Data are presented ± s.e.m.

The remaining amino-acid that may be implicated is serine, for during catalysis a serine is phosphorylated in alkaline phosphatase[17] and acylated in the serine proteases[12]. For the K^+-dependent phosphatase activity associated with the ATPase[18], and apparently reflecting the terminal hydrolytic process[19,20], kinetic studies of product inhibition indicate an enzyme-phosphate intermediate[21]. Moreover, with ^{32}P-nitrophenyl phosphate as substrate, K^+-stimulated labelling of the enzyme preparation occurred at an acidic pH, where dephosphorylation was slowed relative to phosphorylation[22]. To identify this phosphorylated product analogous experiments were performed, followed by acid hydrolysis and electrophoretic

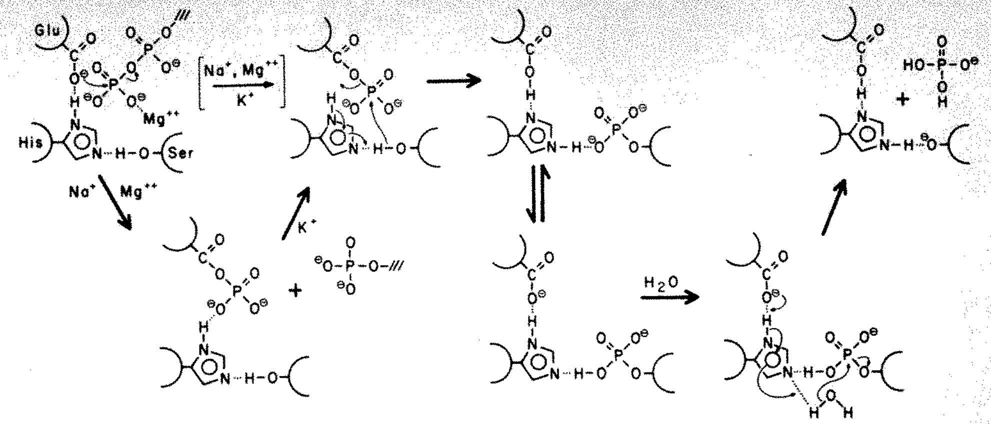

Fig. 1 Proposed reaction mechanism for the (Na⁺+K⁺)-dependent ATPase. For the ATP molecule only the terminal two phosphate groups are shown.

separation of the labelled products. At *p*H 5.0 K⁺ not only stimulated total ^{32}P incorporation, but also the fraction migrating with authentic phosphoserine (Table 2); 0.1 mM ouabain largely abolished the K⁺-stimulated increase. At *p*H 7.8 the Na⁺-stimulated increment in labelling was not associated with phosphoserine (Table 2), in accord with its sensitivity to hydroxylamine[22]. Although experimental uncertainties remain, particularly the possibility of phosphate migration during isolation, these data together with the kinetic studies suggest a K⁺-activated phosphorylation of an enzyme serine group, which is rapidly hydrolysed at neutral *p*H although demonstrable at acidic *p*H. By analogy, these data suggest for the overall ATPase reaction a K⁺-activated migration of phosphate from the glutamyl phosphate complex initially formed in the Na⁺-activated step. (Failure to demonstrate K⁺-stimulated labelling[22] with ^{32}P-ATP would be expected in light of the extremely slow hydrolysis[23] of ATP in the absence of Na⁺: apparently ATP must enter the reaction pathway through the Na⁺-activated formation of an acyl phosphate.)

Given this complement of amino-acids a reaction scheme can be visualized (Fig. 1) modified from that of the serine proteases[12,13] with their aspartate, histidine, and serine groups. First, ATP phosphorylates the enzyme to form the glutamyl phosphate complex in an Na⁺- and Mg²⁺-dependent step. In the absence of K⁺ this acyl phosphate is fairly stable, perhaps through hydrogen bonding; however, with K⁺ (through its effect on enzyme conformation) intramolecular migration occurs from glutamate to serine. This serine phosphate, through a "charge relay system" analogous to that described for the serine proteases[12], is quite labile at neutral *p*H and readily hydrolysed.

Table 2 K⁺-stimulated Incorporation of ^{32}P from ^{32}P-Nitrophenyl Phosphate

*p*H	Additions	Relative incorporation of ^{32}P Total labelling	Labelling in phosphoserine	% of total as phosphoserine
5.0	None	1.00	0.24±0.06	24
	KCl, 20 mM	1.53±0.16	0.54±0.08	35
	KCl+ouabain, 0.1 mM	1.02±0.12	0.29±0.05	28
7.8	None	0.68±0.09	0.12±0.03	18
	NaCl, 20 mM	1.43±0.10	0.16±0.04	11

The ATPase preparation[15] was incubated for 2 min at 30° C in media containing 50 mM Tris-maleate (*p*H 5.0) or Tris-HCl (*p*H 7.8), 1 mM $MgCl_2$, 1 mM ^{32}P-nitrophenyl phosphate (16.9 mCi/mmol), and the additions indicated. The reaction was stopped and the preparation washed with trichloroacetic acid as previously described[22], except that an additional wash with ethanol-diethyl ether (1 : 1) was included. Phosphoserine was isolated by a modification of the method of Schwartz and Lipmann[17]: the precipitated protein was suspended in 1 N HCl and heated in sealed-glass tubes for 16–20 h at 110° C; the hydrolysate was then lyophilized and the residue subjected to paper electrophoresis at 5,000 V for 75 min in 0.05 M ammonium formate (*p*H 3.3), together with authentic phosphoserine. Radioactivity in 0.5 inch strips cut from the paper was measured with a liquid scintillation counter. This procedure clearly separated phosphoserine from inorganic phosphate; together these represented essentially all the radioactivity (recovery of the applied radioactivity was greater than 80%). Data are presented, ±s.e.m., relative to the total incorporation of ^{32}P at *p*H 5.0 in the absence of additions, defined as 1.0; such controls were run with all experiments, and this incorporation averaged 0.07 nmol/mg protein.

The energy flow through the system accompanies the transitions from pyrophosphate (ATP) to acyl phosphate to ester phosphate to inorganic phosphate, with major liberations of free energy at the final two steps. Coupling these free energy changes to cation translocation is unspecified, although opportunities for protein conformational changes are clear (it should be noted that such conformational changes are distinct from the cooperative allosteric effects among cation sites[15,20,24], presumably representing subunit interactions[15,25], which may be associated chiefly with regulatory processes[26]). Finally, it can be seen that the phosphorylated enzyme bears an extra negative charge, which may be pertinent to the stoichiometric transport of 3 Na⁺ and 2 K⁺ for each ATP hydrolysed: while two Na⁺-sites balance two K⁺-sites the added negative charge would neutralize an endogenous positive group, freeing a third site for Na⁺.

The Role of Distortion in the Lysozyme-catalysed Hydrolysis of Glucosides

BLAKE *et al.* proposed that during cleavage of oligosaccharides, the saccharide bound in subsite D of the active site of lysozyme is distorted into a half chair conformation[1,2]. In agreement with this mechanism, Dahlquist *et al.*[3,4] concluded that considerable carbonium ion character is involved in the hydrolysis of the synthetic substrate phenyl-4-*O*-(2-deoxy-2-acetamido-β-D-glucopyranosyl)-β-D-glucopyranoside (NAG-GLU-φ). Lowe and Sheppard[5] found, however, in their study of the hydrolysis of NAG-GLU-φNO_2 that participation of the acetamido group is important in the lysozyme mechanism.

The hydrolysis of natural oligosaccharides by lysozyme is complicated by non-productive binding and trans-glycosylation, making a study of any one feature of the mechanism difficult without the use of synthetic substrates[6]. We report here the results of a nuclear magnetic resonance (NMR) study of the conformation of the glucose ring of NAG-GLU-φNO_2 when bound in the active site of lysozyme (Rand-Meir *et al.*[6] have shown that the productive mode of binding of NAG-GLU-φ-NO_2 to lysozyme is at least competitive with, if not identical to, binding in subsites C, D and E). The chemical shift of the anomeric proton H_1 of the glucose ring (Fig. 1) and its apparent coupling constant to proton H_2 can be obtained from the NMR spectrum of NAG-GLU-φNO_2 (Fig. 2); in the fast exchange limit the coupling constant so obtained is the weighted average of the coupling constants for the free and bound substrate. The dihedral angle dependence of such coupling constants is well known[7-10] and the dihedral angle of the glucose ring obtained in this way is a sensitive indicator of its conformation.

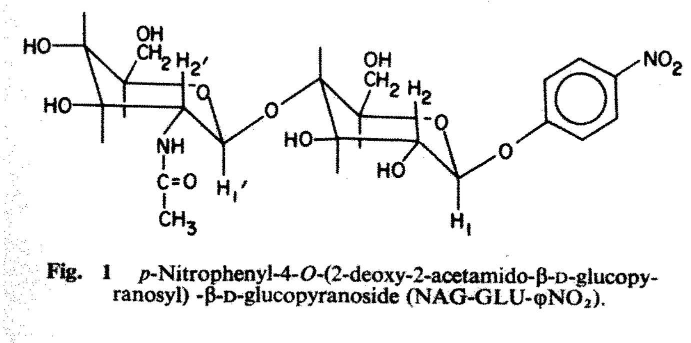

Fig. 1 *p*-Nitrophenyl-4-*O*-(2-deoxy-2-acetamido-β-D-glucopyranosyl) -β-D-glucopyranoside (NAG-GLU-φNO_2).

NAG-GLU-φNO_2 was prepared by a modified method of Rand-Meir *et al.*[6], and the lysozyme was obtained from P.L. Biochemicals, lot LY4. All solutions were made up in 0.1 M citrate buffers in D_2O [*p*H (meter reading) $\simeq 5.5$] containing 12% dioxane. NMR spectra were obtained on a Varian HA-100 spectrometer, using both conventional and Fourier transform time averaging techniques. The measured coupling constants were derived from the spectra by curve fitting programs using linearized least squares techniques[11].

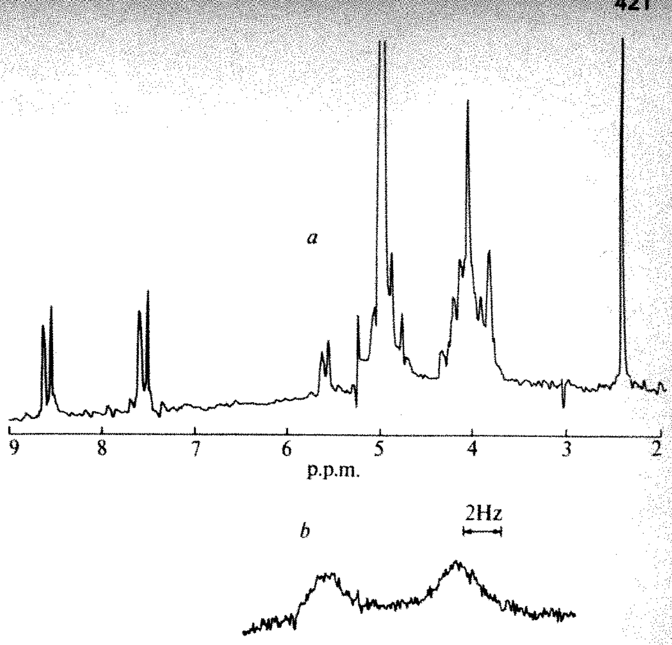

Fig. 2 *a*, 5.1×10^{-3} M NAG-GLU-φNO_2, $pH = 5.5$, 0.1 M citrate buffer in D_2O and 12% (v/v) dioxane at 32° C; 500 scans with Fourier transform (VFT-100), reference HMDS. *b*, 2.6×10^{-2} M NAG-GLU-φNO_2, H_1 region expanded, twenty-five scans with C-1024 time averaging computer.

The NMR spectrum of NAG-GLU-φNO_2 is shown in Fig. 2. The conclusion that the doublet near $\tau = 5.5$ p.p.m. arises from H_1 (the doublet from H_1' is near the HDO peak) was made on the basis of a comparison with the spectrum for GLU-φNO_2.

Upon the addition of lysozyme, the acetyl resonance shifts up field and broadens. The lifetimes for the exchange of the substrate between solution and the active site of lysozyme can be calculated from the linewidth of the acetyl resonance as a function of enzyme concentration[12]. The calculated lifetimes satisfy the fast exchange conditions. The value of the dissociation constant and bound chemical shift obtained from the observed shifts are very similar to those obtained previously[6]. The doublet corresponding to H_1 also broadens, but never so much that the values of J_{H_1,H_2} could not be obtained. The values of J_{H_1,H_2} obtained are given in Table 1.

Table 1 Observed and Predicted Coupling Constants between H_1 and H_2 of NAG-GLU-φNO_2

[EI]/[I] *	J_{H_1,H_2} (observed)	J_{H_1,H_2} (predicted)
0.0	7.0 ± 0.1	7.0
0.1	6.7 ± 0.2	6.5
0.14	7.2 ± 0.2	6.3
0.27	7.2 ± 0.2	5.9

* Calculated from the initial concentrations of enzyme and inhibitor on the basis of $K_D = 1.5 \times 10^{-2}$ M (Rand-Meir *et al.*[6]).

The coupling constant J_{H_1,H_2} for NAG-GLU-φNO_2 and GLU-φNO_2 free in solution is 7.0 ± 0.1 Hz. The relationship between the coupling constant and the dihedral angle between the H_1 and H_2 protons is given by[7-10]

$$J(\psi) = A\cos^2\psi + B\cos\psi + C$$

with the $\cos^2\psi$ term dominant. For the purpose of this discussion, we have assumed the simplified form where $A = 7.0$ and $B = C = 0$. The predicted coupling constant for a dihedral angle of $\psi \simeq 120°$ is 1.7 Hz.

The observed coupling constant is a weighted average of that for free and bound NAG-GLU-φNO$_2$

$$J_{\text{obs}} = P_F J_F + P_B J_B$$

where J_F and J_B are the coupling constants, and P_F and P_B the relative concentrations of free and bound NAG-GLU-φNO$_2$, respectively. This suggests that if the substrate is bound with the glucose ring distorted into the half chair conformation, the observed coupling constant should decrease as P_B increases. Comparison of the observed results with the predicted results (Table 1) indicates that the quantity $P_B(J_B - J_F)$ is small

$$P_B(J_B - J_F) \ll 0.2 \text{ Hz}$$

For the largest value of P_B used,

$$P_B = \frac{[\mathrm{EI}]}{[\mathrm{EI}] + [\mathrm{I}]} \simeq 0.21$$

one obtains

$$J_B - J_F \ll 1 \text{ Hz}$$

Our results suggest that any change in the dihedral angle between H$_1$ and H$_2$ of the glucose ring of the bound substrate is small, indicating that the glucose ring is not distorted when NAG-GLU-φNO$_2$ is bound to lysozyme.

An alternative interpretation of these results is that only a small fraction of the bound substrate is distorted. This could be represented by a mechanism of the kind

$$\mathrm{E} + \mathrm{S} = \mathrm{ES}_1 = \mathrm{ES}_2$$

where

$$K_1 = \frac{[\mathrm{E}][\mathrm{S}]}{[\mathrm{ES}_1]}, \quad K_2 = \frac{[\mathrm{ES}_1]}{[\mathrm{ES}_2]}, \text{ and } K_2 \gg 1$$

such that $K_D = \dfrac{K_1 K_2}{1 + K_2} \sim K_1 = 1.5 \times 10^{-2}$ M; or by a mechanism of the kind

$$\mathrm{E} + \mathrm{S} \overset{K_p}{=} \mathrm{ES} \text{ (productive)}$$

$$\mathrm{E} + \mathrm{S} \overset{K_u}{=} \mathrm{ES} \text{ (unproductive)}$$

with $K_u \ll K_p$ such that $K_D \simeq K_u$.

This dilemma is familiar. If one chooses a substrate which is slowly hydrolysed so that the nature of the bound substrate can be investigated, one cannot guarantee that the enzyme operates on the artificial substrate in a manner similar to that with the natural species. We have found that distortion does play a major role in the cleavage of the natural tetrasaccharide substrate from cell walls[13].

We thank Marcia Robbins and Joseph Maloney for their assistance and the US National Institutes of Health for their support.

In vitro Culture of Rabbit Ova from the Single Cell to the Blastocyst Stage

SEVERAL investigators have reported culturing two and four-celled mammalian ova to the blastocyst stage[1-5]. Although successful *in vitro* cultivation of eggs from the single cell to the blastocyst stage has been achieved in the mouse[6-8], few satisfactory methods have been devised for the culture of the ova, at this stage, of other mammalian species, apart from some experiments with human oocytes[9-10]. We now wish to report a higher rate of success with one-celled rabbit ova cultivated *in vitro* to the blastocyst stage, using a nutrient solution composed of several known synthetic media.

Preliminary trials showed that none of the usual chemically defined media were suitable for this work. The best results were obtained with the solution composed of HamF$_{12}$ solution[11] (Nissan 59% v/v); RPMI 1640[12] (Nissan 20% v/v); Eagle's solution[13] (Hanks' solution + Eagle's amino-acids and vitamins, Nissan 20% v/v); sodium caseinate solution (5 g milk casein dissolved slowly in 40–45 ml. of 0.1 N NaOH was centrifuged for 5 min at 3,000 r.p.m., and the supernatant was used as a sodium caseinate solution, 1% v/v).

Table 1 *In vitro* Development of Rabbit Ova from One-celled Stage

Culture system	No. of eggs tested	No. of embryos at final stage of development: 1∼2-cell	8-cell	Morula	Early expanding blastocyst	Expanding blastocyst
Earle's flask						
Open	24	5	4	9	4	2
Closed	27	3	2	3	4	15
Flat cuvette						
Closed	16	1	0	2	4	9

The medium was adjusted to *p*H 7.5 with NaHCO$_3$, supplemented with 20% v/v calf serum and completed by adding 60 mg of kanamycin sulphate/l.

Ova were flushed with the medium from the oviducts of a rabbit 17–19 h after copulation. In most cases, Earle's flasks (10 ml.) containing 6 ml. of medium were used for cultivation. Two ova were placed in every flask and cultured for up to 4 days at 37° C in a humidified incubator with a constant flow of 5% CO$_2$ in air. About half of the flasks were stoppered tightly with silicon bungs before being placed in the incubator. After incubation, ova were examined by phase contrast microscopy, and classified according to the final stage of development. The microcinephotographic microscope was also used, together with a specially designed cuvette (a flat slender-rectangular solid type, 3 mm internal depth, with 3–4 ml. volume) filled with the medium. The cleavage and behaviour of the embryonic cells could be recorded through the flat sides without distortion under the inverted microcinemicroscope kept at 37° C within the microscopic incubator.

Fifty-eight of sixty-seven ova incubated appeared to have undergone normal cleavage to eight cell, morula, or to the blastocyst. Most of them developed to the blastocyst (65%) rather than the morula (24%). Table 1 summarizes the results of the studies with either the open or closed system of cultivation.

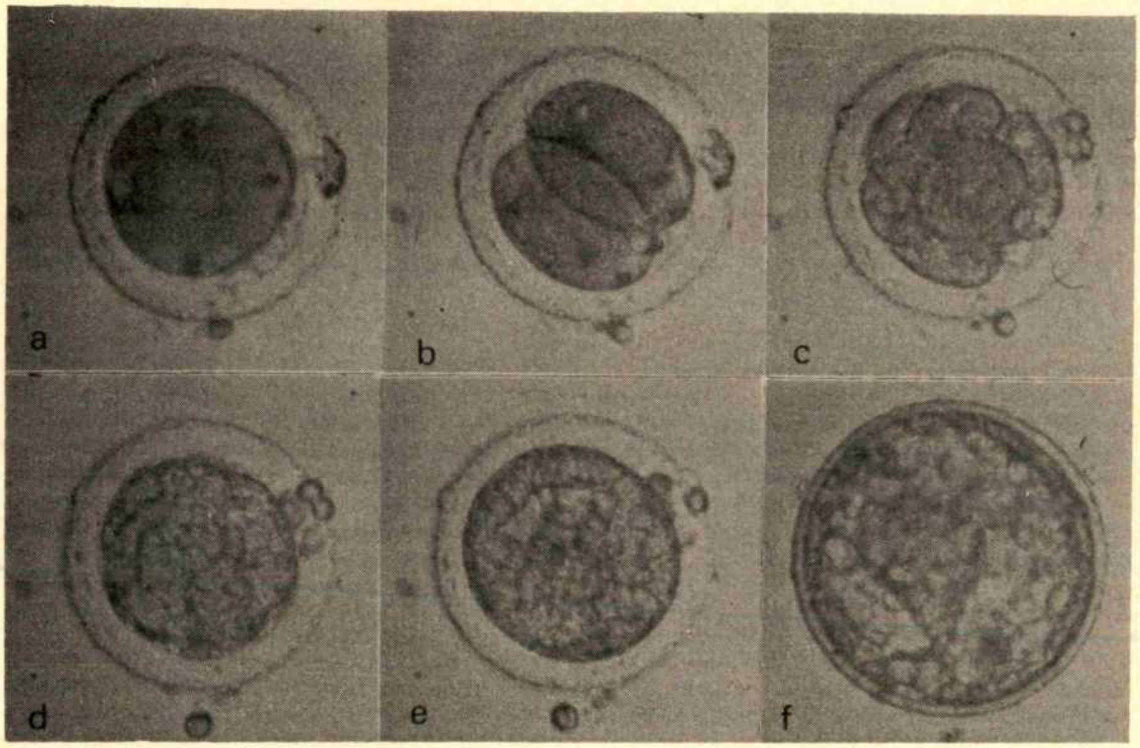

Fig. 1 The development of the rabbit ovum from one-cell to blastocyst stage *in vitro*. From a time-lapse film (16 mm) of an ovum isolated 18 h after mating (× *c*. 200). (*a*) 4.5 h after the start of culture; (*b*) two-cell stage, 6.5 h after (*a*); (*c*) eight-cell stage, 41 h after (*a*); (*d*) late morula to early blastocyst stage, 74 h after (*a*); (*e*) early blastocyst stage, 83.5 h after (*a*); (*f*) expanding blastocyst stage, 122 h after (*a*).

There was a difference in the proportion of ova developing to the blastocyst in the two culture systems; in the open system more embryos remained at the morula stage than in the closed system. There were, however, some cases of the development to the blastocyst stage in the open system. The most advanced development was obtained when we used a closed flask of cuvette without a gas phase. Four consecutive experiments yielded twenty-four expanding blastocysts (56%), eight early expanding blastocysts (19%) and five morulae (12%) from forty-three ova.

Time lapse microcinephotographs (1–8 frames/2 min on 16 mm film under phase contrast) of the embryo which developed from the one-celled stage to the expanding blastocyst (Fig. 1) show a regular pattern of cleavage as the culture passed (two-cell, 20–25 h; eight-cell, 38–45 h; morula, 58–67 h, and early blastocyst, 75–170 h after copulation). This pattern seems to parallel that which can be expected in oviducts and uteri.

We have confirmed by microcinephotography the presence of a rhythmical contraction and expansion, like those reported[14–16] in the mouse blastocyst, accompanying cleavage division of the cell mass in the embryo. The movement occurred at the transitional stage from late morula to early blastocyst and increasingly continued throughout the expanding blastocyst stage. The zona seemed to be thinner and elastic, its volume continuing to decrease, while the volume of the blastocoelic cavity continued to increase.

During the expanding stage, many intracellular particles moved up and down sometimes in a circular movement, within the blastocoelic cavity. The cell mass was finally fixed under the marginal expanding membrane of the blastocoelic cavity.

The composition of the culture medium *in vitro* is a critical factor in the cultivation of mammalian ova. Our medium can supply the necessary nutrients and environment to support a high rate of development of one-celled rabbit ova into early blastocysts. Furthermore, because a CO_2 incubator is not needed it seems to be convenient for the study of development of the rabbit ova *in vitro*. We think that this medium could also be used for the culture of the ova of other mammalian species *in vitro*.

This work was supported by a research grant from the Ministry of Education, Japan. We thank Mr S. Etoh and N. T. Takatsuna for microcinephotography.

Potentiation of Amphetamine-induced Arousal by Starvation

STARVATION and amphetamine both increase behavioural arousal, and have been postulated to act through adrenergic mechanisms in the brain stem. Amphetamine is believed to induce psychomotor excitation by releasing brain catecholamines, blocking their re-uptake from the synapse and mildly inhibiting the action of the catabolizing enzyme, monoamine oxidase[1–3]. The drug also accelerates the turnover of noradrenaline in the brain stem reticular formation[4]. Food deprivation increases electrophysiological arousal in the mesencephalic reticular formation and other areas[5] and Dell[6] postulated that behavioural arousal induced by starvation resulted from the release of catecholamines from the adrenal medulla and their consequent action on brain stem excitatory areas.

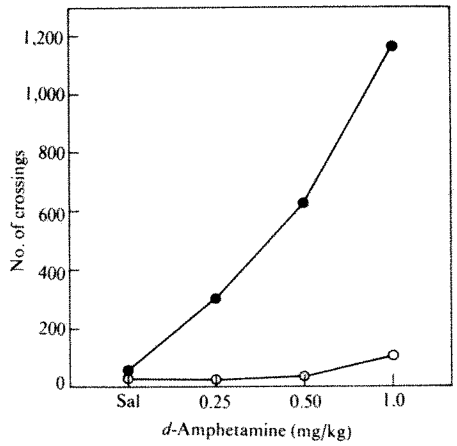

Fig. 1 The effect of 4 days of food deprivation (●) on amphetamine-induced psychomotor excitation. ○, *Ad lib.*

The similar action of these two different means of enhancing arousal raises the question of how the two states would interact if they occurred simultaneously. At one level, a simple summation of the two arousal states might result. At a more complex level there might be some form of synergistic action.

Sprague–Dawley male rats (Perfection Breeders, Douglasville, Pa.) weighing 250–275 g were used. Their locomotor activity was measured in wire mesh, stabilimeter activity cages[7] ($17.5\times20.0\times37.5$ cm) which were mounted on a central axis so that they tipped slightly and activated a sensitive microswitch as the rat moved from one end to the other. The number of crossings was recorded on electromagnetic counters in an adjacent room. Activity rooms were maintained at 22°–23° C with an 80 dB white noise background, and there was 12 h of light followed by 12 h of dark, the lights coming on at 0900 h. Activity was not recorded for 2 h each day (0900–1100 h), when weighing and maintenance of the animals were carried out.

Rats were habituated in the stabilimeter cages for 2 days, during which they had free access to food and water. Then they were divided into two groups which were matched on the basis of the activity on the second day. Food was removed from one group while the other continued to have free access to food. When the experimental group had been deprived of food for 96 h, all animals were injected intraperitoneally with either 0.9% saline or *d*-amphetamine sulphate (0.25, 0.50 or 1.0 mg/kg body weight), dissolved in 0.9% saline. Drugs and saline were injected at 1100 h in a volume of 1 ml./kg body weight, animals were then returned to the activity cages and crossings were recorded on a printing counter at 0.5 h intervals for 5 h (Fig. 1). Eight rats were tested once with each dose.

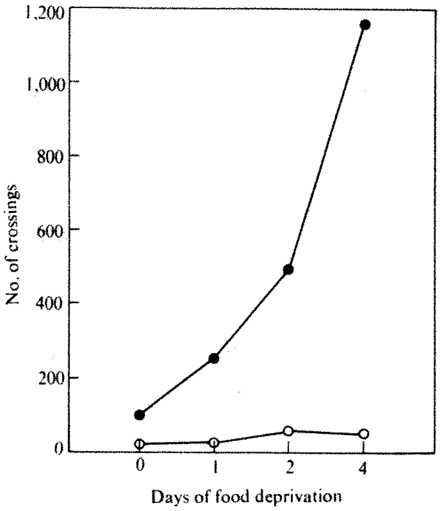

Fig. 2 Effect of duration of food deprivation on amphetamine-induced psychomotor excitation. ○, Saline; ●, *d*-amphetamine.

The same procedures were followed in the second experiment, except that the days of food deprivation were varied. Rats were compared in their response to *d*-amphetamine (1.0 mg/kg) and saline after 0, 1, 2, or 4 days without food. At each period of deprivation eight naïve rats were injected with amphetamine and eight with saline.

There was a significant difference in the activity of the starved and fed groups with all doses of drugs ($F=49.12$, df$=1, 56$, $P<0.01$). There was also a significant increase in activity with increasing dose ($F=17.41$, df$=3, 56$, $P<0.01$). A given dose of amphetamine had a significantly different effect on rats deprived of food compared with those fed freely; only the large dose (1.0 mg/kg) increased the activity of the latter ($t=3.73$, df$=14$, $P<0.01$), but after 4 days of starvation all doses produced significant increases in activity relative to the saline control group. Even the smallest dose (0.25 mg/kg) increased activity significantly ($t=2.64$, df$=14$, $P<0.02$). There was also a small but reliable difference between the starved and freely fed animals after injection with saline which is consistent with many reports of increased behavioural arousal during food deprivation.

The excitatory effects of amphetamine were proportional to the duration of starvation (Fig. 2, $F=12.89$, df$=3$, 28, $P<0.01$). Even after 24 h of food deprivation there was a significant enhancement of amphetamine-induced arousal ($t=2.73$, df$=14$, $P<0.02$). Fig. 3 shows that during each period of deprivation the increased response to amphetamine was due to a heightened peak response in addition to a prolonged action of the drug. The peak drug effect seemed to be more sensitive to deprivation than the duration effect, however, for the group deprived of food for 1 day showed a clear increased peak effect to amphetamine but only a negligible increase in the duration of responding.

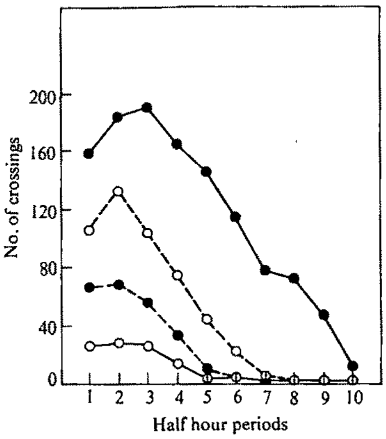

Fig. 3 Time-response curves for 1.0 mg/kg amphetamine after varying durations of food deprivation. ○—○, *Ad lib.*; ● - - - ●, 1 day deprived; ○ - - - ○, 2 day deprived; ●—●, 4 day deprived.

These experiments indicate that there is a substantial change in responsiveness to *d*-amphetamine during starvation. Taken together our results demonstrate that the arousal-inducing properties of starvation interact in a supra-additive summative manner with amphetamine-induced behavioural arousal. The mechanism responsible for the summative interaction of amphetamine and starvation is not known. Angel[8] found higher levels of cocaine in the brain in starved rats and interpreted this to indicate an increased permeability of the blood–brain barrier during starvation. That effect would be equally likely to occur, however, if the metabolism of cocaine was interfered with during starvation. In this regard Dixon, Shunttice and Fouts[9] have shown that during starvation liver metabolism of certain psychoactive drugs is impaired. It is possible that the present results have their basis in an impaired metabolism of amphetamine during starvation.

There has also been considerable work on the effects of stress on central biogenic amines. Although starvation is not typically viewed in this way, food deprivation is obviously a highly stressful experience. The increased sympathetic activity during hypoglycaemia is consistent with this model[6]. Stress significantly alters absolute concentrations, rates of synthesis and release of biogenic amines in the brain[10–13]. Furthermore, amphetamine toxicity is increased by some forms of stress[14,15]. Together these findings indicate that the mode of action of amphetamine and the central biogenic amines through which it is thought to exert its action may be changed in the central nervous system during stress. To the extent that starvation is a stressor, our results may be a reflexion of central neurochemical changes which occur during stress.

Whatever mechanisms underlie our findings, these experiments indicate that in psychopharmacological research the nutritive state of the animal is of considerable importance in determining the magnitude and the nature of the drug response.

Effects of 6-Hydroxydopamine on Sleep in the Rat

THERE is evidence that biogenic amines are involved in the mechanisms of sleep[1,2]. Although the exact relationship is not clear, recent results suggest that decreases in the concentration of catecholamines (noradrenaline or dopamine) in the brain cause increased desynchronized sleep (D) (sleep with rapid desynchronized cortical activity, also known as paradoxical or REM sleep), whereas increases in the concentration of catecholamines decrease D[3–5]. Not all the results, however, are in agreement[1,2,6].

6-Hydroxydopamine depletes catecholamines and large doses cause degeneration of catecholamine-containing neurones in the brain and peripheral sympathetic nervous system[8–15]. Because 6-hydroxydopamine does not cross the blood–brain barrier it must be administered intrathecally to be effective in the brain. The decrease in content of noradrenaline and dopamine in the brain has been found to last for at least 20 weeks[12,13,16,17], and we now report that, during this period, D is significantly increased.

Male Sprague–Dawley rats (190–200 g) were injected intracisternally with 6-hydroxydopamine hydrobromide (Regis Chemical Corp.) or saline, containing 0.1% ascorbic acid which was used as a solvent for the 6-hydroxydopamine. (This solution was kept ice-cold and was bubbled with nitrogen to prevent oxidation of 6-hydroxydopamine.) Each experimental

Table 1 Effect of 6-Hydroxydopamine (6-OHDA) on the Noradrenaline Content of the Rat Brain

Time after 6-OHDA (weeks)	Control (Percentage of control mean ± s.e.m.)	6-OHDA	P
1	100±4.5 (N=6)	27±1.4 (N=6)	<0.001
21	100±4.0 (N=9)	41±5.0 (N=8)	<0.001

In animals killed 1 week after the intracisternal injection assays were performed on extracts of homogenates of whole brain. In these assays the mean concentration of noradrenaline in controls was 764±34 ng per brain. In animals killed 21 weeks after the intracisternal injection assays were performed on extracts of homogenates of various brain regions. The levels in the whole brain were obtained by summing the values for each brain part in each animal. The mean concentration of noradrenaline in the controls was 904±38 ng per brain. N, Number of animals.

rat received two injections of 6-hydroxydopamine; the first contained 200 µg of the free base in 25 µl. of the solvent; the second, administered 72 h later, contained 300 µg in 25 µl. of solvent. Control rats received intracisternal injections of solvent according to the same schedule. The technique of intracisternal injection is described elsewhere[18].

Noradrenaline was determined in whole brain or various regions of the brain by a modification of the method of Anton and Sayre[19]. Experimental and control rats of one group were killed 1 week after the last intracisternal injection and noradrenaline was determined in the whole brain. The other animals were killed 21 weeks after the last intracisternal injection (when all sleep recordings had been completed) and noradrenaline was measured in various brain regions. The content of noradrenaline was significantly lower in brain of animals treated with 6-hydroxydopamine than in the controls (Table 1). The decrease occurred in all brain regions examined: cerebellum, cortex, hypothalamus, pons-medulla, corpus striatum and the remainder of the brain. The greatest depletion was in the cerebellum and cortex.

One week after the administration of 6-hydroxydopamine the content of noradrenaline in the whole brain was 27% of the matched control value, and 21 weeks after treatment the content of noradrenaline was 41% of the matched control (Table 1). If this represents a true change with time, it might reflect a regeneration of some noradrenergic neurones or a compensatory increase in the content of noradrenaline in the remaining noradrenergic neurones in the brains of animals treated with 6-hydroxydopamine. But other investigators have found no evidence of restoration of noradrenaline content in brain during similar time intervals[16,17].

Two to three weeks after the intracisternal injections, eleven animals (seven experimental and four control) were implanted with cortical, hippocampal and nuchal muscle electrodes according to the usual techniques for sleep recordings in the rat[20,21]. During a period of 3 months starting 2 weeks after surgery, sleep patterns of each animal were recorded in specially constructed recording chambers. Each animal had three 8 h "adaptation" recordings and then a further series of 8 h recordings (beginning at 0930 h) at 1 week intervals (Table 2). Two experimental and two control animals were also recorded over 24 h. Subsequently, three of the experimental animals and four of the controls were deprived of D for 72 h on small islands surrounded by water[22] and were recorded during 24 h of "recovery" immediately after removal from the island. All records were scored for waking (W), synchronized sleep (S), and desynchronized sleep (D), according to previously described criteria[20,21].

Results of the 8 h recordings are given in Table 2. Values for W, S and D in the control animals in this study agree closely with our usual results in untreated rats. 6-Hydroxydopamine produced a significant increase in D. This increase was a result of a significant increase in the length of D-period and a slight increase in the total number of D-periods. The increased D-time was obtained at the expense of decreased waking; S-time was almost identical in the experimental and control animals.

Table 2 Effects of 6-Hydroxydopamine on Sleep in the Rat

Treatment	No. of animals	No. of 8 h recordings	W-time $\left(\frac{\text{min}}{\%}\right)$	S-time $\left(\frac{\text{min}}{\%}\right)$	D-time $\left(\frac{\text{min}}{\%}\right)$	No. of D-periods	Length of D (min)	No. of awakenings
Solvent	4	12	$\frac{167.1\pm17.5}{34.6\%\pm3.3\%}$	$\frac{266.0\pm10.4}{55.2\%\pm7.7\%}$	$\frac{48.4\pm6.4}{10.1\%\pm1.4\%}$	24.4±3.0	1.9±0.04	37.8±2.3
6-OHDA	7	19	$\frac{143.1\pm4.7}{29.8\%\pm1.0\%}$	$\frac{268.7\pm5.9}{55.8\%\pm1.2\%}$	$\frac{69.7\pm6.2\dagger}{14.5\%\pm1.0\%}$	29.7±1.3	2.4±0.1‡	45.5±2.2*

W, Waking; S, synchronized sleep; D, desynchronized sleep. Values are given as means±s.e. Values for W, S and D under the horizontal lines are percentages of total recording time±s.e.

* $P<0.05$; † $P<0.02$; ‡ $P<0.005$; t test, two-tailed.

The data were also examined for the changes which may have occurred over the duration of the study (3 months). The only change noted was a slight decrease in D over the several months of the study in both experimental and control animals. This is consistent with the effects of ageing.

The 24 h recordings after 72 h of D-deprivation were almost identical for W, S and D in experimental and control animals; since the absolute amount of D was approximately equal in the two groups, the increase above baseline values was therefore smaller in the experimental animals. In the control, but not in the experimental animals, the length of D-period was greater than the comparable values obtained in baseline 24 h recordings. Recovery of the experimental animals appeared to be complete in 8 h, whereas the control animals showed a sustained increase in levels of D throughout the 24 h.

Our findings confirm that intracisternally administered 6-hydroxydopamine produces a marked decrease in concentrations of noradrenaline in rat brain and that this persists for 21 weeks. The increased D after 6-hydroxydopamine is consistent with our findings of increased D in conditions characterized by decreased catecholamines in the brain[3,4,23]. It is possible, however, that factors other than the decreased catecholamines in the brain may contribute to the effects on sleep patterns. For example, 6-hydroxydopamine has been found to produce a short-term decrease in levels of serotonin in rat brain[11,12,15], and our preliminary findings suggest that

6-hydroxydopamine may also produce a long-lasting decrease in levels of serotonin particularly in the hypothalamus (unpublished data).

6-Hydroxydopamine seems to increase both number and length of D but there is a much more prominent effect on the latter, suggesting that the mechanism controlling the length of D may be particularly influenced by catecholamines. The fact that total S was almost exactly equal in the control and experimental animals suggests that it may not be affected by brain catecholamines. The findings discussed here, as well as our data on the effects of alpha-methylparatyrosine[3,4], suggest that the catecholamines particularly affect the relative amounts of time spent in W and D. This would be consistent with the finding that agents such as amphetamines or the monoamine oxidase inhibitors, which increase concentrations or availability of catecholamines, have been found to produce decreased D and increased waking in several species[24–26]. The results are also consistent with the hypothesis that a biological function of D may be to increase the synthesis or availability of catecholamines or to increase sensitivity of catecholamine receptors[5]. This in turn may have a role in maintaining wakefulness or certain aspects of wakefulness[27].

Trace Metal Variations in Sea Water of the Menai Straits caused by a Bloom of *Phaeocystis*

PLANKTONIC marine organisms often accumulate trace metals greatly in excess of their metabolic requirements and to concentrations 10^2–10^6 times those in sea water[1]. But variations in the concentration of trace metals in sea water are not usually affected unless there is a large production of plankton as there is in bloom conditions[2].

During June 1969, anomalous metal concentrations in the Menai Straits were recorded which could not be explained by variations in run-off supply from the surrounding land. The occurrence of a heavy bloom of the flagellate *Phaeocystis* at this time suggested a possible biological control which was investigated the following year. *Phaeocystis* blooms regularly in the Liverpool Bay region during late spring. At this time, the organism occurs partially in a colonial bladder form, some bladders reaching such a size (up to 4 mm in diameter) that they are readily visible to the naked eye[3].

Sea water samples for metal analysis were collected from Menai Bridge Pier at approximately 4 day intervals throughout the period of *Phaeocystis* occurrence from May 21 to July 18, 1970. Particulate matter was separated by filtration through a membrane filter and dissolved Zn, Cu and Mn were determined by X-ray fluorescence spectrometry[4] after a preliminary concentration by extraction on a chelating-resin[5]. Particulate metal concentrations were also determined. The membrane filters were digested in concentrated nitric acid and the digest was evaporated to dryness. The evaporate was subsequently absorbed into a standard weight of cellulose powder and elemental analyses were carried out by X-ray fluorescence spectrometry[4].

Although inorganic particulate matter also contributes trace metals, particulate concentrations were consistently low (<2 mg/l.) throughout the investigation and measurements both before and after gave particulate metal values of <2 μg/l. in this amount of material.

The total flagellate counts throughout the investigation are shown in Fig. 1. Although quantitative data on the relative amounts of *Phaeocystis* and other flagellate species were not recorded, microscopic examination showed that from June 2 to July 3 flagellate counts were composed almost entirely of *Phaeocystis*. Two peaks of abundance are clear, each representing 10^8 cells/l. at their maximum.

The dissolved and particulate Zn, Cu and Mn concentrations recorded during this study are illustrated in Fig. 2, from which it is apparent that the phytoplankton bloom affects these three metals in quite different ways. Both particulate and dissolved Zn concentrations increased when *Phaeocystis* was present, but for both the increase was of much greater magnitude during the second peak than during the first. But the values of dissolved Zn (up to 45 μg/l.) recorded at this time were so large in comparison with the values just before and just after the bloom that Zn must have been released from *Phaeocystis* during filtration. Rupture of the outer membrane of colonies during filtration has been demonstrated; it releases the mucilaginous fluid which separates individual cells within a colony. Zinc therefore seems to be concentrated in the jelly-like material within the outer membrane. The release of larger amounts during the second peak indicates that there is a greater degree of colonization and a larger amount of mucilaginous material at this time.

Although the observed dissolved concentrations of Cu are relatively constant, the particulate Cu shows a double peaked variation which corresponds well with the changes in the number of flagellate cells. Copper is apparently accumulated almost solely within the flagellate cell itself.

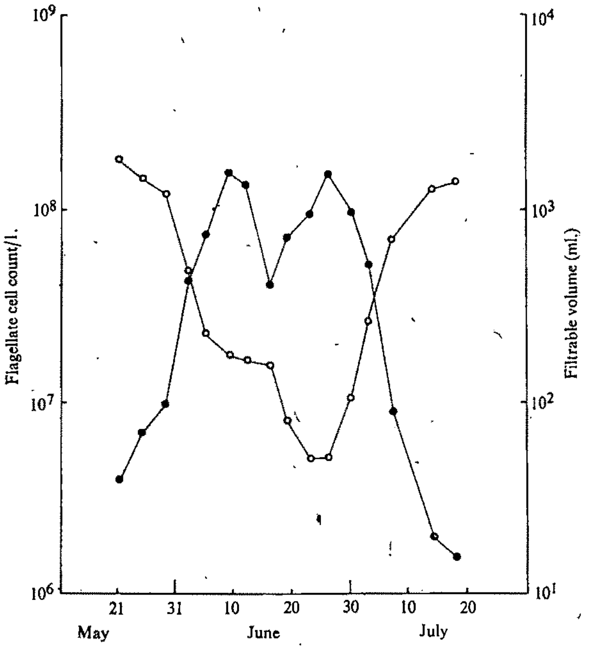

Fig. 1 Total flagellate cell count (●) at Menai Bridge Pier from May 21 to July 18, 1970. The peak values correspond to a bloom of the colonial flagellate *Phaeocystis*. From June 2 to July 3, the flagellates consisted almost entirely of this species. The other curve (○) represents the volume of water which could be filtered through a membrane filter, diameter 4 cm and pore size 0.45 µm, before it was completely blocked. The smaller volume obtained during the second peak in cell numbers indicates that there was a greater degree of colonization of *Phaeocystis* at that time.

Dissolved Mn has a minimum concentration which corresponds temporally to the second peak of *Phaeocystis*, and to a marked increase in particulate Mn. The particulate Mn concentration is very low during the first *Phaeocystis* peak but remains high after the rapid fall in cell numbers following the second peak. Such a pattern is explained best by a mechanism involving surface adsorption of Mn on the outer membrane of the colonies, the persistent high particulate Mn at the end of the investigation being the result of continued association of Mn with the disintegrating bladders. Such a mechanism again requires a greater degree of colonization during the second peak in flagellate cell numbers.

In spite of almost identical maxima in cell numbers for each of the two peaks of *Phaeocystis*, there is a clear difference in their affinity for Zn and Mn. The proposed explanations for these phenomena require a greater degree of colonization during the second peak. Changes in the filtration characteristics of the water during the investigation indicate that this was so.

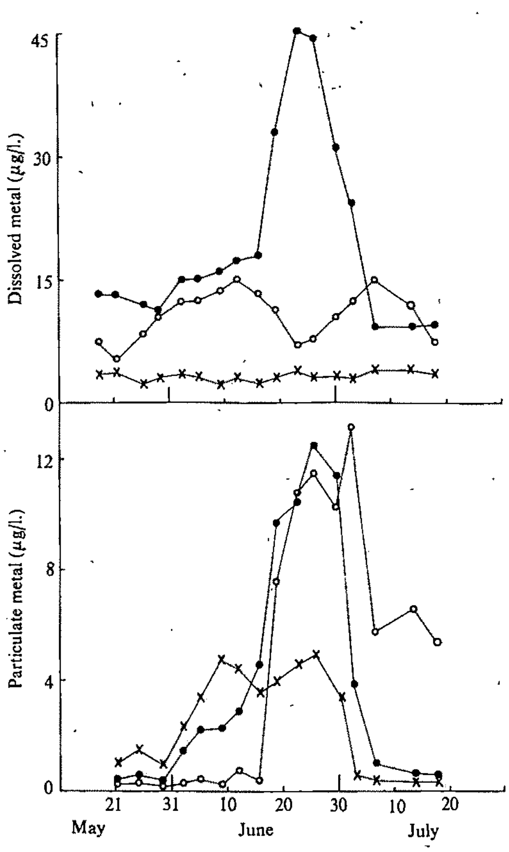

Fig. 2 Changes in concentration of the dissolved (upper curves) and particulate (lower curves) trace metals Zn (●), Cu (×) and Mn (○) in the sea water at Menai Bridge Pier from May 21 to July 18, 1970.

The rate of filtration of sea water containing *Phaeocystis* bladders is reduced rapidly as the bladder membranes spread over and block the filter surface. The remarkable plasticity of *Phaeocystis* bladders has been reported before[6]. As well as flagellate cell counts, Fig. 1 shows the volume of water which could be filtered through a single membrane filter (4 cm diameter) before the rate of filtration was reduced almost to zero; smaller volumes are indicative of the presence of a greater amount of membrane. Clearly the second peak represents a greater degree of colonization and thus a greater amount of bladder membrane and internal mucilaginous fluid.

Although the explanations of the causes of the variations reported here are only tentative, such marked changes can only derive from quite different interactions between *Phaeocystis* and the three metals. Clearly attempts to explain the accumulation of trace metals by marine organisms on the basis of the general chemical properties of the metals, such as the "Irving-Williams order", are not applicable to this species.

This work was partly supported by an NERC research grant. I thank Mr P. Tyler for flagellate counts.

BOOK REVIEWS

Flying into Yesterday

Flights into Yesterday: The Story of Aerial Archaeology. By Leo Deuel. Pp. xvii+302+36 plates. (Macdonald: London, 1971.) £5.

THIS book is the first popular account of archaeological aerial photography to be written from a worldwide viewpoint: as such it is entirely successful. Dr Deuel sets out to tell the whole fascinating story of the development of aerial photography beginning with the exploits of the French balloonist, Nadar, over Paris in 1858 and ending with a look into the future. It was immediately before the First World War that the archaeological potential of the technique began to be realized but it was the war itself which was responsible for training a number of pilots in what was still a novel and largely unexplored approach to area surveying. Some of these men, returning after hostilities had ceased, were not slow to put their new found skills to archaeological use—men like Crawford in Britain, Wiegard working in Gaza and the Negeb, and Beazeley in Mesopotamia—these were the pioneers. But for sheer courage and vision few can compare with the exploits of Father Poidebard, a French Jesuit priest, who flew the Syrian Desert between 1924 and 1932 and published his results in a monumental work, *La trace de Rome dans le désert de Syrie,* two years later. This book is a model of its kind, showing with great clarity how an entire cultural landscape can be built up, painstakingly, from the air. Nor was Poidebard averse to landing his flimsy craft in the desert and taking out his spade to become a more conventional type of archaeologist.

All of these exploits Deuel lovingly describes, gradually extending the story to include chapters on more recent work in Italy and providing a substantial section on the fascinating and little appreciated aerial archaeology of America which owed much of its early impetus to the expeditions mounted by the famous pioneer flier Lindenbergh. It is this American section which will be the most unfamiliar to British archaeologists, and will help to redress the Old World-centred view of aerial photography.

The author pays a just tribute to British archaeologists like O. G. S. Crawford, Major Allen and Dr St Joseph. Nowadays, with archaeological sites being destroyed without record at an alarmingly accelerating rate, it is little short of a national disgrace that Britain has no adequate centralized, government-sponsored institute responsible for archaeological aerial recording. At present, Dr St Joseph's Committee for Aerial Photography at Cambridge and the valiant efforts of a seriously understaffed National Monuments Record, helped by the activities of amateur archaeologists, are all we can boast. Let us hope that Dr Deuel's book will be read by a few of our masters and shame them into a more responsible attitude towards Britain's rapidly disappearing heritage.

This book is clearly aimed at the general reader but its thorough treatment and broad approach will commend it to the specialist even though the writing is at times somewhat over expansive. B. W. CUNLIFFE

Theory in Science

Science as Metaphor: The Historical Role of Scientific Theories in Forming Western Culture. Edited by Richard Olson. Pp. xi+321. (Wadsworth: Belmont, California, 1971.) n.p.

IN recent years a number of attempts have been made to provide students of the history and philosophy of science with selections of readings from both primary and secondary sources. Some of these editions have been ill-conceived in both scope and depth, lacking unity of purpose, while exhibiting a poor selection of material, in spite, if not because, of their commercial possibilities.

The volume under present consideration, however, is to be recommended not only for the editor's intelligent choice of material but also because the scope of the work has been restricted to one of the most interesting and complex, yet poorly documented, aspects of the history of science. The central theme of this book is the influence of scientific theories on various other—often "extra-scientific" — disciplines. Several major scientific movements are considered and in each case readings are given to illustrate how parallel theories have been applied to such fields as law, theology, literature, social theory and so on. In discussing the influence of science on society, most writers take Social Darwinism as their paradigm, whereas this book is much wider and more exciting in its scope. The editor also avoids the pitfall of conflating technology with science.

Eight general subject areas are considered—the change in perspective accompanying the scientific revolution, the mechanical philosophy, Newtonian philosophy, Darwinism, energetics, Freudian theory (a valuable inclusion), positivism and behaviourism, and twentieth century physics. In the introduction to each section the editor presents a perspective of the subject under discussion. The readings themselves, varying in number from two to four, are reprints of short but substantial articles, often *in toto,* with footnotes omitted. The diversity of this selection is a further recommendation for the book, for example, Robert Lenoble's interesting piece on Mersenne's view of God as the Divine Engineer, Emile Zola's theory of the experimental novel, and an article on historical relativity. On the whole this is an admirable selection showing not only how scientific theories and methodologies have been applied in other contexts, but also how they have been misapplied.

The editor has contributed three original essays to this volume. In an introductory essay he stresses that scientific theories have an important place in the development of Western culture—Snow and Leavis please note. He then suggests it is by analogy that scientific theories are adopted for "extra-scientific" use. This discussion of the role of analogy is rather weak compared with the forceful views on methodology stated in some of the subsequent articles. The question of what may legitimately be viewed as the direct influence of science on other disciplines has not yet been satisfactorily answered. This important link is a methodological one, and something stronger than analogy is called for.

The volume concludes with a useful bibliographical essay which is preceded by the editor's analysis of what he considers to be a contemporary cultural lacuna, the reaction of certain "radical" groups against science. This is a fairly sympathetic although limited account of the "alienation" accompanying modern science.

In the preface Dr Olson states that the idea for the book grew out of an interdisciplinary course taught by himself and several other specialists at Crown College in California. This book should help the (intelligent) student, together with the scientist and the "literary intellectual" (to use Snow's pompous term), to appreciate not only that science is an integral part of our culture but also that scientific theories and scientific methodology have profoundly influenced other fields of human endeavour. G. N. CANTOR

Mathematical Past

The Development of the Foundations of Mathematical Analysis from Euler to Riemann. By I. Grattan-Guinness. Pp. xiii+186. (MIT: London and Cambridge, Massachusetts, February 1971.) £4.65.

THE place of history in mathematical education is controversial, and opinions differ widely. There is always a movement among students—with which, it would seem, the publishers of this work sympathize strongly—to demand a more historical treatment of their mathematics. This applies particularly to the elements of analysis which they tend to find difficult and resent having to learn anyway. My former colleague, Dr S. R. Tims, who was an outstandingly brilliant teacher of this subject, always used to claim that it was a mistake to teach the history of it, as students could find plenty of errors for themselves without putting ideas into their heads! I certainly look forward to confronting students with this book and seeing whether they really feel that it is more interesting (or even easier) than taking the subject straight.

The book places the development of nineteenth century analytical ideas in the context of the problems, starting with the vibrating string, in which they arose. Not surprisingly the central character of the book is Cauchy, whom the author effectively portrays in a not altogether amiable light. There is a deal of useful background information which enables the uninitiated reader to follow a lot of contemporary infighting which could otherwise be unappreciated. Perhaps the most important historical point made is that Cauchy had benefited (without a hint of direct acknowledgment) from a study of the writings of Bolzano. This assertion shows up neatly the nature of the difference between mathematical and historical proof, but clearly Dr Grattan-Guinness has made out a highly plausible case which could not be questioned by anybody less deeply immersed in the sources.

The author has clearly benefited from much recent historical work but it is perhaps a pity that by confining himself to a historical period, rather than being guided by the mathematical ideas, he is prevented from discussing the work of Abraham Robinson on non-standard analysis. Robinson's justification of the use of infinitesimals will certainly have to be taken into account in the definitive treatment of the ideas under discussion here, and yet this account, when it is eventually produced, will have again to go over a lot of the ground covered in this volume.

In spite of the claims on the dust cover the book appears to be intended by the author primarily for the benefit of his fellow historians. The historian's mastery of, and need to identify, his sources (as demonstrated by the copious footnotes) is to some extent at variance with providing a narrative which is easy to read. I wonder if the author has fallen stylistically between two stools. The presentation of the mathematical arguments (even when all allowances are made for the need to convey the flavour of past errors) seems somewhat uncomfortable for students of mathematics, and it is not clear that it will be found more helpful in putting the technical ideas across to possible historical readers with comparatively slight mathematical backgrounds.

D. B. SCOTT

Statistical Physics

Statistical Physics. By F. Mandl. Pp. xiii+379. (Wiley: London and New York, July 1971.) £2.75.

Statistical Physics. By A. Isihara. Pp. xv+439. (Academic: New York and London, June 1971.) $18.50; £8.65.

ALTHOUGH the two books reviewed here have the same title, they belong to two completely different worlds: Mandl's book is written for undergraduates and is clearly a textbook, while Isihara's book is clearly a reference book, even though the publishers in their blurb suggest that it might be adopted as the required text for certain advanced courses. Mandl's book covers both thermodynamics and statistical mechanics, while Isihara's book deals only with statistical mechanics; Mandl's book has a restricted coverage, while Isihara seems to include just about everything; finally, Mandl's book is cheap by present-day standards—and, I feel, excellent value for money—while Isihara's book is rather expensive and not such good value for money.

Mandl's book is a volume in the Manchester Physics Series which provides a set of textbooks for undergraduate degree courses in physics. In common with many modern books on the subject, statistical mechanics and thermodynamics are developed at the same time. This makes it necessary to stick to basic principles and to a restricted number of applications. One can hardly quarrel with the choice of material: I found in this book practically all the topics which I would like my own undergraduate pupils to know. As one has come to expect from the author, the book is carefully written and all steps are carefully and clearly presented. I shall certainly recommend this book to my pupils and see to it that it will be in my college library.

Mandl's book starts with the first two laws of thermodynamics, followed by a chapter on paramagnetism, including a section on negative temperatures. A second chapter on the second law includes a section on the third law, and is followed by a chapter on simple thermodynamic systems, and one on specific heats of solids. The next chapter is devoted to the perfect classical gas. A chapter on phase equilibria follows, and the book is concluded with chapters on perfect quantal gases, black body radiation, and systems with variable particle numbers. There are plenty of problems and hints for solving them. As every reviewer should find at least one point of disagreement, I shall mention the fact that the discussion of the relation between spin and statistics for composite particles is not quite correct and does not pay proper attention to the complications of the situation.

I cannot be so laudatory about Isihara's book. He has made important contributions to the subject, and many parts of the book are based on his research. This has as an important result that the book is foremost a research monograph, rather than a textbook. While I shall be glad to have it on my own bookshelves, I would not have bought it, as the contents to a very large extent can be found in research papers in the scientific literature—and more or less in the same form as they are presented here. I feel that the only people who will benefit from the book are those research workers who will themselves work in the fields covered by the author. In my opinion, the author would have produced a better textbook by restricting its scope and covering some topics in more depth and breadth: there are 132 sections in just over 400 pages, which means that the average length of a section is a mere three pages. The fifteen chapters in the book cover, respectively, kinetic theory, including elementary transport theory, principles of statistical mechanics, including ergodic and H-theorems, partition functions, including fluctuations, ideal bosons and fermions, including a very brief discussion of parastatistics and the de Haas–van Alphen effect, the linked cluster expansion, distribution functions, including hypernetted, Percus–Yevick, and Born–Green theories, Brownian motion, lattice statistics, including "melting" of DNA, phenomena near the critical temperature, including a one-page discussion of critical exponents, propagator methods for partition functions, propagator methods for distribution functions, transport phenomena in degenerate systems, including the Kondo effect, irreversibility and transport coefficients, including the master equation, second quantization, including spin and statistics, and Green functions, including superconductivity. As a result of the breakneck speed, the reader gets lost: to mention one instance, the author mentions that Fermi liquids should have a linear temperature dependence, but nowhere makes it clear why the quasi-particles are still fermions, or why the procedure for calculating the specific heat is the same as for a perfect gas and what is the meaning of the effective mass. Another objection I have against the book is the sloppy treatment of names and references: Birkoff instead of Birkhoff, Kammerlingh Onnes as well as Kamerlingh Onnes, Nozier or Nozière, instead of Nozières, Schöfield instead of Schofield, Soviet Phys.-JETP instead of Zh.Eksp.Teor.Fiz.

D. ter Haar

Interference and Waves

Interference of Electromagnetic Waves. By A. H. Cook. (International Series of Monographs on Physics.) Pp. viii+253. (Clarendon: Oxford; Oxford University: London, June 1971.) £5.

Interferometry is a discipline which, especially during the past two decades, has intruded more and more into science and engineering. Its classical beginnings were in the visible region of the spectrum, but it has spread over the whole electromagnetic gamut from X-rays to radio waves; it has even sidestepped into de Broglie waves.

Dr Cook's book declares its interest in the electromagnetic spectrum. He sets out, as he says in the preface, ". . . to deal with selected topics in the interference of electromagnetic radiation in a fundamental way while yet introducing them in an elementary manner". His choice of topics is, not unnaturally, coloured to some extent by his own experience. While in the Standards Division of the National Physical Laboratory (ultimately as its superintendent) he was concerned with extremely precise measurements which included the determination of the density of mercury, the measurement of the acceleration due to gravity and the establishment of the length of the standard yard in terms of the orange wavelength of krypton. In all of these interferometry was used as the method of choice for determining lengths with the utmost accuracy. Inevitably many exponents of interferometry could bridle at the fact that their own specialities have been left out. But, in the samples he has selected, Dr Cook has discussed the underlying principles with sufficient thoroughness to give the reader a clear notion of what goes on in virtually any interferometer. This he has done with the aid of mathematics which are merciful compared with those found in some other books on the same subject.

After introducing the concept of coherence, he devotes much of the book to the Michelson, Fizeau and Fabry–Perot interferometers and some of their applications. These include X-ray and microwave interferometry. Fourier transform spectroscopy is covered in this part of the book, as is the birefringence filter. A very useful chapter on the general theory of spectrometers is given.

The theory of "angular interferometers", covering Michelson's stellar interferometer and its radio counterpart, is presented in a very interesting chapter. It is a pity that, here, Homer has nodded; Dr Cook implies that the spacing of the fringes in the focal plane can be calculated from the separation of the outside mirrors and the focal length. This can only be done in "star-space"; in fact, the fringe spacing as calculated is wholly unrealizable. (I was "hung up" over this matter many years ago.) The difficulty with the early instruments at Mount Wilson was not the fineness of the fringes but their motion due to the "seeing"; Gebbie and Twiss sought to remedy this, to a first order, by an ingenious servo mechanism.

A short chapter on beats between independent sources reminds the reader firmly that times have changed since R. W. Wood wrote. Finally, the topic of intensity interferometers is discussed, another field of which the title seems at first sight to be a contradiction in terms. Unhappily, the curious jinx on the "angular interferometer" appears again; by an obvious slip of the pen "path difference" is used for "base-line". But, if the reader has absorbed Dr Cook's exposition of basic principles, he should, having read this far in the book, be in no danger of being misled.

These few quibbles—together with a few misprints—detract only negligibly from the value of a book written with clarity and authority. It will be a most useful introduction to a subject about which increasing numbers of scientists need to know.

J. Dyson

Palaeoecology Introduced

An Introduction to Quantitative Paleoecology. By R. A. Reyment. Pp. xii+226. (Elsevier: Amsterdam, London and New York, 1971.) n.p.

It is a pleasure to read such a clearly written and disarmingly simple little book whose contents quite belie the somewhat arid title. "How to enjoy using fossils and figures" might have been more apt as a description. The book is a short and very personal account of the way in which one palaeoecologist looks at his subject. He starts by introducing straightforward statistical concepts and then writes about such topics as the orientation of shells, the ways in which the environment can affect the size and shape of animals, the identification of predators, prey and population dynamics, the distribution of organisms in space, and some of the ways in which fossil assemblages can be analysed using statistical methods.

Part of the charm of the book lies in the twenty-eight case histories. In each example the problem is described, a model proposed, a statistical method and calculation provided, and the results discussed. Most of the examples are directly or indirectly the outcome of the author's own research and tend therefore to rely on ostracods and molluscs and be more concerned with younger than with older rocks. The last forty pages of the book give statistical tables, some short Fortran programs, references and an adequate index.

It does not really matter that the animal kingdom and the geological column have been selectively sampled. More than twenty of the more common statistical methods of particular interest to palaeoecology are described—more than sufficient for many of the present practitioners of the art. The author asks the question in the preface, "Am I kidding myself or is this result, or these data, really genuine? I have tried to do the same thing myself in the following pages but it is not always easy." It is pleasant to record that I believe that Professor Reyment has been successful not only with his data but with his approach. The book should appeal to a wide range of advanced students and thoroughly deserves to be successful.

G. Y. Craig

Rubber Text

Rubber Technology and Manufacture. Edited by C. M. Blow. Pp. xxii+527. (Butterworth: London, May 1971.) £9.

The first impression of a book which purports to cover the whole of rubber technology in just over 500 pages is inevitably one of superficiality. The wording on the dust cover implies that this book is "a definitive volume covering rubber technology and manufacture". The foreword says that it is intended (among other things) as a "guide" for undergraduates reading for the AIRI and for degrees in polymer science or technology. The latter is certainly a more realistic assessment, and in consequence some readers may feel that £9 is an excessive price to pay for what is merely an introduction to the subject. A selection of leading references is given for those who wish to follow up the various topics in greater detail, and this feature enhances the value of the book very considerably.

Most of the principal areas of rubber technology are dealt with, but rarely is space available to permit treatment in any depth. According to the foreword, the brief prepared by the editor stated that "the book is intended for graduates in chemistry, physics and engineering wishing to acquire a sound practical knowledge of rubber technology with emphasis on the processing, compounding and manufacturing of rubber products rather than on the chemistry and physics of rubbers, although the basic facts and theories of the latter must be adequately, though briefly, covered". In general, it seems that the objectives of this brief have been satisfactorily met. Subjects which have been deliberately omitted from the book include lattices, ebonite and adhesives. Engineering applications of elastomers have deliberately received "scant" treatment only, on the grounds that many conferences have been held and several books published on this subject in recent years.

The subject unfolds in a logical manner. Introductory chapters deal with the history of the rubber industry, an outline of rubber technology, and rubber physics. Then come chapters on raw polymers, vulcanization, compounding materials, reinforcement, machinery and production technology, compounding and manufacturing techniques. The book concludes with chapters on testing procedures and standards, and professional, trade, research and standards organizations.

Being the work of thirty-two separate authors, the book inevitably has some repetition and some unevenness of treatment. A stronger editorial hand could undoubtedly have been wielded. Thus, for example, the important phenomenon of swelling of elastomers is dealt with separately in several different places, and in no case is the treatment satisfactory. Furthermore, in discussing the determination of crosslink density by swelling, no mention is made of the important method of swollen compression modulus (which provides an effective procedure for eliminating the Flory χ-factor). Again, plastimeters are dealt with in two separate chapters, and space wasted through overlap could have been put to better use in amplifying some of the issues raised.

D. C. BLACKLEY

Safety in Numbers

Physical Biochemistry. By Edward Kensal Van Holde. Pp. ix+246. (Prentice Hall: Englewood Cliffs, N.J., July 1971.) $9.75 cloth. $4 paper.

THE achievements of molecular biology during the past two decades are too well known to need enumeration; it may well be asked, however, what contribution the physical chemist has made to all the excitement. Faced with the Augean stables of biological systems, the molecular biologist has been presented first with the problem of separating and assaying minute amounts of chemical species differing in but subtle ways. The solution of these problems would have been unimaginable without the efforts of a whole generation of physical chemists. But if you scratch a physical biochemist you are likely to find a polymer chemist or spectroscopist beneath the skin. Such preoccupations have of course led to many notable advances, but all too often the physical biochemist has left the dangerous waters of real biological systems to measure the size and shape and properties of proteins and nucleic acids, uneasily steering a course between the shoals of biological irrelevancy and sheer unanalysable complexity.

This brief and unpedantic book leads the embryo physical biochemist down similar traditional byways. After a quick review of classical thermodynamics it provides some insights into the implications of the Boltzmann distribution and the second law, an introduction to solution thermodynamics and a page or two on the nature of macromolecules. After this prolegomenon the author discusses chemical equilibria with a useful section on multiple equilibria and a mention of cooperative helix coil transitions. Then the traditional preoccupations return with a concern for the theory and practice of various methods of investigating the size and structure of macromolecules. Thus the last two sections deal with transport processes and with the interaction of radiation with biological matter. In passing, the principles behind various separation methods are discussed.

There is, oddly, little on the polyelectrolyte nature of biological macromolecules and nothing on surface chemistry or kinetics. The reader should know something about proteins and nucleic acids, but in case he doesn't, he is frequently referred to other volumes in this series (Foundations of Modern Biochemistry).

The style is lucid and informal with the occasional well chosen metaphor, but the high flown phrase is eschewed. The text is illustrated with pictures of pretty girls standing by pieces of apparatus and clear and elegant diagrams in green and grey. The reader should know about integral signs and partial differentials but may rest assured that, when the going gets too tough, rigorous analysis is neatly evaded by reference to higher texts. In the final section, quantum mechanics hovers in the background, letting drop the occasional arcane pronouncement. The text is not overburdened with references but there is a useful reading list at the end of each chapter together with a selection of numerical problems—without answers. I noticed a few misprints but no serious errors.

The biochemist endeavouring to understand the physical methods he encounters in his reading will find this book useful and it may be recommended to final year biochemistry students. The serious physical chemist will, however, prefer a more solid text.

E. G. RICHARDS

Chemistry Evolution

Biochemical Coevolution. By Kenton L. Chambers. (Proceedings of the Twenty-ninth Annual Biology Colloquium, April 26–27, 1968.) Pp. x+117. (Oregon State University: Corvallis, December 1970.) $5.

IN a respectable enthusiasm for the study of biochemical mechanisms, from the replication of DNA to the contraction of muscle, biologists have recently tended to neglect the precise and marvellous manifestations of evolutionary adaptation. It is therefore refreshing to find a book that points the way to studying these phenomena at the biochemical level. The book does not do more than point the way, and nobody should be misled by the title into supposing that its biochemical content is very great. Nevertheless it is a tantalizing introduction to a subject that must surely become more important during the next decade.

The book reports the proceedings of a symposium, and in common with others it harbours a motley collection of papers. In the first essay, P. R. Ehrlich manfully and almost successfully sets out to develop a theoretical framework on which the remainder can be hung. He has interesting things to say about the evolutionary interactions between plants and herbivores, predators and prey, parasites and hosts, flowers and pollinators. The second essay, by C. H. Muller, is a fascinating account of the airborne and waterborne toxins by means of which some plants inhibit the nearby growth of others. S. J. Karakashian writes the inconclusive history of the relations between a symbiotic alga, *Chlorella,* and its invertebrate "hosts". L. P. Brower, in the most thorough and closely reasoned contribution, summarizes his studies on the assimilation by Danaine butterflies of cardiac poisons from their food plants, and explores the effects of this assimilation on the interactions between the butterflies and their predators. Finally, C. H. Dodson describes his elegant work on the nature and species-specificity of the volatile substances by which orchids attract their insect pollinators.

In 1949, with characteristic prescience, J. B. S. Haldane drew attention to the unexplored territories of biochemical coevolution. More recently, the discoveries of enzyme polymorphism, and other aspects of protein evolution, have demanded a clearer knowledge of these territories. The studies reported in this book represent a few tentative forays, hopefully to be followed by more extensive colonization.

BRYAN CLARKE

CORRESPONDENCE

Doomsday Syndrome

SIR,—John Maddox's address to Section X of the British Association (*Nature*, 233, 15; 1971) shows him giving reasonable voice to the backlash against the "doomsday syndrome". He will find a warm welcome in many quarters for his suggestion that the whole thing has been a "wave of fashion". But there are some dangers in this particular role, and I would like to comment on them, in the light of my experience as the junior minister in the Labour government most concerned with environmental control.

Two phrases in the extract from Mr Maddox's address define his position. Talking about carbon dioxide in the atmosphere and the possible "greenhouse effect", he says: "In reality, nobody can be sure that the effect will be as predicted, and in any case the accumulation of carbon dioxide in the atmosphere is by no means the inexorable process that the doomsday men suggest. Other recent fears . . . are similarly unfounded."

Now to begin with, Mr Maddox implies that because nobody can be sure there will be a greenhouse effect, we ought all to forget about it. It seems to me that the contrary view is more rational, certainly more prudent; that we ought not to forget about it because nobody can be sure there will not be a greenhouse effect.

Nevertheless, Mr Maddox does not assert that the prediction is unfounded. But he does immediately go on to say that other fears are *similarly unfounded.* Into the logical gap between the statement of uncertainty and the statement of certainty a host of special interests will leap. Some of the oil firms are currently engaged in just this bad logic over lead in petrol; their scientific spokesmen are virtually saying that because there are holes in the anti-lead argument, therefore lead does no harm. *Non sequitur*.

When we were assembling the information which enabled Harold Wilson to appoint the new Secretary of State and the Royal Commission on the Environment and the Holdgate Unit, I found this attitude was widely held and powerfully defended by the more hidebound civil servants, both scientific and administrative. It is still *very* well represented in Whitehall, particularly in the more production-oriented sections such as the Ministry of Agriculture, the Department of Trade and Industry, and the former Ministry of Transport.

Another quarter where Mr Maddox's stand will be welcomed is among the already very powerful and well organized commercial interests whose testing and publication policy, as *Nature* has pointed out editorially before now, often leaves something to be desired.

To be sure the doomsday men and their disciples are overstating their cases; but this does not mean it is time for a general backtrack on the public consciousness and the legal and administrative measures of the last few years. The slogan "guilty until proved innocent" is no doubt a perfectionist one about new substances coming into use. But I would far sooner those in authority had it at the back of their minds than Mr Maddox's "other recent fears are similarly unfounded". It is the sounder slogan not only on ecological grounds, but on economic ones too: the true costs of a product, including certain, probable, and possible social costs, should be known before the product is marketed, so that they can be included in the price.

Yours faithfully,

WAYLAND KENNET

House of Lords

Working Europeans

SIR,—While I have full sympathy with the tenor of your editorial (*Nature*, 233, 152; 1971), I should like to suggest that a good deal more could be done through efforts of individual scientists in responsible positions, such as heads of departments or institutes. It is not really necessary to wait patiently till official agencies produce collaboration for us like a rabbit out of a hat. "When," you ask, "will the British Government agree that the Agricultural Research Council . . . should employ scientists from France or the Netherlands?" There is nothing now to stop them employing foreign nationals as research assistants at quite high salaries. In my department we had for some years a Swiss biologist whose salary was paid by the ARC, and we now have an Italian whose salary comes from the SRC. Both of these were on relatively short-term grants lasting only a few years, but we also have a Swiss citizen as a member of an MRC group, with a long term commitment. Again there is nothing to prevent integration at the level of university departments, at least at postgraduate level, where it is probably likely to be most useful. We have operated for the past few years an Anglo-Italian postgraduate course in epigenetics, with lecturing and laboratory work contributed jointly by our university staff and staff of the Laboratory for Molecular Embryology at Naples. The latter is funded by the Italian Council for Scientific Research, who have shown themselves very willing to meet the expenses of moving their teachers to Edinburgh and accommodating the students in Naples. The expenses on the British side, over and above the normal university contribution, are, it must be admitted, provided not by any governmental agency, but by the Leverhulme Trust. Such funds do, of course, have to be looked for. But they exist, and collaboration, at this perhaps rather minor level, can be what the Americans would call a grass-roots operation.

Finally, is there anything, except timidity, which stands in the way of the suggestion, which I have been urging for some years, that the research councils should appoint, to their main working committee which vets grant applications, one or two non-British European scientists? Some of us who find ourselves faced with steering the projects of our staff through committees of their colleague-rivals would welcome the judgment of respected outside opinion; and Europeans privileged to serve on such committees would gain valuable experience of how the really rather effective British system works.

Yours faithfully,

C. H. WADDINGTON

Research Associations

SIR,—I wholeheartedly endorse the letter of Mr Jobling (*Nature*, 231, 477; 1971). The problems of research associations are similar in all countries and the same errors are being made in many places. My experience suggests that it is completely wrong to want the RAs to be commercially viable, because the services they render are for the most part of a general character and the earnings following from these are mostly invisible. As a typical example I would single out the laundry and dry-cleaning industries, which comprise almost exclusively small or very small firms. What they need is independent information on new products and machines, relevant abstracts from the literature, control of their technical and commercial operations and statistics. Such services may be vital to a firm and save it from bankruptcy, but in the opinion of the manager £10 would be a quite sufficient fee.

Moreover, the existence of a sound laundry and dry-cleaning industry backed by appropriate RAs is also essential to the benefit of the consumer. Difficult though it may be to calculate this in hard cash, the benefit may well be immense. There are examples of great countries which could serve as a warning in this respect.

Lastly, in order to communicate efficiently with government services, with other industries and with international organizations, RAs are invaluable.

All this leads up to the following conclusions. RAs should have a stable income from some system of government imposed compulsory fees (such as in France) to finance their normal routine work. Research proper should be financed by individual firms, organizations or governmental departments, on a project basis, and it could best be done in association with a university or a very large institute. Rotation of personnel between research and routine duties would ensure flexibility, feedback and awareness of practical problems.

Yours faithfully,

S. V. VAECK

Chief of the Laboratory,

Bradford's Law

SIR,—In considering the application of Bradford's Law of Dispersion[1] as a guide to acquisition policy in the research library or information centre it is pleasant to contemplate a bibliophilic Utopia of a complete collection in a library with unlimited space and acquisition funds. Utopias are rarely found, however, and the library *does* have limited resources. Given this restriction, the librarian or acquisitions specialist, in even the largest and most pecunious libraries, must make choices. These choices are rational only to the extent that the library collection maximizes the timely provision of requested documents to the satisfaction of the largest number of users.

In this light, A. Faser's letter[2] suggesting that a library is derelict in not purchasing a specialized journal of interest to only one user treats the occasional request with the same degree of importance as the on-going demand for the heavily used journals. An inventory policy in a department or food store, part-supply depot, manufacturing concern or library, based on ignoring frequency-of-demand distributions, leads to inefficient allocation of resources. Designers of sewer and flood control systems know they cannot design economic drainpipe and culvert systems of sufficient capacity to handle the runoff from the one-in-a-thousand chance that rainfall will exceed, say, 6 inches in any 1 h period. And mass merchandisers stock only a few or no items in the extremely low and high size ranges of shoes, hats and all attire in between.

Bradford's Law promulgates that a library can supply *most* of the requests for material with a relatively modest inventory of book and journal titles, geared to the *normal* pattern of demand. This demand pattern is one in which a relatively few items from among all possible items in the inventory satisfy a majority of the actual transactions. Progressively fewer transactions are satisfied from the balance of the inventory, or from further augmentation of the number of titles held. Abiding by the Bradford distribution, then, is an important factor in the library's overall success at demand-fulfilment.

The most efficient way for a library to exploit its collection and maximize utilization of its document file is to share its bibliographic resources with as many patrons as possible. It cannot *reasonably* be expected to serve *every* individual request. Carried to the extreme, if the only requests were one-time requests, there could not be an *economic* central library. The most efficient way of handling such a situation would be for each individual to have his own private collection.

Yours faithfully,

Ageing Ova

SIR,—The recent article[1] published in your journal, showing increased chromatid disjunction in mouse eggs which were some time in the oviduct, is the latest in a line of papers all demonstrating that delayed fertilization can result in abnormal development of the embryo. The author points out that this could explain the increased frequency of trisomy among the offspring of older women. It should also be pointed out that the rhythm method of birth control might increase the possibility of fertilization occurring some time after ovulation, and thus also increase the chance of producing a malformed embryo. This is not entirely speculation as Iffy[2] found that eighteen out of twenty-one cases of abnormal embryonic development could be related to post-17th day ovulation and fertilization, while Cross[3] suggested that increased practice of the rhythm method might be responsible for the higher frequencies of anencephalus and spina bifida among Roman Catholics. The results of this latest paper[1] suggest that a more searching investigation into this possible danger is called for.

Suckling Etymology

SIR,—Dr Spratling bemoans the misuse of suck and suckle (*Nature*, **233**, 73; 1971). The confusion can be blamed on the medieval yeoman, rather than on *Nature*[1]. Suckling, like its German and Dutch parallels Saugling and suigeling (=baby), is a noun with the suffix -ling, as in weanling, yearling, duckling, gosling, and, more recently, ratling. The English yeoman assumed that suckling had the suffix -ing, as in paddling and speckling, and coined a new verb "suckle". He gave no thought to whether it meant anything other than suck. Shakespeare does indeed use suckle in the sense nurse or nourish at the breast. The Authorized Version prefers the older Germanic idiomic "give suck" (*cf* German saugen geben, Dutch zuigen geven). The *Shorter Oxford English Dictionary* traces the "misuse" of suckler to mean a suckling calf back to 1473, whereas "correct" use to mean an animal that is suckling young dates only from 1850. The difficulty now, and undoubtedly the origin of the modern "error", is that a baby pig still in its mother's tender care can be called either a suckling or a sucking pig. The term piglet is, of course, briefer; the British Society of Animal Production recommends its use for a pig up to about 8 weeks of age, irrespective of time of weaning[2]. I would recommend that the mother be called a nurse-sow or nursing sow. German Ammenkuh, literally "foster-cow", can be approximated to "multiple suckling" without defining whether the cow or calf is suckling.

Equally to be bemoaned is the imprecise use of "feed". Traditional is: The farmer feeds cows. Or the passive: Cows are fed. The meaning is not identical with: Cows eat. The *Shorter Oxford* gives two innovations from 1883 that have since become established. First: Cholera feeds on impurities . . . Bacteriologists might object to the word "eat" but surely for animal nutritionists "Cows eat hay" is far better than "Cows feed on hay". Second: Mangel-wurzel . . . is fed to the cows. . . . This type has become far too common, even being telescoped into: The farmer feeds cows mangel-wurzels. The meaning has been reduced to "give" or "supply". Even St Matthew is no longer sacrosanct: we may now feed pigs pearls[3].

Retino-rectal Connexions?

Sir,—I notice that there are at least two errors in your correspondent's report of the Glasgow embryological meeting (*Nature*, **233**, 232; 1971). The first is obviously a trivial deletion: "leg disks" and not "legs" were bisected. The second is more profound as it has the optic nerve connecting with the rectum. This rarely occurs in Amphibia, to which I think he was referring. When it does it leads to an annoying condition known as tunnel vision.

Announcements

University News

The title of honorary professor of thoracic surgery in the **University of Birmingham** has been conferred on **Mr J. Leigh Collis.**

Professor J. O'M. Bockris, University of Pennsylvania, has been appointed to a chair of chemistry in the School of Physical Sciences, **Flinders University of South Australia.**

Professor F. G. Heath, University of Manchester Institute of Science and Technology, has been appointed to the new second chair in the Department of Electrical and Electronic Engineering at **Heriot-Watt University.**

The following appointments have been made in the **University of London: Professor W. Brumfitt,** to the chair of medical microbiology tenable at the Royal Free Hospital School of Medicine; **Dr C. A. C. Mims,** to the chair of microbiology tenable at Guy's Hospital Medical School; **Dr J. Pitt-Rivers,** to the chair of anthropology tenable at the London School of Economics; **Professor J. G. Taylor,** to the chair of mathematics tenable at King's College.

Mr J. S. Ellis, director of postgraduate studies for the Wessex Regional Hospital Board, has been appointed to the chair of orthopaedic and accident surgery in the **University of Southampton.**

Appointments

Dr I. Steele Russell has been appointed director of the **MRC Unit on Neural Mechanisms of Behaviour,** in succession to **Professor G. C. Drew.**

Professor R. Baskett has been appointed a member of the **Agricultural Advisory Council,** in succession to **Sir Gordon Cox.** Professor Baskett will also succeed Sir Gordon as secretary of the Agricultural Research Council.

Sir Alan Wilson has been appointed chairman of the board of governors of the **National Institute of Agricultural Engineering,** in succession to **Major-General Cyril Lloyd.**

Miscellaneous

Professor L. J. Bruce-Chwatt, London School of Hygiene and Tropical Medicine, and **Professor A. Corradetti,** Istituto Superiore di Sanita, Rome, have been awarded jointly the **Darling Medal and Prize of the World Health Organization,** for services to research on and control of malaria.

Professor Luigi Broglio, University of Rome, has received the **1971 Daniel and Florence Guggenheim International Astronautics Award.**

Two **A. E. Bennett research awards,** one in basic and one in clinical science, are offered by the **Society of Biological Psychiatry** for the purpose of stimulating research in biological psychiatry by young investigators. The awards, each worth $750, will be made for papers describing work currently in progress, which shows particular independence of thought and originality. Further information can be obtained from Dr Sabit Gabay, chairman of the Committee on Research Awards, Biochemistry Research Laboratory, Veterans Administration Hospital, Brockton, Massachusetts 02401, USA.

International Meetings

October 18, **Phloem Transport,** London (Assistant Secretary, Society of Chemical Industry, 14 Belgrave Square, London SW1).

October 26–28, **Chemistry and Biological Activity of Cannabis,** Stockholm (Dr J. Lars G. Nilsson, Apotekarsocieteten, Stockholm, Sweden).

November 10, **Are Consumers Offered the Food Products They Want?,** London (Dr N. C. Robson, 5 Crest Road, Bromley, Kent BR2 7JA).

November 11–13, **Mammary Neoplasia,** Cherry Hill, NJ (Mrs Diane Meredith, Executive Secretary, Institute for Medical Research, Copewood Street, Camden, NJ 08103, USA).

December 3, **Alcohol in Nutrition,** London (Dr J. D. Sutton, National Institute for Research in Dairying, Shinfield, Reading RG2 9AT).

British Diary

Tuesday, October 12

Communications in Control (5.30 p.m.) Dr R. H. Barker, Institution of Electrical Engineers, at Savoy Place, London WC2.

Pigmentation of Plastics (7.30 p.m.) Mr J. E. Todd, Oil and Colour Chemists' Association, at the Griffin Hotel, Boar Lane, Leeds.

The Interface Between Biological and Mechanical Systems (7.30 p.m.) Mr S. V. Hayes, Society of Environmental Engineers, at the University of Birmingham.

The Mechanism of Nerve Conduction (5.30 p.m.) Professor A. F. Huxley, FRS, Royal Institution, at 21 Albemarle Street, London W1. (Lecture for Sixth Form Pupils from Schools in London and the Home Counties. To be repeated on October 13, 18 and 19.)

Wednesday, October 13

A Blood Analyser Using the PDP-8/L (5.30 p.m.) Mr E. T. Oram, joint IEE/IERE Medical and Biological Electronics Group, at the Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

A Review of Printing Inks and Printing Processes (4.30 p.m.) Mr F. Lewis, Oil and Colour Chemists' Association, at the Manchester Literary and Philosophical Society, 36 George Street, Manchester 1. (Student Lecture.)

Comparison of PCM and FDM/FM Microwave Radio Relays (6.30 p.m.) Mr S. G. Allen, Institution of Electronic and Radio Engineers, at the Civic Centre, Chelmsford, Essex.

Conversations with Computers (7 p.m.) Dr C. R. Evans, Institution of Electrical Engineers, at the Culham Laboratory, Culham, Abingdon, Berks.

Cost Effectiveness and Profitability in the Paint Industry (2.15 p.m.) Mr D. E. Eddowes, Oil and Colour Chemists' Association, at the South Bank Polytechnic, Borough Road, London SE1.

On-Line Sampling and Analysis (5.30 p.m.) Institution of Chemical Engineers, Yorkshire Branch, at the College of Technology, Queens Gardens, Hull, Yorkshire.

The Role of Data Links in Air Traffic Control Systems (5.30 p.m.) Mr B. D. Parker, Institution of Electrical Engineers, at Savoy Place, London WC2.

Thursday, October 14

Computer Control (7.30 p.m.) Institution of Chemical Engineers, at the Grammar School, Brigg, Lincs.

Computers and the Professional Engineer (5.30 p.m.) Professor J. F. Coales, FRS, Institution of Electrical Engineers, at Savoy Place, London WC2.

Corrosion and the Automobile (7 p.m.) Mr H. L. Quick, Oil and Colour Chemists' Association, jointly with the Institute of Metal Finishing, at the British Rail School of Transport, London Road, Derby.

New Approaches to Safety (6 p.m.) Mr J. R. Melluish, Institution of Chemical Engineers, North Western Branch, at ICI Offices, The Heath, Runcorn, Cheshire.

Personalized Marketing (6 p.m.) Mr W. A. Coom, Oil and Colour Chemists' Association, at the St Enoch Hotel, Glasgow.

Problems of Diagnosis of Tumours of the Lung (5.45 p.m.); **Unilateral Exophthalmos** (7.15 p.m.) British Institute of Radiology, at 32 Welbeck Street, London W1.

Rapid Transport and Suburban Electric Railways (7.30 p.m.) Mr B. J. Prigmore, Institute of Electrical Engineers, at High Wycombe College of Technology and Art, High Wycombe, Bucks.

Friday, October 15

The Importance of Electrokinetics in Electrode-position (6.30 p.m.) Professor G. D. Parfitt, Oil and Colour Chemists' Association, at the Chamber of Commerce and Industry, 75 Harborne Road, Birmingham.

The Limitations of Error Detection Coding at High Error Rates (5.30 p.m.) Mr J. D. Ralphs, Institution of Electrical Engineers, at Savoy Place, London WC2.

What Shall We Make?: The Chemist's Problem in Drug Research (6.30 p.m.) Dr B. W. Langley, Society of Chemical Industry, Fine Chemicals Group, at 14 Belgrave Square, London SW1.

Saturday, October 16

Excavations at Swanscombe in 1970 and 1971 (3.30 p.m.) Dr John Waechter, Inner London Education Authority, at the Horniman Museum, London Road, Forest Hill, London SE23.

Monday, October 18

Syndicate Studies: an Assessment of Their Value in Undergraduate Courses (5.30 p.m.) Mr G. J. Edwards, Institution of Electrical Engineers, at Savoy Place, London WC2.

HOW TO BUY NATURE

Volumes start in January, March, May, July, September and November, but subscriptions may begin at any time.

The direct postal price per subscription is:

12 MONTHS* (52 issues per title)

	Surface Mail UK and worldwide	Airfreight U.S.A. & Canada
Nature (Friday)	£14	$48
Nature + Nature Physical Science	£24	$83
Nature + Nature New Biology	£24	$83
All three editions	£29.50	$108
Annual Index	£1	$3

* Rates for shorter periods *pro rata* (minimum three months)

(Charge for delivery by air mail on application)

OCTOBER 15 1971

DDT may be Good for People

DR N. E. BORLAUG is entirely right to protest, as he did in Washington last week, that too zealous a campaign to regulate the use of DDT, and in particular a ban on it, will do much more harm than good. He might have added that it is an immense irony that a comparatively simple chemical widely regarded twenty years ago as a great benefaction has almost become a symbol of all things fearsome. Part of the trouble is that DDT and the other organochlorine pesticides such as dieldrin and aldrin were the centrepiece of Miss Rachel Carson's book *Silent Spring*. In some atavistic way, however, pillorying this chemical serves to satisfy a great many vague but common fears—that governments are incompetent in regulating the uses of innovation, that greedy manufacturers are urging farmers to use more of these materials than is strictly necessary, thus demonstrating yet another way in which the search for private profit will undermine society, and also, given the apparent ubiquity of DDT in the environment, that it is never possible in the modern world to escape from the secret threat of technology, the centre of fashionable paranoia. It is regrettable that in the past few years, professional scientists have done as much as anybody to lend support to what has become a thoroughly irrational protest against the persistent pesticides. It would be a great public service if some members of the profession were to respond to Dr Borlaug's plea by helping to put the dangers of DDT in some kind of a perspective.

If many facts are still uncertain, it is at least possible to say what the uncertainties consist of. Since DDT was first introduced to agriculture and public health immediately after the Second World War, there have been many occasions on which this and other persistent pesticides have been misused. Sometimes excessive doses have been used, so that animals have been killed off as well as insects. Sometimes, so little has been understood of the natural pressures to which a pest is subject that DDT and its relations have killed not the pests at which they were directed but their natural predators, with entirely unpleasant results. And there are always circumstances in which the organochlorine pesticides can be concentrated at the top of a food chain, thus imposing a strain on species quite unrelated to pests.

For reasons like this, there is a strong case for better methods of regulating the application of pesticides so as to ensure that their use in agriculture or public health does not bring about unwanted side effects. Even if this should imply that the modern pesticides are too potent to be left in the hands of farmers and others without professional training, as the United States Administration's new proposal for legislation would suggest, that would not be an insuperable obstacle to the successful use of these materials. It is, however, quite another matter to suggest a more general restriction of the use of DDT and related chemicals as pesticides. That might be throwing out the baby with the bath water.

In spite of a decade of research, there is at present only enough evidence to justify an agnostic position on DDT. Nobody should complain, for the problems have turned out to be unexpectedly difficult. It is, after all, worth remembering that the persistent pesticides are by their nature chemically inert, so that analysis must depend on physical methods such as chromatography, mass spectrometry and spectral absorption. The most headway has been made with gas–liquid chromatography, but only recently has it been appreciated that the polychlorinated biphenyls are easily confused with the pesticides proper. To be sure, discriminating practitioners know that a sequence of otherwise inexplicable peaks in a chromatography plot may be indicative of a mixture of biphenyls and pesticides, but less careful workers, or earlier workers, have often ignored such evidence. The result is that many of the measurements in the early sixties of concentrations of DDT in the environment may be misleading. Although there is no doubt that substantial quantities of the pesticides such as DDT are to be found in the flesh of fish and seabirds and in the fatty tissues of mammals, human beings included, there is at present no means of being sure whether the organochlorine pesticides are distributed on a truly world-wide basis or whether their spread is more a regional or even a local phenomenon, a measure of agricultural practice in the neighbourhood. In the past few years, it does appear that concentrations of DDT in human fatty tissue are more than twice as great (twelve parts per million) in the United States as they are in Britain. For what it is worth, the reports of DDT in the tissues of Antarctic penguins, portentous though they may be, refer to proportions which are smaller by a factor of ten or more. What this implies is that there may be a high degree of correlation between the use made of DDT in some agricultural region and the proportions which find their way into the fatty tissue of the people eating the food produced there. Before too many breasts are beaten on the altar of global pollution, it would be helpful if there were a better understanding of the distribution of these pesticides.

The great uncertainty which persists about the effects of DDT on human beings is another question that needs to be resolved. In these heady days of anxiety about the environment, it tends to be forgotten that only twenty-five years ago DDT was welcomed because it was effective against insects and much less harmful to people than other insecticides then in use. To be sure, DDT itself is poisonous in sufficiently large doses and its relatives are usually more toxic still, so that there is already a long and depressing record of death by accidental poisoning. On the other hand, no serious harm seems to have come to those who work in factories where pesticides are manufactured and who have avoided acute toxic doses. Careful studies have shown, with samples which are admittedly small, that working in pesticide factories brings neither an increased risk of liver disease nor an increased risk of cancer. So what of the hazards of the small quantities of these pesticides now stored in fatty tissues ? The simplest statement of the position is still that of the Mrak Commission which said in December 1969 that "the only demonstrable effect of this exposure in man is the tissue residue". For practical purposes this view was confirmed last month by the United States Environmental Protection Agency's DDT Advisory Committee (see *Nature*, **233**, 299 ; 1971) which said that "DDT has a very low acute toxicity to man and his domestic animals, and exposure to high doses for short periods of time does not appear to cause any irreversible damage". The same committee goes on to say that the risk of carcinogenesis is low—the only suggestions so far of such effects are a series of experiments with laboratory rodents. Clearly, the danger that DDT and its relatives may damage human beings is exceedingly small in spite of the profligacy of the use of DDT in the years immediately after the Second World War.

So what is the case for banning the use of DDT ? Other species than human beings are the only causes that carry weight. Careful experiments with birds in captivity have shown that DDT can make eggshells thinner and thus impede the hatching of young birds. Such effects may well be responsible for the reduction of pelican populations in the Mississippi Delta and off the west coast of the United States in the past few years, but it remains a sobering truth that more eagles have been shot by farmers than can possibly have been killed by DDT. Outside the United States, it remains to be seen whether changes in the sizes of bird populations are to be explained by pesticides in the diet, by other causes such as the urbanization of the countryside or simply by changes in the vigilance of bird watchers. On balance, however, it does appear that the damage so far done to wild life, while important and regrettable, is not disastrous and is easily attributable to extravagant use of DDT in the United States in the late fifties and early sixties. To be sure, there are more remote dangers to be considered—the possibility that pesticides might affect the metabolism of phytoplankton and thus exert an influence on the productivity of the oceans, but more needs to be known of the processes involved before anything but a hypothesis can be put forward.

In all the circumstances, there is a danger that speculation, sometimes quite proper speculation, about the effects that pesticides might have will be dignified by the status of received doctrine. The difficulty is that DDT and many of its works are economically important and, as Dr Borlaug points out, have a specially important part to play in helping to make sure that food production in the world will rise more quickly than the population. This is why it is important that the present wave of sentiment in favour of a ban on the use of DDT and such materials should be replaced by a proper and necessary case for regulation and supervision of the ways in which these pesticides are used. At the same time, of course, it is essential that there should be a better understanding both of the mechanics of the distribution of DDT, the mechanism by which it is accumulated in human tissue and the damage which it is likely to do to human beings. One absorbing question, for example, is why there should be such a large spread of DDT concentrations in human fat about the average value. University research could have an important part to play in furthering this understanding, for governments and industry have axes of their own to grind. But professional scientists everywhere could help by insisting that the present wave of discussion about DDT and other pesticides is conducted with a better sense of proportion than in the past.

Where are the Bounds of Decent Practice ?

THERE have in the past few days been allegations that the experiments carried out in the past eleven years at the University of Cincinnati have offended against one of the essential principles of medical research—that human beings should not be used as experimental subjects without volunteering for the role and without being fully aware of all the circumstances. In all the discussions that there have been in the past few years of the problems of medical ethics in laboratory situations, this principle has been repeatedly affirmed. It is fair to say, of course, that the principle by itself is insufficient. What precisely is intended by the injunction that a potential experimental subject should "understand"? How can laymen hope to appreciate all the subtleties of a medical experiment, even if they grasp the essential objectives ? And there are also difficulties in knowing what should be done in circumstances in which people may be tempted to volunteer in ignorance or under pressure (as when participation in an experiment carries with it the promise of early parole from prison). It would be in the public interest that there should be an investigation into the circumstances in which the Department of Defense let a contract to the College of Medicine at the University of Cincinnati and the circumstances in which this has been administered in the past eleven years. Whether Senator Kennedy's congressional committee is the best forum is another matter. The hope now is that extraneous issues will not confuse the overriding question of how human experimental subjects should be dealt with and whether on this occasion they have been dealt with wrongly.

One obvious irrelevancy is the involvement of the Pentagon. No doubt there are many people who will say that it is in all circumstances reprehensible to use animals, human or otherwise, in experiments which are preparations for some nuclear battlefield. This, however, is entirely beside the point. So long as the military forces of the United States, the Soviet Union and Western Europe are organized so as to defend themselves against nuclear attack, it is clearly unreasonable to expect that the services responsible will refrain from taking steps to know what doses of radiation soldiers can withstand. Those who say that the College of Medicine at the University of Cincinnati should not have accepted a contract from the Department of Defense on grounds like these have no logical alternative but to spend their energies on a refutation of the defence policy to which the governments of the principal powers are committed. But that is a wider issue, not relevant to what is said to have been happening at Cincinnati.

It is also beside the point to complain that therapy should also be used as an occasion for research. In medical research, there is also a long and heroic tradition of willingness on the part of one generation to endure discomfort voluntarily for the sake of a better understanding of some condition or disease. Patients with terminal disease have frequently been concerned with such experiments and, such is the inherent altruism of many people, have participated willingly. But it is clear that the dignity of everybody concerned, and that of the profession of medical science, demands that there should be a full disclosure of all the circumstances to those who are asked to participate. If one objective of a study is to make it easier to know what doses of radiation can be tolerated, by troops or by civilians, it is obviously incumbent on the people in charge to help their patients to understand by giving not merely a laconic description of the purpose of the experiment but also an account of the ways in which the information is likely to be valuable. If the Pentagon is a sponsor of the work, this should be spelled out.

From the reports so far available, it is not clear how far these conditions have been met, although some of those concerned have said that patients were told that "this research will be valuable if somebody is injured on the battlefield". What will need to be determined now is whether it is a sufficiently large step. An especially taxing feature of the Cincinnati case is the allegation by the *Washington Post*—it is no more than that—that many of the patients in the experimental series were in some way or another less able than they might have been to appreciate what was being asked of them. Circumstances like these are necessarily hard to reconcile with the essentials of what should be the code that governs the relationship between a patient–subject and his doctor–experimenter, but the only workable rule is that if a prospective subject is thought to be incapable of understanding fully what is expected of him, he should not be involved. As yet, there is nothing to suggest that the people at Cincinnati have not behaved with great propriety. It is, however, essential for everybody, and for medical research as such, that this should be demonstrated clearly and publicly.

One Way to Europe

WITH the British political parties preoccupied with their invariably introspective party conferences at British seaside towns (Brighton this year), and with the question of whether the British Government will eventually accept the terms of membership offered by the European Communities reduced to questions of which party leader will be able to carry how many of his supporters with him, the initiative for taking a few practical steps towards Europe has fallen to others. And as luck will have it, there is an obvious and urgent task for universities in Britain and on the mainland. Will they dare ?

In the past few months, there have been several declarations of how necessary it will be, once the European Communities are enlarged, for there to be a coordination of European policies on research and development. Because development is necessarily linked closely with industry and with commercial interests, the best place to start devising machinery for collaboration is in basic research, in the universities and government laboratories. This point was put forcefully by Sir Brian Flowers, chairman of the Science Research Council, at the British Association meeting in September. One difficulty is that the coordination of research between European countries entails the free movement of people between one laboratory and another. But there are at present practical difficulties which prevent this happening. And so is there not a case for a serious attempt by European universities to work out among themselves some method of doing this job ? On this occasion, as luck will have it, they could act more quickly than their governments.

---

100 Years Ago

Extract from Helmholtz on the Axioms of Geometry.

With all due deference to so eminent a man as Helmholtz, I must hold that his article includes an *ignoratio elenchi*. He has pointed out the very interesting fact that we can conceive worlds where the Axioms of our Geometry would not apply, and he appears to confuse this conclusion with the falsity of the axioms. Wherever lines are parallel the axiom concerning parallel lines will be true, but if there be no parallel lines in existence, there is nothing of which the truth or falsity of the axiom can come in question. I will not attempt to say by what process of mind we reach the certain truths of geometry, but I am convinced that all attempts to attribute geometrical truth to experience and induction, in the ordinary sense of those words, are transparent failures. Mr. Mill is another philosopher whose views led him to make a bold attempt of the kind. But for real experience and induction he soon substituted an extraordinary process of *mental experimentation*, a handling of ideas instead of things, against which he had inveighed in other parts of his " System of Logic." And the careful reader of Mr. Mill's chapter on the subject (Book II. chapter 5) will find that it involves at the same time the assertion and the denial of the existence of perfectly straight lines. Whatever other doctrines may be true, this doctrine of the purely empirical origin of geometrical truth is certainly false.

W. STANLEY JEVONS

OLD WORLD

TRADE UNIONS

Enter the APST

ONE of the first bodies to apply for registration under the Industrial Relations Act at the beginning of October was the Association of Professional Scientists and Technologists, which was formed recently by the Council of Science and Technology Institutes. When the council itself was set up in 1968 by five professional scientific institutes (including the Institute of Physics and the Royal Institute of Chemistry), its principal aim was to put forward the views of its member institutes on such subjects as the training of technicians and teachers; but when it became clear in the summer of 1970 that the government's legislation on industrial relations could pose problems for professional scientists, the council set up a working party to examine the desirability of forming an independent protective association.

Although the Industrial Relations Act does cater for professional bodies to a certain extent—they can be included on a special register and thus enjoy some of the rights of trade unions, for example—many of the professional organizations find their hands tied in other ways. Activities by the science institutes in the financial interests of their members are restricted to varying extents by their charters or articles of association, and separate salary negotiations for scientists in different disciplines would anyway be unacceptable both to employers and to employees.

The association is at present run by staff from the council's member institutes and the principal permanent staff will not be appointed until early 1972 when the association hopes to have a permanent headquarters and a healthy membership. The council says that between 5,000 and 10,000 members will have to be recruited during the next month or two so that the association can make itself felt before employers become too involved with the intricacies of the Industrial Relations Act. The annual subscription for a full member will be £5.

Dr Louis Cohen, secretary of the Institute of Physics, said this week that the association would probably attract principally those scientists who work in industry; he estimates, for example, that there are 4,000 to 5,000 potential members of the association in the Institute of Physics.

The Council of Science and Technology Institutes is conscious that, especially outside the industrial sector, some groups of scientists (for example, those in the civil service) already have effective negotiating bodies and that "there is no question of trying to usurp their position in any way". Mr William McCall, general secretary of the Institution of Professional Civil Servants, says that competition for members between the association and the institution is unlikely and that it would anyway be self-defeating.

EUROPEAN LABORATORY

Vain Effort?

A CAMPAIGN to avert the threatened closure of the European Space Research Institute (ESRIN) is gathering momentum as a result of a conference of the Plasma Physics Division of the European Physical Society held at ESRIN in September. A united front was formed against the proposed closure under the leadership of Professor B. Lehnert of the Royal Institute of Technology, Stockholm, chairman of the Plasma Physics Division.

The decision to close the laboratory was made at a meeting of the council of the European Space Research Organization in July. The chairman, Professor G. Puppi of Bologna, proposed a plan for ESRO which was adopted by the council and which recommended that "circumstances enforce consideration of closing down ESRIN" but "the council would welcome any alternative viable solution". This decision is to be ratified at a further meeting of ESRO in November.

Professor Lehnert said this week that one particularly distressing feature of the affair was the lack of warning given to the scientific community of the closure. The presentation of the *fait accompli* has undermined the morale of the laboratory and, even if the laboratory can still be saved, the damage is probably irreparable. Lehnert, on behalf of the Plasma Physics Division, has this week sent a letter to ESRO protesting against the decision. He stresses that the laboratory has made several contributions to plasma physics and "during the existence of ESRIN, members of the [Plasma Physics] Division have established contacts with the staff and realize the high value of the scientific work performed at ESRIN". The letter continues, "The ESRIN laboratory must be considered an essential and important part of activities within ESRO and not as a luxury. We consider the proposal to relinquish ESRIN a retrograde step in European space research. Any apparent saving in the budget will be nullified by a decrease in the efficiency of ESRO and by increased pressure on national research budgets." It is very difficult to argue with this logic and an ESRO spokesman did not attempt to deny it when he said this week that ESRIN could not carry on in its present form because of financial problems. He said, "ESRO is entering the applications field—air traffic control, meteorology and telecommunications—and some of the money now being spent on scientific programmes must go. The programmes least connected with essential ESRO activities—the ones at ESRIN and the rocket sounding programme—are being run down."

The reason for the precipitate decision to close the laboratory has aroused speculation in the European press in recent weeks. An article in *Die Welt* on September 30 says that the decision was forced upon ESRO by a French threat that they would withdraw from ESRO if the laboratory was not closed. Professor Lehnert said that he did not know why the decision had been taken but he was certain that pressure was being exerted on ESRO from a member country. It is known that the French feel that the science budget of ESRO should be limited.

The efforts to save the laboratory within ESRIN seem doomed but the scientists hope that the laboratory can be maintained in its present form under the auspices of some other European or Italian organization. An ESRO spokesman said on Monday that the director general, Dr A. Hocker, is in touch with Italian organizations to find a solution. He said, "The Italian authorities accept the idea that the present ESRIN activities cannot continue permanently within ESRO and the director general is actively negotiating to see what activity could be carried out at ESRIN."

A problem with transferring the laboratory to Italian hands is the current unrest among Italian scientists. At present there are unfilled positions in Italian national laboratories and another addition to their number will probably not be welcomed by the Italians. A more feasible possibility, if the laboratory is to be maintained in its present form, is for another European organization to take ESRIN under its wing. EURATOM seems the obvious candidate although CERN is a possibility. A difficulty that the scientists are facing in their campaign is that ESRIN is not unique in Europe. There are several national laboratories that rival ESRIN in quality of work and so the motivation for keeping the laboratory as a viable entity is not so strong as it might be.

It is still possible that ESRIN will remain within ESRO but with a different purpose. The ESRO office in Paris said on Monday that the director general is now negotiating with the Italian authorities to see what activity could be carried out at ESRIN instead of plasma physics. There is no information on what this new purpose might be but a spokesman said that it would be more closely related to the activities of ESRO than previously.

INSECTICIDES

Pyrethrin Prospects

One of the most promising developments in pesticides in these days of great public concern for the environment has been the development and marketing of pyrethrin analogues. Pyrethrum, a natural pesticide from the ground flowers of *Chrysanthemum cinerariaefolium* and *C. coccineum*, has been known since the early nineteenth century; six esters are found in the pyrethrum of which the most important and plentiful are known as pyrethrins I and II. They are used against houseflies, mosquitoes and cockroaches, mainly in the domestic field; their great advantage is that pyrethrin I has a high kill rate and pyrethrin II a high knockdown rate and that, once used, they degrade quickly in the light, leaving no appreciable toxic residues.

Pyrethrum has never been cheap; today a kilo of 100 per cent active pyrethrum costs about £38 compared with about £0.2 for DDT. Work was begun years ago to find a synthetic analogue but only recently have really significant advances been made. Since 1962, work on pyrethrin analogues has been carried out at Rothamsted supported by the National Research Development Corporation and two analogues, resmethrin and bioresmethrin, have recently been produced which are a considerable advance on the analogues previously available, notably tetramethrin and bioallethrin.

The new synthetic products have a kill rate many times higher than the natural product. Their knockdown rate is, however, lower although high when compared to other insecticides. This has been overcome by mixing them with the natural pyrethrin and a synergist which increases their effect.

The synthetic products appear to have all the advantages of the natural pyrethrins, without the drawback of the natural pyrethrins of causing nasal irritation if present in the air in sufficient quantities (pyrethrins are often used in aerosols). Indeed, the synthetic pyrethrins seem to be safer; the acute oral toxicity (LD50, rat) of bioresmethrin is approximately 8,500 mg per kg of body weight, that of resmethrin approximately 2,000 and that of natural pyrethrin approximately 600. In feeding trials conducted by Cooper McDougal and Robertson, one of the two companies marketing bioresmethrin in Britain, no ill effects have so far appeared.

Where the potential of synthetic pyrethrins may lie is in agricultural applications where cost has so far prevented the use of natural pyrethrins. At present synthetic pyrethrins are even more expensive than the natural product (about £40 a kilo for resmethrin and about £65 for bioresmethrin), but their relative non-toxicity, allied to their high kill rate, could make them a viable substitute for organochlorine and organophosphorus insecticides, many of which tend to break down less quickly than the pyrethroids.

The only known drawback to pyrethrin, both natural and synthetic, is that it is highly toxic to fish. This may not limit its use near rivers, however, as both water and light produce rapid breakdown, and tests may well prove that the quantities in which it will be used will present no danger to life in nearby water, should it be used for agricultural applications.

At present, however, the analogues are competitive with pyrethrum for a wide variety of largely domestic uses, and will be used overseas to replace other insecticides in household aerosols.

The development of synthetic pyrethrins has led to speculation that the market for the natural product may disappear, and Coopers admit that that was their first reaction, but the present need to mix synthetic with natural pyrethrins to achieve rapid knockdown, plus the expected expansion of the market, may well mean that the natural product is safe for some time to come. Kenya produces a large share of the world's natural pyrethrum and a spokesman at the Kenya High Commission said this week, "We think that synthetic pyrethrum will have some effect."

Ironically it was a world shortage of pyrethrum, caused by a fall of exports, that brought about the rapid commercial exploitation of the analogues, although Kenya claims that its output is now rising again. But whether the market for natural pyrethrum disappears—and experience with other synthetic substitutes for a natural product, for example, quinine, suggests it might—the future for the pyrethrum analogues looks bright.

COAL

Robens Recollects

Lord Robens's first public address since leaving the Coal Board surveyed the position of coal during this century and speculated on the uses of coal in future years. His address, the twentieth, and possibly the last, Coal Science Lecture of the now defunct Coal Utilization Research Association, was given on Monday to 400 scientists—most of them employed in coal research.

Lord Robens declared that more efficient use of man's resources must be made. In particular, it is now becoming clear that coal, which was considered the poor relation of gas and oil until very recently, has an important part to play in the future energy equation of Britain. Coal is Britain's only indigenous energy source and, although the rich veins are being fully mined, a large supply of low quality coal is, as yet, unexploited.

One of the chief efforts of the coal board to this end has been directed towards the efficient burning of low grade coal and coal dust by fluidized combustion. In this process a mixture of coal and ash constitutes the fluid bed and the NCB effort has been devoted to obtaining a high efficiency of heat exchange between this and immersed boiler tubes. The practicability of such systems has been established in the laboratory and future effort will be devoted to making the system work on a large scale. A further advantage of the fluidized bed combustion is, as Lord Robens pointed out, its ability to suppress the emission of sulphur into the atmosphere when limestone is mixed with the fuel. This aspect of the process has interested scientists in the United States where there are large undeveloped supplies of low grade fuels and Lord Robens issued a warning that this might yet be another technique developed in Britain but exploited in the USA.

One of the problems that will face Britain towards the end of the century will be the gradual decrease in supply of North Sea gas. Lord Robens pointed out that efforts should be made to supplement this by synthesizing a gas that can be blended with supplies from the North Sea. At present the Gas Council is devoting considerable research effort to synthesizing gas from oil and Lord Robens stressed that in view of the uncertain future of oil—which is obtained mostly from politically unstable countries—efforts should be made to obtain such a gas from coal. Historically the way to achieve this has been by coking but this process is not efficient. Also the gas obtained has a low calorific value that is not commensurate with natural gas. The British effort towards achieving this end is at present concentrated solely in a combined Gas Council–NCB working party.

The NCB was, in Lord Robens's view, caught unawares in the early 1960s by the full implications of the Clean Air Act. The board was faced with having to develop in a short time either a smokeless solid fuel or appliances that would burn bituminous coal smokelessly. The board's quandary was finally resolved when it was decided to proceed with making smokeless fuels but Lord Robens stressed that this was no easy decision and, as he aptly put it, "the choice between the two approaches was by no means a simple black and white one." He added that it took ten years to solve all the technical problems of making smokeless fuels, after a smaller research effort into the design of appliances to burn bituminous coal smokelessly.

NEW WORLD

Fighting the Great ABM Battle Again

by our Washington Correspondent

A REPORT sharply critical of the professional conduct of some of the scientists who took part in the 1969 debate on the Safeguard anti-ballistic missile system has triggered off a controversy in the scientific community that could seriously damage relationships between scientists and Congress. Whatever the quality of the report and the validity of its conclusions (both of which are being vigorously contested), there is little doubt that it will be remembered for the impression it has generated—that prominent participants in the ABM debate sought to mislead Congress and the public on technical matters. Also at issue are the ethics involved when a professional society is seen to ally itself with participants on one side of a highly political debate by impeaching non-members for their alleged professional misconduct.

The basis of the controversy is a report written by an *ad hoc* committee of the Operations Research Society of America (ORSA) and published last week in the society's journal. Based on a study instigated at the request of Professor Albert Wohlstetter, the chief conclusion of the committee is that "when prominent experts outside the Administration supported their opinions on Safeguard deployment with arguments or results of an operations-research nature, these analyses were often inappropriate, misleading or factually in error".

The six-member committee also says that opponents of the Safeguard system were more unethical than their colleagues who supported the Administration. In particular, the report singled out for criticism Dr Jerome Weisner, Dr George Rathjens and Dr Steven Weinberg, all from Massachusetts Institute of Technology.

For their part, however, the MIT scientists charge the committee with lack of professional ethics because it took a narrow and biased view of the debate and failed to comment on the arguments and alleged mis-statements of supporters of the ABM. The MIT group also suggests that the analysis may have been instigated for personal rather than for altruistic reasons, and points out, in a rejoinder to the report, that whatever the findings of the *ad hoc* committee, arguments put forward by opponents of the ABM have been vindicated by subsequent events.

The report concentrates chiefly on the arguments which surrounded the possible vulnerability of US Minutemen silos to pre-emptive attack by the Soviet SS-9 rockets, paying little attention to the fierce debate over the ability of Safeguard to do the job specified for it and ignoring almost totally the discussions on whether or not the system could easily be overwhelmed or made useless by destruction of the Missile Site Radar (MSR) which guides the

THE Operations Research Society of America was launched into the ABM debate by a letter sent in November 1969 by Professor Albert Wohlstetter to Dr Tom Caywood, then president of the society. The letter listed points of difference between calculations performed by Wohlstetter and by opponents of the ABM, in particular by Rathjens, Weisner and Weinberg. Rathjens, Weisner and Weinberg responded to an invitation to cooperate by saying: "Any general inquiry that would widen the public's understanding of the issues would be welcomed by us but we feel that for the Operations Research Society of America to carry out an inquiry into the ABM debate along the lines suggested by Professor Wohlstetter would be absurd". The scope of the inquiry would be too narrow, the MIT scientists suggested, and "could well appear to the nation as an ugly resurgence of those attacks on civil liberties and dissent that were far too common fifteen years ago".

One member of the committee, Dr Howard Berger, a former president of the Military Operations Research Society, had had a serious disagreement with Rathjens when both were employed at the Institute of Defense Analysis. According to Rathjens, the disagreement led to his relieving Berger of responsibility for a project, and eventually to Berger's resignation from the institute. Caywood said last week that he was aware of some disagreement between Berger and Rathjens when he formed the committee.

The *ad hoc* committee presented its report to a meeting of the ORSA council in May this year, at which it was adopted by a vote of 11 to 1, with only Professor John Little of MIT dissenting. Subsequently, however, five members of the council submitted a minority statement for inclusion in the journal alongside the report, pointing out that they consider it inappropriate for an organization such as ORSA to take on the quasi-judicial function of investigating the professional behaviour of individuals. The ORSA council is therefore now itself divided on the issue of whether it should have carried out and published the report, and to add to the internal troubles of the organization, Professor Philip Morse, also of MIT and a founder member of ORSA, wrote a letter to the *Boston Globe* last week in which he strongly protested against the report and threatened to resign from the society. The burden of his argument is that, by denouncing by name individuals who are not members of the society, the report suggests ORSA is "on the side of ex-Senator Joe McCarthy, is promilitary and supports the assumption that experts always know best".

When the report was published last week, Rathjens, Weisner and Weinberg sent out a rejoinder in which they said that the report had substantiated virtually every criticism raised in their original letter to Caywood. The rejoinder was not, however, sent to members of the committee, or to Wohlstetter, who complained in an interview that this was simply another instance of the MIT scientists' "form of arrogance and elite contempt of the lay public".

Professor Little has taken the different view that, since the society should not have attempted an analysis of the debate and since it should not have placed itself in a quasi-judicial position, Rathjens had every right not to take part.

intercepting rockets to their targets. The committee says that it chose to study these areas because of their importance to the debate and because the calculations are simple enough to allow major points of difference in the assumptions underlying the various calculations to be singled out.

The ORSA report chooses to analyse in particular the arguments put forward by Rathjens and by Wohlstetter, which respectively came up with predictions that 75 and 95 per cent of the US Minutemen force could be destroyed in their silos by the stock of SS-9 rockets thought to be available to the Soviet Union by the mid-1970s. Rathjens argued on the basis of his calculations that the threat was not sufficient to justify deployment of Safeguard, while Wohlstetter suggested that if 95 per cent of the US retaliatory force of intercontinental ballistic missiles (ICBMs) could be knocked out by a pre-emptive strike, then they needed protecting.

The *ad hoc* committee found in effect that Wohlstetter's calculations were correct, and that he had presented them in a professional manner, but that Rathjens's performance was less than adequate. In particular, the report suggests that Rathjens assumed that the SS-9s would have less than their possible complement of independently targeted warheads (MIRVS), that he misread a chart presented in testimony to the Senate Armed Services Committee by Deputy Secretary of Defense David Packard, and that all the MIT scientists, together with Dr Wolfgang Panofsky, Director of the Stanford Linear Accelerator Center, ignored the possibility that some of the SS-9 rockets that may fail during launch or in flight could be replaced by other rockets by an intricate system of reprogramming. The committee finds that if all these alleged errors in calculation are taken into account, a preemptive strike by SS-9s could be expected to dispose of 95 per cent of the undefended Minuteman silos by 1976, if the trends in Soviet arms deployment evident in 1969 were maintained.

Rathjens assumed in his calculations that the SS-9s would each have four MIRVS, each with a yield of one megaton, while Wohlstetter based his calculations on the assumption that the missiles would each carry three five-megaton warheads. The basis of Rathjens's assumption is claimed to be data supplied by Deputy Secretary of Defense Paul Nitze in 1967, and he pointed out in a letter published in the *New York Times* in June 1969 that he assumed the SS-9 payload before the Administration suggested that each would have three five-megaton warheads. In any case, Rathjens points out that the payload likely to be employed on the SS-9 is not the most sensitive assumption in the calculation, and that he is not even now convinced of the Soviet Union's ability to deploy large yield warheads on its missiles. Nevertheless, in the rejoinder to the ORSA report, Rathjens does not answer this particular criticism of his calculations.

As for the suggestion that he misread the chart submitted by Packard, Rathjens admits that he assumed the chart was calibrated in statute rather than in nautical miles and that this misreading led to his adoption of an unduly high value for the blast resistance of the Minuteman silos. But as he pointed out in a letter to Wohlstetter in June 1969, this error in fact was offset by an error in the accuracy of the SS-9, which also occurred from misreading the Packard chart in statute miles.

The chief point of disagreement between the opponents and proponents of Safeguard in 1969 was whether or not the SS-9s could be reprogrammed so that those which failed in launch or in flight could be replaced by fresh rockets. The OSRA report suggests that if Rathjens's calculations are altered to include the correct value for blast resistance of the Minuteman silos and a substitution is made to include three five-megaton instead of four one-megaton warheads in the SS-9, the number of Minutemen assumed to survive a first strike is reduced from 25 per cent to 16 per cent. But if the attacking missiles can be reprogrammed to replace some failures, only five per cent of the Minuteman silos would remain intact.

Why did the opponents of the ABM not consider reprogramming ? According to the MIT rejoinder to the ORSA report, they did not consider sophisticated reprogramming to be technically feasible, particularly reprogramming to compensate for failure of a single reentry vehicle that had gone astray. The ORSA report points out, however, that failures occurring during launch and during early flight could be compensated for relatively easily with a significant improvement in the efficiency of the strike.

The rejoinder in fact does not attempt to rebut the ORSA report point by point. In fact, Weisner, Rathjens and Weinberg point out that they feel no obligation to do so but instead attack the report for not tackling all of the relevant issues. In particular, they suggest that the ORSA committee should have looked at the arguments concerned with the vulnerability to attack of the missile site radar, especially since the Administration is now admitting the limitations of the system and is looking into designs for an improved defence of missile silos, they chide the ORSA committee for not investigating the possibility that Safeguard may be overwhelmed, they point to a statement attributed to President Nixon that the Safeguard system could "provide a virtually infallible defence" against Chinese attack, and ask why it was not examined, and finally they suggest that an examination of the shifting justification of Safeguard could well have found a place in the report.

There is little doubt that opponents of the ABM employed incorrect assumptions at times and came up with incorrect conclusions as a result (in fact the rejoinder admits as much), but Weisner and his colleagues point out that their calculations have been proved essentially correct by events. For example, they point out that the threat suggested by the Administration from the SS-9 has not materialized—the Administration was predicting a force of 420 SS-9 missiles by early 1972, but according to testimony given by Dr John Foster to the Senate Armed Services Committee on April 19 this year, the USSR has about 300 SS-9s and the rate of deployment was slowed down. A recent study carried out by TRW Inc., a California firm, suggests that the re-entry vehicles on the SS-9 may not be accurate enough to pose much of a threat to Minuteman silos, at least not a sufficient threat for a first strike capability—and the vulnerability of the missile site radar is now recognized and the Department of Defense is pressing ahead with design of a system specifically designed for protection of Minuteman (the Hardsite system).

Whatever the merits of the case that the committee has argued—and it cannot be denied that it has provided some evidence of errors—the report is likely to achieve little more than to cast doubt on the validity of testimony of future witnesses before Congressional committees. Moreover, in presenting what seems to be a one sided investigation, at least as far as examining and reporting on statements and arguments from both sides is concerned, the report has caused internal strife in the Operations Research Society of America itself (see box). In any case, there seems to be little point in digging over past debates when a more productive exercise would be to examine the validity of present assumptions about the ABM system.

CANCER

Defence Therapy

TERMINAL cancer patients at the University of Cincinnati College of Medicine are being exposed to large doses of radiation in a study paid for by the Department of Defense. One aim of the study is to determine the likely effect on troops of radiation from nuclear weapons, but members of the Cincinnati team claim that the treatment is given primarily for therapy and that it does not harm the patients. Since the details of the study were disclosed last week in the *Washington Post*, however, they have raised some doubts about the ethics of undertaking this type of research.

Total body radiation therapy has been used at the University of Cincinnati for the past fifteen or sixteen years, according to Dr Edward Gall, one of the Cincinnati team, but the investigative part funded by the Department of Defense has a history of eleven years. Dr Gall claims that the Pentagon became interested in the radiation therapy when some of the results were first described, and although the programme has been expanded the therapy has not been altered. In effect, he claims that the Department of Defense is simply interested in results derived from normal therapy at the hospital.

The therapy involves exposing patients suffering from cancer that has progressed beyond surgery to total body radiation of between 100 and 300 rads, or occasionally to partial body doses of 50–100 rads. The Department of Defense is interested in monitoring the doses of radiation that produce nausea and vomiting and other effects that might impair the performance of troops on the battleground. Patients are told that the results of the treatment may be helpful in case people are exposed to large doses of radiation, but they are not told that the study is being funded by the Department of Defense.

So far, 81 people have been given the total radiation treatment at the University of Cincinnati, but 108 have been approached—27 were excluded either because they were found to be unsuitable for treatment or because they had indicated that they did not want to take part. They included patients suffering from cancer of the colon and lung and Ewing's tumour, and all had already been given treatment at the University of Cincinnati hospital. They are told that the therapy may relieve some of their pain but that it will not necessarily lengthen their lives. But they are not told that they may suffer nausea from the treatment, since that may bias the results.

The treatment is approved each year by the Committee on Human Research at the university. Some other cancer therapists have expressed doubts about both the ethics of the research and the efficacy of the therapy, however. In particular, it has been suggested that total body radiation is not used as a therapy elsewhere, and the Department of Defense says that it is not funding any similar research. The Cincinnati team, although unwilling to claim substantive evidence of success from its therapy, points out that out of four children treated for Ewing's tumour, three have survived for three and a half years.

DDT

Borlaug's Warning

by our Washington Correspondent

An impassioned plea on behalf of DDT was delivered in Washington last week by Norman E. Borlaug, recipient of the 1970 Nobel Peace Prize for his work on high yield wheat strains. Borlaug, who testified in a public hearing on the cancellation order imposed on the pesticide by the Environmental Protection Agency, said at a press conference later:

"Environmentalists today seek a simple solution to very complex problems. The pollution of the environment is the result of every human activity as well as the whims of nature. It is a tragic error to believe that agricultural chemicals are a prime factor in the deterioration of our environment.

"The indiscriminate cancellation, suspension, or outright banning of such pesticides as DDT is a game of dominoes we will live to regret.

"DDT, because it is a name popularly known to most segments of the public, has been the first target. Once that is accomplished, the so-called ecologists will work on hydrocarbons, then organophosphates, carbamates, weed killers, and, perhaps, even fertilizers will come under the assault of their barrage of misinformation.

"If this happens—and I predict it will if most DDT uses are cancelled—I have wasted my life's work. I have dedicated myself to finding better methods of feeding the world's starving populations. Without DDT and other important agricultural chemicals, our goals are simply unattainable.

"Perhaps more than any other single factor in the world today DDT has a unique contribution to the relief of human suffering. I need not reiterate its vital importance in malaria control.

"DDT critics will say, of course, that only domestic uses of the chemical are being reviewed in the hearings at which I appeared today. But I have spent my life working in the nations of the world to help them feed themselves. I know how they will react if we terminate uses of DDT in this country and, in effect, label it 'poison'. If it is not good enough for your purposes, they will reason, then it shouldn't be used in our countries. The impact will be catastrophic.".

DRUG ADDICTION

Fort Worth Deleted

by our Washington Correspondent

Plans to transfer a drug addiction research and rehabilitation centre from the National Institute of Mental Health to the Bureau of Prisons seems to be going ahead in spite of stiff opposition from powerful members of Congress. The centre, situated at Fort Worth in Texas, was due to be transferred to the Bureau of Prisons this month (see *Nature*, **232**, 597; 1971), but in July the House of Representatives blocked the move with a resolution designed to keep open all Public Health Service hospitals and outpatient clinics pending the findings of a thorough review of their functions. The resolution has, however, reportedly been emasculated in a conference committee appointed to iron out differences in the versions of the resolution passed by the House and by the Senate, and all references to the two research centres at Fort Worth and at Lexington in Kentucky have been deleted.

Opponents of the plan, led by Paul G. Rogers, chairman of the House Subcommittee on Public Health and Environment, argued that transfer of the Fort Worth centre to the Bureau of Prisons would in effect close down badly needed facilities for the treatment of drug addicts. NIMH officials have, however, countered that the loss of facilities will be offset by a sharp increase in the number of community health centres offering rehabilitation treatment and that, in any case, an addict is more likely to be rehabilitated if he is treated in his own community and not an isolated hospital.

While discussions about the future of the Fort Worth centre were taking place in Washington, however, many of the hospital's staff left, giving rise to serious doubts about the ability of the hospital to carry on operating in its present role, even if Congress did grant a stay of execution.

If, as now seems likely, the Fort Worth centre is transferred to the Bureau of Prisons for use as a medium security geriatric, alcohol and drug addiction hospital for prisoners, the move would underline the failure of the Narcotic Addict Rehabilitation Act of 1966. That act gave the courts the power to commit drug addicts for treatment instead of for prosecution for certain non-violent crimes such as mail theft, stealing cars and forging cheques.

Addicts committed under the terms of the Narcotic Addict Rehabilitation Act are sent to the Lexington and Fort Worth clinical research centres for detoxification and are then usually sent to aftercare centres in their local communities. In the first three full years of operation of the act, however, between July 1967 and June 1970, only 179 addicts were committed for treatment, and only 509 were committed after trial.

Congress had expected that about 900 addicts a year would be committed before trial alone, and that Lexington and Fort Worth would be bursting at the seams. Instead, the hospitals are running at half strength and seem destined for other things.

NEWS AND VIEWS

Seafloor Spreading and Mountain Building

CAN tectonic events on the continents be related to seafloor spreading several thousand kilometres away? The article by P. J. Coney on page 462 of this issue of *Nature* and that of R. W. R. Rutland in an earlier issue (*Nature*, **233**, 252; 1971) relate mountain building episodes in North and South America to changing seafloor spreading in the Atlantic. The bordering areas, the Caribbean and Scotia Arc, have also been studied recently in the light of seafloor movements by G. L. Freeland and R. S. Dietz (*Nature*, **232**, 20; 1971) and by I. W. D. Dalziel and D. H. Elliot (*Nature*, **233**, 246; 1971). This sudden flurry of articles reflects how details of seafloor spreading are now becoming available so that it is possible to relate such distant events with each other.

Perhaps the chief reason why seafloor spreading was not considered seriously until the 1960s was the apparent discrepancy between the essentially simple, localized pattern of spreading compared with the extensive, complicated patterns of mountain formation. The creation of new ocean floor takes place in an extremely narrow zone, possibly less than 30 m wide, at the centre of the ridge system, and this new oceanic lithosphere eventually descends back into the Earth's mantle at the oceanic trenches—again narrow zones compared with mountain systems of up to 1,000 km width. Between these two narrow active zones, the tectonic picture is quiescent; oceanic lithosphere is moving towards the trenches at different rates in different areas, although it is consistent over vast lithospheric plates on which only sedimentation is taking place, and the odd, persistent hot spot in the Earth's mantle is giving rise to a trail of volcanic islands. In contrast, mountain building occurs over wide regions of the continental crust with many phases of folding, faulting, igneous activity and metamorphism.

The discovery of major transform faults in the oceanic basins provided the first indisputable evidence of crustal movements of the magnitude required by the proponents of continental drift. On the whole, however, these faults could not be traced inland so that, for several years, it still seemed that there was little relation between the tectonics of the ocean floors and those of the continents. The establishment of plate tectonics indicated that there must be at least some broad correlation between these tectonically active areas although it still seemed improbable that detailed correlations would be made between changes in spreading rate and direction of the plates and the precise sequence of events in an orogenic system, even on the same plate.

It is, however, the simplicity and narrowness of the mechanism by which new ocean floor is added that are allowing determinations of detailed movements of the plates. If the creation ofseafloortook place over a wide region, many of these details would be lost in the "noise level" of the changing polarity of the Earth's magnetic field. These details, as they become available, are, however, becoming increasingly linked to specific changes in the degree of deformation, changes in the motion along faults, and so forth, within the orogenic systems of the continents. The current series of articles, such as that by Coney, mark only the start of this detailed correlation as they are based, so far, on magnetic records from those parts of the oceans which seem to reflect the simplest patterns, that is, where the locus of spreading has remained fixed, although the rate and direction of motion have changed. Coney is therefore able to distinguish three principal changes in spreading of the Atlantic plate from its initiation 150 to 180 million years ago, at 80, 40 and 9 million years ago. This means that he is able to correlate, for example, the evolution of the Azores with the Laramide orogeny and so forth, with only slight reference to movements of the Pacific plate.

Areas, such as the Atlantic north of Ireland, will take longer to interpret as changes have also taken place in the position of the axis of spreading. Similarly, the discovery that not all plate motions are symmetric with respect to the oceanic ridges (J. K. Weissel and D. E. Hayes, *Nature*, **231**, 518; 1971) must complicate the interpretation in some regions. Clearly, however, a synthesis of oceanic and orogenic motions on the Atlantic plates is becoming more feasible and, before long, the interaction between different plates will begin to emerge so that the tectonic activity will be seen in its true global perspective.

Putting the Cerebellum to Sleep?

ON page 481 of this issue of *Nature*, Siggins, Hoffer, Oliver and Bloom add another link to the growing chain of evidence which indicates that brain stem neurones rich in catecholamines are important regulators of activity levels in the cortices of the brain. They have demonstrated in rats that electrical stimulation in the neighbourhood of one such group of neurones leads to a prolonged inhibition of the impulse discharge from Purkinje cells—the output neurones of the cerebellar cortex. The amine-rich neurones concerned are those of the locus coeruleus (LC) in the rostral part of the pons. That axons of LC neurones terminate in the cerebellar cortex was first shown using histochemical techniques but the work of Siggins *et al.* represents the first attempt to use neurophysiological techniques to investigate the functioning of the pathway at the single neurone level. The potential importance of the path is emphasized by the finding that a single LC stimulus can produce a detectable decrease in the probability that individual Purkinje cells will discharge impulses; repetitive stimulation often leads to complete suppression of discharge.

It is difficult to speculate on the role of the projection in the normal operation of the cerebellar machinery. As Siggins *et al.* recognize, it has yet to be shown that the inhibition observed was directly mediated by synapses between the LC axons and the Purkinje cells. Such synapses have not been described but electron microscopical studies may yet help. At any event the long latent period of the effect suggests that the path is unlikely to be important in that aspect of cerebellar function which currently attracts most attention—the control of evolving movements. A role as a long-term regulator of cerebellar cortical responsiveness seems more plausible.

Interest in the result is enhanced when it is viewed against a more general background. Histochemical studies by Olson and Fuxe (*Brain Res.*, **28**, 165 ; 1971) have shown that the axons of LC neurones terminate at destinations as diverse as the cerebral cortex, the hypothalamus and the lateral and medial geniculate bodies, not to mention the pathway terminating in the cerebellar cortex. The pathway to the cerebral cortex has been investigated in a general way by observing the behavioural changes caused by pharmacological agents believed to stimulate or to depress it. These experiments suggest that high LC activity leads to behavioural arousal and an alerting of the cerebral cortex and this activity is signalled by desynchronization of the electroencephalograph. Reduced activity in the nucleus, or outright destruction of it, leads to the synchronous electroencephalograph which is characteristic of light sleep or waking repose. The new results apparently show that the LC axons to the cerebellum are inhibitory and the odds are therefore high that the other LC projections are also inhibitory, in which case the path to the cerebral cortex clearly does not cause arousal directly by exciting cortical neurones. It may prove necessary to regard the projection as functioning by turning down some cerebral cortical element the unchecked activity of which leads to electroencephalographic synchronization and behavioural repose.

HAEMOGLOBIN

Hammering the Sickle

from our Molecular Biology Correspondent

THIS week, dear reader, a tale with a moral, about molecular remedies for molecular disease. Sickle-cell haemoglobin is in all respects a normal functional molecule, except for the property, which the single substitution in the β-chain confers on it, of associating in the deoxygenated state to large tactoidal aggregates. When this happens in the cell, the consequences are exceedingly disagreeable. A simple problem, one might suppose, and an open challenge to protein chemists, to prove that theirs is a useful art, such as the hard-faced men by the National Institutes of Health should appreciate in tangible form. Better not to dwell on the more risible details, but to say only that until now they have failed prodigiously.

A new approach by a group of clinicians to the treatment of the condition was recently given wide publicity: having apparently encountered allusions to hydrophobic interactions between proteins, and the effect of urea on such forces, they proceeded to inject their patients with urea solutions. Protein chemists, knowing about the urea concentrations that might be effective in such situations, and guessing at the difficulties which might be involved in filling a patient with 8M urea, might have been permitted a pitying sneer. Astonishingly, however, this primitive ruse seemed to work. It is now apparent that this was in fact a consequence of the gradual formation in urea solutions —as every protein chemist also knows —of cyanate ions, which react with protein amino-groups.

The urea (which would not work anyway if too freshly made up) should therefore clearly be replaced by suitable doses of sodium cyanate. Kraus and Kraus (*Biochem. Biophys. Res. Commun.*, **44**, 1381 ; 1971) have now improved on this strategy by introducing carbamyl phosphate, a physiological substance, which is evidently capable of entering the red cell, with beneficial effects on the sickling tendency. They suggest that because phosphates in general compete with the natural cofactor, 2,3-diphosphoglycerate, for its site on the haemoglobin molecule, the carbamyl phosphate functions as an affinity reagent, entering the putative diphosphoglycerate site at the N-termini of the β-chain, and carbamylating the α-amino-groups (which indeed would be the most reactive at physiological *p*H). Indeed Caldwell, Nagel and Jaffé (*ibid.*, 1504) have shown that not only cyanate ions, but also carbon dioxide, which is known to bind noncovalently at the same site, will chase off diphosphoglycerate from normal human haemoglobin. One may also reflect that the loss by carbamylated haemoglobin of the capacity to bind the cofactor will lead to a relative increase in oxygen affinity (because the diphosphoglycerate binds only to the deoxygenated form). Thus the red cells will be less readily deoxygenated, and if they contain sickle-cell haemoglobin, the sickling will be inhibited. It is interesting to note that this provides a new retrospective rationale for the attempts once made to mitigate sickle-cell anaemia by administering carbonic anhydrase inhibitors. In addition to the decrease in *p*H that the accretion of carbon dioxide will engender, thereby bringing into play the Bohr effect to increase the oxygen affinity of the haemoglobin, inhibition by carbon dioxide of diphosphoglycerate binding would work in the same sense.

The ramifications of diphosphoglycerate binding are evidently endless. Lian, Roth and Harkness (*ibid.*, 151) now report that in intact red cells, the shift in the oxygen uptake curve on addition of the cofactor is substantially increased when the cells contain sickle-cell haemoglobin. It has long been known that the oxygen affinity of such cells is lower than those containing only normal haemoglobin, and Lian *et al.* also now find that this difference is still present, though much diminished, when the cofactor is absent. These findings must be set against the well-established identity of both the oxygen and diphosphoglycerate affinity of normal and sickle-cell haemoglobins in dilute solution, out of the cell. The situation is complex, and Lian *et al.* indulge in some contorted efforts at explanation. The formation, however, of aggregates in sickle-cell haemoglobin only at high concentrations must stabilize the deoxygenated state, and it is therefore reasonable to suppose that this will decrease the oxygen affinity, and increase the disphosphoglycerate binding in the cell which in turn will enhance the change in oxygen affinity.

The aggregation reaction in sickle cells is complicated by possibilities of participation of other forms of haemoglobin that are commonly present, such as normal adult and foetal haemoglobin. The true complexity of the situation has now been revealed by Bookchin and Nagel (*J. Mol. Biol.*, **60**, 263 ; 1971), who use the device of introducing cyanmethaemoglobins, which have the oxyhaemoglobin conformation, but do not bind oxygen, into mixtures. Sickle-cell haemoglobin forms gels only in the deoxygenated site, but the normal adult pigment will co-aggregate with it both in the deoxy- and the cyanmet- (that is, oxy-) conformations. Foetal haemoglobin by contrast will enter the aggregates in the cyanmet- but not in the deoxy- state. In another abnormal variant (Harlem C), capable of aggregating when deoxygenated, the interactions with other forms and other conformations are quite different. The results are by no means easy to explain in detail, but the authors are able, starting from the notion, originally advanced by Pauling, that the aggregates are helical structures, to make some inferences about the existence of separate secondary interaction sites across successive turns of a tight helix of low pitch; these are envisaged as distinct from the primary association in which the sickle-cell haemoglobin molecule is regarded as bivalent.

MITOCHONDRIAL DNA

Arrested Replication?

from our Cell Biology Correspondent

IF the exquisite experiments—for once that is no exaggeration—reported by Kasamatsu, Robberson and Vinograd in the current issue of the *Proceedings of the US National Academy of Sciences* (**68**, 2252 ; 1971) are anything to go by, it seems likely that the enigma of the mechanism of DNA replication will be solved by studies of mitochondrial DNA. And on reflexion that claim is not perhaps as surprising as it may seem at first sight, for the mitochondrial chromosome is after all probably nothing more than a heavily pruned bacterial chromosome.

Vinograd's group, in their peerless manner, have found that in two strains of mouse L cells growing exponentially about half the mitochondrial DNA molecules (closed circular DNA duplexes with a molecular weight of about 10×10^6) contain a short segment of triple stranded DNA called a displacement or D loop. This curious structure, revealed in their electron micrographs with a clarity that denies dispute, consists of a short chain of DNA which is apparently base paired to one of the closed circular DNA strands, such that a corresponding segment of the complementary closed circular DNA strand is displaced and loops out from the rest of the molecule. By heating mitochondrial chromosomes with these D loops to 90 C in 0.03 M NaCl, the short chain of DNA is released—it sediments at 7S in sucrose gradients—and concomitantly the two closed circular strands snap back together and the D loop is lost.

As Kasamatsu and her colleagues comment, the sedimentation properties of mitochondrial DNA with D loops suggest that the short displacing strand is about 3 per cent of the total length of the mitochondrial DNA molecule. On electron micrographs it measures 3.2 to 3.5 per cent the length of the complete molecule and assuming that the lower estimates of its length are the most accurate the displacing chain must be about 450±80 nucleotides long. This chain hybridizes with the light but not the heavy strand of L cell mitochondrial DNA and it is therefore probably a short segment of the heavy strand. Furthermore, the position of the D loop, and therefore the sequence of the 450 base segment of the heavy strand, seems to be unique.

Vinograd and his colleagues reach this latter conclusion from ingenious argument and experiment. As Clayton, Davis and Vinograd have shown, circular dimeric mitochondrial DNA molecules in human cells consist of two monomeric molecules joined head to tail. If this is also true of dimeric mouse L cell mitochondrial DNAs there should be two D loops per dimer and they should be diametrically opposed and separated by one genome length. Measurements of the position of D loops in electron micrographs of such dimeric molecules fulfil these expectations.

In short the properties of D loops eliminate the idea that they are intermediates in some DNA repair mechanisms, for repair would surely not be restricted to a unique site in the genome. But because they are present in up to 50 per cent of the mitochondrial DNA molecules isolated from exponentially growing cells, D loops may be an early stage in the synthesis of progeny mitochondrial heavy strands during a replication process initiated at a unique origin. Vinograd and his colleagues suggest that the initiation and synthesis of the progeny heavy strand can occur without a nick being introduced into either of the closed circular parental strands but growth of this chain is arrested when it is about 450±80 bases long. Further extension is then dependent upon nicks being introduced into the parental strands to allow their free rotation and unwinding. The occurrence of molecules which have nicked parental strands and displacement loops which range in size up to that of the complete genome supports this interpretation. In brief, closed circular molecules with D loops may well be mitochondrial genomes which have begun their replication but are hung up awaiting the attention of a nuclease without which they cannot continue. No doubt we shall not have long to wait before Vinograd's group can tell us more about this process and also about the synthesis of progeny light mitochondrial DNA strands complementary to the new heavy displacing strand.

Geometric Refinement of Crystal Structures

ALTHOUGH known interatomic distances are often used to find a chemically acceptable crystal structure concordant with an observed diffraction pattern, they are hardly ever used in the subsequent refinement stages of the analysis. In next Monday's *Nature Physical Science* W. H. Baur shows how, in some contexts, they can be incorporated most profitably and even used to overcome shortcomings in the observed crystallographic data.

Least-squares refinement, the most widely used refinement procedure at present, attempts by adjustments of the atomic coordinates and thermal parameters to improve the agreement between the observed and calculated structure amplitudes. It relies on the fact that the number of observed structure amplitudes greatly exceeds the number of adjustable atom parameters, but the ultimate accuracy achieved for any structure depends on the accuracy and extent of the intensity data. In the past, geometrical constraints have only been introduced into the process to treat certain atoms as a rigid group.

Inorganic crystallographers, especially those concerned with silicates, enjoy a situation not shared by many of their colleagues, and this has been exploited by Baur. Inorganic crystals are based on dense packing of anions interspersed by smaller cations and, although the cation angles may be distorted, the wealth of interatomic data now available (much of it derived from accurate single-crystal studies) has shown that contact distances are remarkably uniform. In 1969 Meier and Villiger (*Z. Krist.*, **129**, 411 ; 1969) realized that the number of interatomic distances in these structures exceeds the number of adjustable atom coordinates, described a least-squares procedure for adjusting the coordinates to minimize the spread of distances of a given type and demonstrated the usefulness and scope of the procedure. Baur, who has elsewhere been able to show that changes of interatomic distance are linearly related to changes of bond strength (using an extended electrostatic valence theory) and to derive empirical constants for a number of atom pairs, has now combined these linear relations with Meier and Villiger's least-squares refinement of distances. In particular he has shown how a rather poorly defined structure for the medium-pressure β-polymorph of $MgSiO_4$, originally deduced from powder data, could be refined to produce a far more homogeneous set of distances corresponding closely ($\langle \Delta d \rangle = 0.027$ Å) with those recently derived from a careful single-crystal study of the isomorphous β-$CoSiO_4$. Experience gained with earlier trials had shown that even more preferential weight should be given to the cation-oxygen distances than had been given by Meier and Villiger, and that this weighting is critical. When applied to accurately known structures the approach has proved capable of predicting Si–O distances to 0.01 Å or less.

It is a pity that the method is not more widely applicable: those people who study molecular crystals will surely be forgiven if they seem a little envious of a technique that allows their colleagues to transcend the limitations of their data.

ELECTRON MICROSCOPY

High Voltage at NPL

from a Correspondent

THE six AEI 1 MeV electron microscopes (installed at UKAEA, Harwell, the National Physical Laboratory, Imperial College, the Universities of Oxford and Birmingham and the British Iron and Steel Research Association, Sheffield) plus the 1 MeV JEOL machine at the Central Electricity Generating Board, Berkeley, and the original 750 keV instrument in Cambridge represent a UK investment in high voltage electron microscopy far exceeding that of any other country. About eighty people—mostly materials scientists using these various instruments and a few biologists—attended a conference organized by the Institute of Physics and the Royal Microscopical Society in conjunction with the National Physical Laboratory at Teddington from September 22 to 23.

Dr A. Howie (University of Cambridge) reviewed recent progress in understanding the penetration of electron beams in crystals and the remarkable channelling effects occurring above the "critical voltage". This voltage and related interference fringe spacings can be accurately measured to give information about lattice potentials as was shown for gold by Dr J. Steeds (University of Bristol) and for uranium by Drs B. Hudson and A. J. E. Foreman (UKAEA, Harwell). Local temperatures or alloy composition and order can also be determined in this way. Dr E. Butler (Imperial College, London) showed that in nickel-gold alloys 1 per cent compositional change could be detected over distances of about 1μ. Use of a mini lens to reduce the size of the illuminating spot to perhaps 0.1μ could make this a very powerful microanalysis technique. The discussion indicated that an improved theory which takes account of non-systematic reflexions would be useful for this work.

Above the threshold energy at which the fast electrons can knock atoms out of their lattice sites, the high voltage microscope is unrivalled for radiation damage studies *in situ*. Void growth, which causes serious swelling problems in fast reactor materials, can be simulated in the microscope at a rate 10^4 faster than in the reactor (Dr K. R. Williams *et al.*, CEGB). Accurate knowledge of flux density in the beam and temperature rise in the specimen are essential for quantitative interpretation of these experiments, as was pointed out by Dr M. J. Makin (UKAEA, Harwell).

The transparency of crystals several microns thick to fast electrons allows *in situ* experiments which are reasonably typical of bulk materials. Results presented included recrystallization processes in copper alloys (Dr R. Ray *et al.*, University of Birmingham), growth of strain-induced martensite in a titanium-zirconium alloy (Drs H. Flower and P. Swann, Imperial College, London) and an interesting film of dislocation motion during creep of polycrystalline aluminium (Drs K. F. Hale and M. Henderson Brown, NPL). The possible role of point defects in these experiments when the damage threshold energy is exceeded has not yet been assessed.

High voltage microscopes usually have more available space near the specimen which, in addition to the greater penetration of the electron beam, makes them very suitable for *in situ* experiments involving special stages. Some of these experiments were surveyed by Professor U. Valdrè (University of Bologna) and several new straining stages and environmental cells were described. The latter have been used in studies of cement hydration (Dr D. Allinson, NPL), the reduction of haematite (Drs N. Tighe and P. Swann, Imperial College, London) and the observation of 70 Å fringes in wet, partially stained catalase (Drs P. R. Ward and R. F. Mitchell, University of Cambridge).

Dr A. Glauert (University of Cambridge) listed the chief advantages of the high voltage microscope in biology as the ability to observe wet (but not living) specimens and to obtain both better resolution and, with stereo methods, a better three-dimensional picture of the structure in thick specimens. The ionization damage in organic materials is reduced at higher voltages but, as the polymer work of Drs M. J. Richardson and K. Thomas (NPL) demonstrated, this is often cancelled by the increased exposure time required with the photographic plates currently used.

Professor J. M. Cowley (Arizona State University) described a 1 MeV transmission scanning microscope now under construction and emphasized the advantages (chiefly reduced chromatic aberration and improved signal processing) which this technique has over conventional microscopy. This scanning instrument, which operates below the damage threshold, may well (at the cost of some resolution) offer significant advantages for the transmission studies of thick crystals. Its role at higher voltages, whether or not the probable damage produced is of interest, is rather more uncertain and Professor Cowley's results will be awaited with interest. In the meantime, the bold initiative which placed the high voltage conventional microscopes at the disposal of workers in Britain is being followed up with imagination and vigour.

HEPATITIS

Among Drug Addicts

from our Medical Virology Correspondent

TRANSMISSION of viral hepatitis through the communal use of syringes and needles by addicts for the injection of

---

Messenger RNA and the Endoplasmic Reticulum

THE elucidation of the way in which messenger RNAs, transcribed in the nucleus of eukaryotic cells, are matured, packaged and transported to the cytoplasmic translation machinery is one of the great challenges of cell biology. Over the past several years evidence has been accumulated which suggests that messenger RNAs occur in cell nuclei in the form of ribonucleoprotein particles—so-called informosomes—and in *Nature New Biology* next week Faiferman, Cornudella and Pogo report experiments with Krebs ascites cells which, they believe, indicate that these ribonucleoprotein particles migrate to the cytoplasm and become associated with the endoplasmic reticulum.

Faiferman and his colleagues gently lysed Krebs cells which had been labelled with RNA precursors and, by differential centrifugation, isolated the cell nuclei to which remained attached most of the cell's endoplasmic reticulum. After disrupting the nuclei in a French press, the nuclear chromatin was pelleted and the supernatant was found to contain 40–50S ribonucleoprotein particles as well as fragmented reticulum. The 40–50S particles are made in the presence of low doses of actinomycin D which block ribosomal RNA synthesis but cordycepin, which blocks messenger RNA synthesis in HeLa cells, blocks the synthesis of these particles in Krebs cells. To eliminate the possibility that the 40–50S particles are of mitochondrial origin, Faiferman and his colleagues have shown that their synthesis is not affected by ethidium bromide, which specifically inhibits the transcription of mitochondrial DNA.

Pulse chase experiments reveal that in the presence of amino-acids the 40–50S particles are rapidly chased into the endoplasmic reticulum. By contrast, when the cells are starved of amino-acids not only are the 40–50S particles broken down in the cytoplasm but also large numbers of ribosomes, which are normally attached to the reticulum, are found free in the cytoplasm. Faiferman *et al.* suggest therefore that the attachment of ribosomes and the 40–50S particles containing messenger are concurrent events. In short, they believe that messenger RNA is delivered to the reticulum in a 40–50S particulate riboprotein complex.

heroin, methylamphetamine and other drugs is a common and an increasingly serious problem in major urban centres throughout the world. The infection is spread by needles and syringes contaminated with blood. In a report from the Centre for Disease Control, Atlanta (*Hepatitis Surveillance Report*, No. 32; 1970), males between the ages of 15 and 29 years were identified as a high risk population for abusing parenteral drugs and the incidence of hepatitis among this age group is high. Once hepatitis is introduced into a group of drug addicts who use communal intravenous equipment, the disease spreads rapidly.

Cherubin and his associates (*Amer. J. Epidemiol.*, **95**, 510; 1970) detected the Australia antigen, which is specifically associated with serum hepatitis, in 54 per cent of patients who were known addicts and who were admitted with viral hepatitis to two hospitals in New York. In another group of young adults with clinical hepatitis who denied the use of drugs, Australia antigen was found in 50 per cent. On the other hand, the frequency of detectable antigen among healthy volunteer blood donors in New York is only 0.1 per cent. It was suggested that the high incidence of serum hepatitis in New York City might be attributable to a greater drug addiction problem than had hitherto been considered. It is, of course, true that the problem of hepatitis among drug addicts may well have been underestimated because there is some evidence that the virus of serum hepatitis may be transmitted not only by the parenteral route but also by the oral route and by sexual intercourse.

Another disturbing report has recently been published by Collins and Wells (*Milit. Med.*, **136**, 572; 1971) who noted a dramatic increase in the number of patients admitted with acute viral hepatitis to Brooke General Army Hospital between July 1969 and June 1970. The greatest increase in admissions was related to hepatitis associated with illicit drug abuse.

Drug abuse may be regarded in practice as a contagious disease because the habit is transmitted from one person to another. This approach makes it possible to apply to the study of drug addiction the methods used in the epidemiology of infectious disease and notification of hepatitis in young adults may well be used as one marker of drug abuse. Knowledge of the epidemiology of viral hepatitis among drug addicts is so far incomplete, but there can be no doubt that illicit drug users constitute an important reservoir of serum hepatitis in the community and the spread of infection to close family contacts, medical and nursing personnel and indeed to the population at large presents a real hazard.

ACETYLCHOLINE

Regulation of Binding

from our Neurochemistry Correspondent

A FURTHER addition to recent rapid advances in the application of techniques of molecular biology to the study of drug-receptor interactions (see, for instance, *Nature*, **229**, 523; 1971; and **231**, 91; 1971) is provided by evidence reported by M. E. Eldefrawi and R. D. O'Brien of Cornell University (*Proc. US Nat. Acad. Sci.*, **68**, 2006; 1971) that the binding of acetylcholine (ACh) to a preparation from the *Torpedo* electric organ containing cholinergic receptors is reduced at high concentrations of ACh.

Binding was measured by equilibrium dialysis using ^{3}H-ACh, and a particulate fraction in which all the acetylcholinesterase (AChE) was inhibited irreversibly. The binding sites studied were probably acetylcholine receptors, because O'Brien and his colleagues have shown previously that the binding of muscarone (a stable cholinergic agonist) to the same preparation was reduced after treatment with a variety of drugs known to act at cholinergic receptors, but was unaffected by other drugs. In the present experiments, binding of acetylcholine was found to reach saturation at a concentration just below 1 μM, but was markedly reduced at higher concentrations.

As pointed out by Eldefrawi and O'Brien in their discussion, this "autoinhibition" of acetylcholine binding to receptors is analogous to the reduction in activity of many enzymes, including acetylcholinesterase, at high concentrations of substrate. The latter effect,

Anti-θ Antisera and T Cells

IN recent years cellular immunologists have come to rely heavily on means of identifying the cell populations involved in immune responses. It is no longer good enough to say that changes have occurred in lymphoid organs after an antigenic stimulus, though the classic approach of the histopathologist is still obviously a prerequisite in any comprehensive study. The means adopted for cell identification have been many and various and are in most instances still only suitable for experimentation with small rodents of which the genetic constitution in relation particularly to tissue strain and species specific antigenicity can more readily be controlled.

One of the most useful devices has been the use of the theta (θ) alloantigen as an indicator for (T) cells of thymic origin. A recent review by Raff (*Transplant Rev.*, **6**, 52; 1971) summarizes such work. The problems with θ, however, are numerous. It is not absolutely specific for cells of thymic origin because it has been known for some time that some brain cells are θ positive. This is usually a minor problem for the experimentalist, but more serious are the possibilities, first, that not all T cells have easily detectable amounts of θ, as has been suggested by Miller and Sprent (*Nature New Biology*, **230**, 267; 1971), and, second, that the anti-θ antisera in use are not completely specific for T cells, which is the burden of a paper by Greaves and Raff which is to be published in next Wednesday's *Nature New Biology*.

Greaves and Raff prepared two batches of anti-θ antisera by injection of CBA thymocytes into AKR mice. Both sera had the same cytotoxic titre in the presence of guinea-pig complement as adjudged by either dye exclusion or release of ^{51}Cr from labelled target cells. It was found, however, that when the first serum (anti-θ_1) was used against lymphoid target cells in the presence of rabbit complement many more cells were killed than in the presence of guinea-pig complement. The conclusion was that a supposedly specific anti-theta serum was killing B cells. It is argued that the θ_1 antiserum contained an antibody directed against a previously unknown surface alloantigen which is present on the surface of B cells. The new antibody, however, required rabbit complement for expression of its cytotoxic potential.

Greaves and Raff present further studies in which anti-θ antisera were used to inhibit splenic rosette forming cells in the presence of guinea-pig complement. Anti-θ_1 had the capacity to inhibit both background and "immune" rosettes, but if it was absorbed with (autologous) AKR thymocytes its capacity to inhibit immune rosettes in the early phase of the response was limited. The authors conclude that anti-θ_1 contains an autoantibody which can act synergistically with anti-θ. Anti-θ_2, their second batch of antiserum, was deficient in the autoantibody. A corollary is that reacting T cells are deficient in θ antigen, a conclusion in line with that of Miller and Sprent.

Thus it seems that care must be taken in the use of anti-θ antisera as absolute criteria of T cells. This may restrict the use of fluorescent anti-θ antisera on tissue sections—because of staining of non-T lymphocytes. It should not, however, be thought that the analyses of the composition of various lymphoid cell populations in terms of T and B cells by the use of anti-θ sera in the presence of guinea-pig complement are invalid. Such a conclusion would be premature and almost certainly wrong.

however, is usually caused by an alteration in the effectiveness of the catalytic process rather than of the binding.

Of greater interest is the possible relation between this autoinhibitory effect and the blockade observed physiologically when neuromuscular preparations are exposed to high concentrations of acetylcholine—the phenomenon of "desensitization". Classical drug-receptor theory supposes that drug effects are a consequence of a change in the receptor to an "active" form, induced by binding of the agonist. On this basis, desensitization has been interpreted as being caused by the formation of "inactive" acetylcholine-receptor complexes, with a reduced ability to generate a physiological response. Receptors can thus exist in two forms, effective—R, at low ACh concentrations of acetylcholine—and desensitized—R″, at high concentrations of acetylcholine. The model also assumes that the affinity of R″ for acetylcholine is lower than that of R, but suggests no explanation of how these changes are brought about.

Eldefrawi and O'Brien propose a scheme whereby receptors may possess more than one type of binding site, occupation of low affinity sites leading to a reduction in binding to the high affinity or active sites and ultimately to a conformational change in the receptor, such that the affinity of the active sites for acetylcholine is decreased greatly. This would provide an attractive explanation for the molecular mechanism underlying desensitization, essentially analogous to the model for allosteric properties of enzymes. But so far there is no direct proof of multiple binding sites on receptors, and the authors should also perhaps first demonstrate a direct coincidence between physiologically observed desensitization and inhibition of binding *in vitro*.

BEHAVIOUR

Ethology in Edinburgh

from our Animal Behaviour Correspondent

THE wide range of topics discussed at the twelfth international ethological conference held in Edinburgh from September 7 to 15 reflects the diversity of interests of ethologists. The first morning of the conference was devoted to the neurophysiological mechanisms underlying sequences of invertebrate behaviour, and several speakers, including Dr A. O. D. Willows (Washington University), showed that patterns of overt behaviour may in some cases arise from patterns of impulses originating in particular neurones. Other plenary sessions covered imprinting, behaviour of social insects and orientation. Dr W. T. Keeton (Cornell University) reviewed the most recent evidence on the homing ability of pigeons and concluded that biologists simply do not understand how these birds are able to find their way home. Displacement activities (behaviours appearing "out of context" or at least where ethologists don't expect to find them) were discussed by Dr P. Sevenster (Leiden University) and Dr D. J. MacFarland (University of Oxford).

Professor N. Tinbergen (University of Oxford) stressed the importance of investigating not only the causation of behaviour but also its adaptedness—how it helps the animal to survive—and Professor K. D. Roeder (Tufts University) pointed out that this applies as much to physiology ("behaviour below the skin") as to ethology. As an illustration of the interaction between these two disciplines, he described the violent escape response of a sphingid moth to ultrasound, a response which he has recently found to depend on a novel type of sound receptor near the moth's mouth.

Dr R. P. Michael (Institute of Psychiatry) described work carried out at the Primate Research Centre at Beckenham which has revealed that the smell of certain substances in the vaginal secretions of female rhesus monkeys has the effect of dramatically increasing sexual activity in the males. Dr Michael is continuing this work on other species including humans.

For the first time, the conference included a representative from the Soviet Union. Dr D. K. Belyaev (Novosibirsk University) described the unexpected morphological and chromosomal changes that took place in a population of silver foxes selected primarily for behavioural traits.

During the afternoons three parallel sessions were held in different halls so that it was impossible for everybody to hear all of the hundred or so contributions. Judicious flitting from one room to another, however, did enable one to learn of the ability of electric fish to recognize the sex of other individuals on the basis of the frequency of their electrical discharge (Dr C. D. Hopkins, Rockefeller University), of the precision with which caddis fly larvae build their houses (Dr M. H. Hansell, University of Glasgow) and of the function of the "dance" that blowflies perform when they come across a drop of food (Dr M. C. Nelson, Tufts University), to mention just three from several noteworthy contributions.

Reactivity of Portland Cement Minerals

OF the two calcium silicates, which form the bulk of Portland cement, $3CaO.SiO_2$ is much more reactive than $\beta 2CaO.SiO_2$. Both these phases, however, develop similar ultimate strengths on hydration and, from the manufacturing point of view, cement richer in $\beta 2CaO.SiO_2$ is easier and cheaper to make than a cement richer in $3CaO.SiO_2$. Various empirical attempts have thus been made to increase the reactivity of $\beta 2CaO.SiO_2$ without gaining any fundamental understanding of the factors controlling the intrinsic reactivity of the minerals. In a communication to be published next Monday in *Nature Physical Science*, Ramachandran and Sereda have applied the Hedvall effect to gain some understanding of this difference in reactivities of $\beta 2CaO.SiO_2$ and $3CaO.SiO_2$.

$AgNO_3$ has a phase transition point at about 190° C. When a mixture of $AgNO_3$ and a reactive material, for example CaO, is cycled through this transition temperature a reciprocal pair forms very quickly. The authors have taken advantage of this fact in determining the reactivities of different minerals that may be present in Portland cement. The authors heated mixtures of $AgNO_3$ and an individual cement mineral (or fully hydrated $3CaO.SiO_2$) in a DTA (differential thermal analysis) apparatus and estimated the amounts of $AgNO_3$ used up to form reciprocal pairs in each case. From these data they calculated the quantities of Ca ions that took part in each case. For CaO and $Ca(OH)_2$, all the Ca ions took part in the reaction, but in the case of $3CaO.SiO_2$ and of $\beta 2CaO.SiO_2$ only 27 per cent and 6 per cent respectively of the Ca ions were involved. The presence of a higher proportion of more reactive Ca ions in $3CaO.SiO_2$ than in $\beta 2CaO.SiO_2$ seems to account for the higher reactivity of $3CaO.SiO_2$. The authors then infer that "in tricalcium silicate all Ca ions are not equivalent, a part of it being more reactive".

The origin of this high reactivity of some of the Ca ions in tricalcium silicate is not so obvious. In the structure of $3CaO.SiO_2$ (Jeffery, *Acta Cryst.*, **5**, 26; 1952), all the Ca ions are surrounded by six oxygen ions. In $\beta CaO.SiO_2$ (Midgley, *Acta Cryst.*, **5**, 307; 1952) half of the Ca ions have six oxygen ions as first neighbour and the other half have eight. Thus origins of the higher reactivities of some of the Ca ions in different calcium silicates seem to be extra-structural, and they may not be directly related to the intrinsic reactivities of different calcium silicates. The origin of the difference in reactivities of the cement compounds thus still remains unexplained.

PALAEONTOLOGY

Mammalian Evolution

from our Vertebrate Palaeontology Correspondent

THE nineteenth symposium on vertebrate palaeontology and comparative anatomy was held at Bristol on September 28–29, followed by two days of field excursions. The evolution of mammals, especially those of Africa, was a principal theme, because there is a large and active group at Bristol concerned with this subject. New work on the earliest known mammals, *Eozostrodon/Morganucodon* and *Kuehneotherium*, of the Triassic was described by Professor A. W. Crompton (Harvard University). Some workers have suggested that each of these two mammals gave rise to some of the groups of Jurassic mammals, but that they are so different from one another that they must have arisen from different lines of advanced mammal-like reptile—so making the mammals diphyletic. Professor Crompton strongly dissented from this view, pointing out a number of similarities between the two Triassic genera. He also noted that the epipterygoid of such cynodonts as *Probainognathus* is not greatly enlarged, indicating that this group could be ancestral to all the mammals, including the triconodonts (whose epipterygoid, unlike that of most other mammals, is small). An interesting discovery of early mammals in Britain was that of Dr M. Waldman (Stowe School). Though difficult to detect, and also difficult to remove from the hard matrix, his find of Middle Jurassic mammals in the Isle of Skye is of great potential interest, because the only other mammalian fauna of this age comes from the Stonesfield Slate of Oxford, which is no longer quarried.

Professor P. M. Butler (Royal Holloway College, London) suggested that the directions of jaw movement, as indicated by wear striations on the teeth, had passed through three principal phases in mammalian evolution. In Jurassic forms, the movement is partly transverse and becomes progressively more so, but the teeth shear past one another. Not until the Cretaceous do the teeth collide at the end of the jaw movement, so giving a crushing action. This in turn provided the possibility of a subsequent movement in another direction, so that two different sets of facets can be distinguished in the Tertiary herbivores and omnivores.

The studies of African mammals ranged from the problems of the phylogeny of the older forms to those of evolutionary rates and the comparison of later forms with those still extant. Mr G. J. Heal (University of Bristol) described sirenians which showed that two families of this order were already distinguishable in the Eocene, and Mr A. W. R. Wight (University of Bristol) described new specimens of Proboscidea and discussed the Eocene stratigraphy of Libya. Dr V. Maglio (Princeton University) analysed the rates of appearance and replacement of species in the Elephantinae and suggested that the group was in the middle of a phase of adaptive radiation when, in the Upper Pleistocene, there was a dramatic crash from eleven lineages to the present two. Dr A. W. Gentry (British Museum (Natural History)) compared the African Pleistocene antelopes with those of the continent today and pointed out that, because horn shape is a species recognition feature, the whole antelope fauna of any one time, within which such distinctions were essential, should be considered in any analysis.

At the other end of the chordate evolutionary story, Dr R. P. S. Jefferies (British Museum (Natural History)) described a new mitrate echinoderm which he believed showed evidence of being ancestral to the cephalochordates. Professor D. L. Dineley (University of Bristol) gave an interesting account of the Late Devonian fish fauna of Escuminac Bay, Canada, and Mr D. S. Broad (University of Bristol) described new heterostracans from Arctic Canada which showed evidence of the growth of each plate by accretion around a small number of original tubercles. The problem of interpreting the patterns of tetrapod tooth replacement was discussed by Dr R. DeMar (Liberal Arts College, Chicago), who showed that Edmund's Zahnreihe is only one of a number of theoretically possible alternatives, and that computer studies can show why some of these are not acceptable, because they lead to lengthy gaps in the tooth row.

Dr A. C. Charig (British Museum (Natural History)) pointed out that reptiles colonized more new ways of life in the Triassic than ever before or since, and suggested that this might be more than mere coincidence—though other possible reasons were not obvious. A valuable approach to the study of pterosaurs was presented by Dr G. R.

Visualizing Agglutinin Sites on Cell Surfaces

DURING the past several months the suggestion that transformed cells are more readily agglutinated by plant agglutinins than their untransformed counterparts because transformation leads to an increase in the number of agglutinin-binding sites exposed on the cell surface has been abandoned. For experiments such as those reported by Cline and Livingston and Ozanne and Sambrook in *Nature New Biology* (**232**, 155, 156; 1971) have shown that there is apparently no significant difference between the numbers of these binding sites on the surfaces of transformed and untransformed cells. These workers have suggested therefore that it is the distribution of agglutinin-binding sites rather than their numbers which is changed by transformation and in next Wednesday's *Nature New Biology*, Nicholson reports observing in the electron microscope just such a change; after transformation by SV40 virus the concanavalin A binding sites on the surface of mouse 3T3 cells are clustered whereas before transformation they are dispersed.

Nicholson was able to make these most elegant observations by preparing ferritin conjugated concanavalin A and then devising a new technique for preparing the cell surface membrane for electron microscopy. His technique involves first "strengthening" the cell membrane by briefly incubating the cells in 0.1 per cent formaldehyde before lysing them on an air–water interface and then picking up the membrane on electron microscope grids. Once on the grids the membranes can then be stained with the ferritin tagged concanavalin A.

The micrographs of stained membranes from transformed and untransformed 3T3 cells reveal at a glance the striking difference in distribution of binding sites. Single ferritin tagged concanavalin A molecules are randomly distributed on the membranes of the untransformed cells. By contrast the tagged concanavalin A molecules are in clusters, which are randomly distributed, on the membranes of the cells transformed by SV40. Although there are some 3 to 3.5 times more molecules of bound concanavalin A per unit area of transformed than per unit area of untransformed cell membrane, Nicholson points out that the total surface area of the transformed cells is only about half that of their untransformed counterparts.

Nicholson has also shown that after exposure to weak trypsin solutions, the concanavalin A sites on the surface of untransformed cells tend to be clustered, but within a few hours of enzyme treatment the sites assume their normal distribution.

There could therefore scarcely be a clearer demonstration of the fact that transformation causes a change in the distribution of these agglutinin-binding sites, which presumably accounts for the increased susceptibility of these transformed cells to agglutination. Whether this particular surface change also alters the social behaviour of cells remains to be seen.

Whitfield (University of Reading), who outlined the way in which theoretical aerodynamic studies and conventional anatomical studies can combine to throw new light on the functional anatomy of *Pteranodon.*

In two studies on modern reptiles, Dr G. L. Underwood (City of London Polytechnic) explained a dendritic classification which provides a very satisfactory picture of the evolution of boid snakes, and Mrs L. Sheppard (St Mary's Hospital, London) showed that the joints between the neural arches in lizards and snakes contain menisci, and suggested that these provide a flexible and compressible element needed in joints which permit movement in more than one plane.

SCHIZOPHRENIA

Biochemical Aspects

from a Correspondent

THE first joint meeting of the schizophrenia associations of Canada, America and Great Britain was held in London on September 28 and 29. Work on the genetic basis of schizophrenia was reviewed by Mr J. Shields (MRC Psychiatric Research Unit, Maudsley Hospital, London) in relation to current hypotheses and he concluded that the evidence for the existence of genetic factors rests on general arguments. Dr L. R. Mosher (National Institute of Mental Health, Bethesda), referring to a study of identical twins discordant for schizophrenia, reported having found different patterns of interaction between one parent and one twin (who was later to become schizophrenic). The twin as a result was repeatedly less favoured and a relationship was established with a contradictory and incomplete role expectation and without cognitive and communicative clarity.

Schizophrenia is a changing concept, said Dr D. Richter (MRC Neuropsychiatry Unit, Carshalton); it has altered as various subgroups have been isolated from the chief group of schizophrenias. Dr A. P. Ridges (University of Liverpool) emphasized the need for a definition of the criteria used in selecting patients and conducting experiments under carefully controlled conditions. She supported Dr Richter and said that altered activity of several enzymes or more probably isoenzymes could finally affect common metabolic pathways producing the symptoms of schizophrenia. Pink spot excretion seems to be associated with an altered catecholamine metabolism in schizophrenia. She reviewed other biochemical considerations including the suggested association between coeliac disease and schizophrenia.

The possible central effects in schizophrenia were considered by Dr A. Randrup (St Hans Hospital, Roskilde), who presented evidence indicating an association between schizophrenia and dopaminergic hyperactivity in the brain. Professor J. Yaryura-Tobias (University of Buenos Aires) considered that the basal ganglia are of prime importance in the aetiology of schizophrenia. Dr K. Smith (Washington University) reported that she has found trans-3-methyl-2-hexenoic acid in schizophrenic sweat. This finding has not yet been confirmed independently by other workers nor has its presence in other psychiatric patients been investigated. The adrenochrome hypothesis has evolved into the aminochrome-melanin hypothesis. Dr M. Altschule (Harvard Medical School) said that these unstable compounds are rapidly converted to melanin by everybody and, regardless of whether schizophrenics make more aminochromes or not, the fact is that at least one of their tissues, blood, is abnormally sensitive to the toxic effects of these compounds.

The term "orthomolecular psychiatry" introduced by Professor L. Pauling in 1968 has taught American psychiatrists to appreciate a principle well known to scientists. Dr R. Maclean (Vancouver) defined orthomolecular psychiatry as the treatment of mental disease by the provision of the optimum molecular environment for the mind especially the optimum concentrations of substances usually present in the body. Reports which followed testified that large doses of vitamins together with other therapy can improve the functioning of the brain in a variety of conditions. Successes with both children and adult psychiatric patients were reported by Dr A. Cott (New York) and Dr D. Hawkins (Nassau Medical Health Research Center, Long Island). Dr A. Hoffer (Saskatoon, Saskatchewan) outlined the treatment which is based on administering vitamin B3 in combination with other vitamins. The over-regulating mechanism of the body in various forms of stress results in hypoglycaemia and although this is not specific for schizophrenia it is common in schizophrenics and ought to be treated, said Dr R. Meiers (Belmont, California).

REACTOR TECHNOLOGY

Structural Mechanics

from a Correspondent

REACTOR technology requires a synthesis of many skills. The ability to deal with the structural mechanical problems which arise is vital to achieving economic, reliable and safe exploitation of nuclear power. For the first time, largely due to the inspiration of Professor Dr Ing T. A. Jaeger (Bundesanstalt für Materialprufung (BAM)), more than nine hundred delegates from the many disciplines involved in reactor technology met in West Berlin from September 20 to 24 to discuss these problems.

Introductory lectures allowed comparisons to be made between the different strategies applied to power reactor development within the European Community, in the United States and in the United Kingdom. The development of the different types of reactor systems was traced with particular emphasis on the ensuing mechanical–structural requirements.

The rapid progress of reactor technology has given rise to many structural problems which are consequent upon the use of sophisticated materials for various reactor system components. These components are required to operate under severe loading and hostile environmental conditions, and the analyses that must be made range from fuel element and cladding performance under mechanical thermal and irradiation, containment requirements, involving prestressed concrete steel lined vessels or heavy section steel vessels, to dynamic response characteristics of complete power installations. This stimulus has resulted in tremendous strides being made in the area of computational methods. It was underlined by the work of Professor J. H. Argyris (Stuttgart University) and others who have found that with the present generation of large computers it is quite possible to analyse almost any component, however complex, under virtually any loading conditions.

The basis of this development is the "finite element" method which, as the name suggests, splits up the problem into a large number of simpler standard elements which are combined in a suitable way. It has frequently proved to be the only feasible method in complex situations. There are, nevertheless, obvous limitations on cost and there remains the implementation of these procedures (or others) to produce the information required for design. Unfortunately analyses seem to have progressed faster than information on material response and it is not yet agreed how the working life of a structure can be predicted on the basis of failure criteria particularly in complex situations where irradiation damage, fracture and creep may interact. Similarly, analyses can only be as good as the input data they receive for situations such as accident conditions, earthquake disturbances or blast loading. It was emphasized by Professor R. K. Penny (University of Liverpool) that material and component testing of the correct type is essential and should be an interactive process with analyses in the overall optimization of design problems.

Politics of Nuclear Power in the United States

RICHARD WILSON
Department of Physics, Harvard University

In this article the issues surrounding nuclear power generation in the United States are critically examined and some of the misunderstandings are clarified.

NUCLEAR power came of age in the United States in about 1967. At that time about fifty large, new nuclear power stations were started. This dramatic switch from fossil fuel power came because the development of the power reactors had reached a point at which the cost became competitive with fossil fuel power. Two commercial experiments had been constructed and had worked well since 1961—a pressurized water reactor (PWR) at Rowe, Massachusetts, and a boiling water reactor (BWR) at Dresden, Illinois. In spite of rising construction costs, nuclear power remains competitive; oil and gas are beginning to run out in the USA and their prices are rising rapidly.

The American public was, however, slow to react. Scientists who had been arguing in favour of nuclear power—because it is cleaner than fossil fuel power—were pleased but took no particular notice or action. But during 1970 the public became alarmed as the full extent of the US nuclear power programme was made apparent. Until a few years ago, few public hearings in the USA on any subject were well attended and construction permits were obtained for these power stations without too much difficulty. But in 1970 the public began to question the wisdom of these plants both in hearings dealing with construction permits and in those dealing with operating licences.

The reactors being installed in the USA at present are of two types, both using enriched uranium fuel (up to 7% ^{235}U) with water as a moderator. In the PWR, water heated by the reactor produces steam in a heat exchanger inside the containment vessel and there is little release of radioactive gases. But, to make them easy to control, boron is added to the primary water in quantities which diminish as the fuel is consumed; this produces tritium which is released and added to the water effluent. The heat exchanger is omitted for reasons of economy in the BWR and the steam condenser after the steam turbine must be evacuated to achieve high efficiency. Air enters the condenser through leaks in seals and must be released, carrying with it a little radioactivity. The thermal efficiency of these stations is about 30%, compared with 40% for the advanced gas cooled reactors.

The first attacks on the nuclear power industry can be considered as a continuation of the attacks on the Atomic Energy Commission (AEC) because of weapons testing; the hazard to the general population due to radioactivity from weapons had been dramatized by Linus Pauling, Ernest Sternglass and others. The dose commitment from past tests (to the year 2000) of the US population is about 60 mrem (about 2 mrem a year). This is small, and it could be argued that it is tolerable but most of the scientists who were willing to argue in this way wanted to stop weapons tests anyway. Now the situation is different—Dr Sternglass has been joined by Dr John W. Gofman of the University of California and applies the same arguments to nuclear power. Dr Gofman argues[1,2] that if the whole population were exposed to the maximum allowed radiation as given by the International Commission on Radiological Protection (ICRP) guidelines (whole body dose 170 mrem per year), then between 9,000 and 110,000 more cancer deaths would be caused each year (depending on his assumptions). It seems probable from the recent work of Dr Alice Stewart at Oxford[3] that the unborn foetus is much more sensitive to cancer than is the adult; the probability of cancer induction also seems to remain linear with dose even at low doses. And cancer cases keep appearing for years after the insulting radiation dose. These findings seem so reasonable that, once understood, they are quickly accepted, although some would quote numbers a factor of five smaller than those of Gofman[4]. Dr Gofman's attacks on the AEC were made in a polemical style which delayed recognition of the issue, and brought forth an inept response from the AEC. Dr Storer[5], a pathologist, argued that there is non-linear behaviour at low doses—a proposition unsupported by reliable experiment and contrary to sound public policy. Moreover, the AEC unnecessarily defended the ICRP guidelines, and failed to define their admonition "as low as practicable".

Restricted Releases

The real answer is only just becoming apparent. Nuclear power now produces much less than 170 mrem average exposure a year. After intervention by scientists in Minnesota (led by Dr Dean Abrahamson) the Monticello reactor is being operated with releases restricted to less than 10% of the AEC regulations (10 CFR/20) and a simple computation shows that the average dose to the public within twenty miles will be less than 10^{-4} of 170 mrem a year. The State of Minnesota supported this restriction and tried to enforce it legally; Congress had, however, specifically given the AEC the right to set radiation regulations for nuclear plants, and this has been upheld by the US Federal Court. But in practice Minnesota will have its way. In Vermont, the Vermont Yankee Power Company signed an agreement with several conservation groups to abide by the lower standards of the Vermont Bureau of Public Health. Even so, Vermont Yankee is now entering what promises to be a long operating licence hearing; operation of the power station was scheduled for December 1971 and will certainly be delayed at a cost of $80,000 a day.

At Plymouth, Massachusetts, the Advisory Committee of the AEC on Reactor Safeguards has insisted on the earliest possible installation of a holdup filter to stop gases with short half lives. All existing BWRs will now be modified in a similar way. In May the AEC introduced new design criteria for light water reactors; the design must limit the worst fence post dose to 10 mrem per year, and the designed equipment must be used. Only two old reactors fail to meet this criterion now. The newer ones give lower radiation by a factor of as much as 10. The reprocessing plants are planning to hold up even ^{85}Kr within a few years.

The AEC is not the only agency to hide behind the ICRP and is not the worst offender. In spite of excellent practices by some of the leading hospitals, the average radiation dose to Americans due to diagnostic X-rays was 95 mrem in 1970 (ref. 6), twice the 1964 dose and seven times the average British dose. The American Medical Association has been silent.

Thermal Problems

Environmental groups have forced through important changes in thermal pollution standards. This is an old story in England where the River Trent, for example, which is small and sluggish by US standards, has 12,000 MW of installed generating capacity, more than any comparable river in the USA; cooling towers abound. Not only do nuclear power stations give out twice as much heat as fossil fuel power stations, but nuclear power is at present less efficient and there is no loss of heat up the chimney.

The first nuclear power station where this problem was faced was Connecticut Yankee at Haddam's Neck near the mouth of the Connecticut River. Cooling is done with river water, but a study of the effects of the heating is under way[7]. Other power companies have not been so fortunate; further up the Connecticut River at the Vermont Yankee station mechanical draught cooling towers which can work on a closed cycle have had to be installed. In the region of the Great Lakes, the Lake Michigan Environmental Conference wishes to set and enforce a rule allowing a maximum water temperature rise of 1° F. This matter involves many states and is being considered by the director of the newly formed US Environmental Protection Agency (Mr W. Ruckelshaus). Some scientists think the rule is extreme and unnecessary[8]. Lake Michigan, for example, has an area of 10,000 miles^2, and the heating from each power station is equivalent to solar heat over 1 mile^2. If the water is spread over the whole surface of the lake, all power stations up to the year 2000 could be accommodated[9] with a temperature rise of only 0.1° F, so the problem becomes one of achieving this uniformity. Particularly at issue is the fate of eight power stations under construction—the power companies estimate a cost of $200 million to add cooling towers at this stage.

The AEC was sensitive to criticisms of excessive political power and had no expertise in this field; hence it tried to avoid considering thermal pollution. It tried merely to "certify" the state or other federal standards and to consider only radiation and reactor safety in its hearings. Many people have tried to persuade the AEC to "hand over" all the hearing and compliance procedures to the Environmental Protection Agency. The Environmental Protection Act, as interpreted in July by the US Court of Appeals in the consideration of a nuclear power plant at Calvert Cliffs in Chesapeake Bay, insists, however, that the AEC has the right and duty to control all environmental matters. This will involve more delays—especially for those power stations which are now involved in operating licence hearings. It is ironic that conservation groups have forced the AEC into taking on more political power at a time when others accuse it of having too much.

Accidents and Safety

The third issue, least emphasized but most important politically, is that of safety. Each reactor makes enough plutonium in a year for thirty atom bombs, and radioactive material in proportion. Could an accident occur which would spread this over the countryside? Clearly a direct hit from a hydrogen bomb would do so, but what else?

If there is a catastrophic pipe failure in a light water reactor (which in itself is unlikely ever to happen) the depressurization (blowdown) will lead to loss of coolant (and moderator). Emergency core cooling must immediately be applied to prevent fuel melting and release of radioactivity. In a typical PWR 17,000 gallons of borated water held under pressure would immediately be injected into the vessel. But small scale (9 inch instead of 18 foot) tests held at the National Reactor Testing Station at Idaho in November of 1970 showed that the water injected during the blowdown fails to stay. Although calculations suggest that the system behaves better in the full scale reactor, the AEC first stalled on all new operating licences, and then in June issued tighter standards. The utility company must prove that the reactor can cope with a double-ended guillotine break, even if all water injected during the blowdown is lost. Superficially this does not affect the BWRs or the two helium gas-cooled reactors, but a few scientists argue[10] that none of the old safety arguments can be trusted, and that no new reactors should be licensed until a new independent study has been made.

This aspect of nuclear power is probably the least well comprehended. To understand this, we must understand other serious accidents. One can talk about the 88,000 direct coal mining deaths since 1907 (in addition to black lung and various other diseases) or the 2,000 people killed when a hydroelectric dam gave way near Belluno, Italy, in 1963, but there is no public understanding of such comparisons and even less acceptance. The US public will probably not accept nuclear power finally until there is a complete understanding of all types of accident—and an understanding which can be simply expressed.

The power companies are now becoming reconciled to long hearings on any power station. The Long Island Lighting Company has been trying to obtain a construction permit for a BWR at Shoreham, but this has already taken 12 months of hearings in spite of the help of some local citizens who work at Brookhaven National Laboratory. The President's Office of Science and Technology[11] has recommended that site searches take place in public over several years. This is a good development, but the USA will be faced with power shortages in the next few years while the power companies adjust to the new situation. Westinghouse is now designing reactors on barges to be floated 20 miles offshore.

The AEC, for its part, must quickly undertake the vital task of restoring public credibility. As a result of many factors, and in particular the SST and the Vietnamese war, the American public have learned to distrust the experts in Washington. The AEC has been talking for twenty years, but few members of the public have been listening. Now people are listening but the AEC must learn how to talk clearly and simply.

One possible consequence of failure to reorganize promptly is apparent in New York. Faced with forthcoming power shortages, and a completed nuclear power station which is not allowed to operate, Mayor Lindsay has overruled many of his advisers, and has allowed the installation of 2,000 MW of gas turbine power on the East River in New York, which now operates every hot summer afternoon. These are little better than jet engines blowing against windmills. The disadvantages in noise, thermal pollution, and consumption of expensive scarce fuels are obvious.

In Midland, Michigan, where a nuclear power station is held up by intervention in public hearings, Dow Chemical Company announced the transfer of part of its operation to New Orleans where power is cheaper. Local citizens took out a full-page advertisement attacking the interveners. Conservation societies now have great political power in the US—particularly on nuclear questions; they must use this power wisely.

The Oxford Botanic Gardens: 1621 to 1971

C. D. DARLINGTON
Botany School, University of Oxford

On July 24 this year, the 350th anniversary of the old Physic Garden in Oxford was celebrated by the university. A guide to the old and new gardens has been published by the Oxford University Press and an exhibition set up in the Divinity School to mark the event.

LORD DANBY, the founder of the Oxford Botanic Garden, was one of the great adventurers of the Elizabethan age. Sir Philip Sydney took him as a page on his fatal expedition to the Netherlands in 1586 and soon afterwards he was exiled by Elizabeth to France for a murder; his brother was later beheaded for rebellion. This was the violent phase when he served as the model for the Romeo of Shakespeare[1]. But after these youthful indiscretions, Henry IV of France befriended him, James I made use of him, and in good time he found himself an Earl and a Knight of the Garter. It is in this respectable phase that his bust appears adorning the Inigo Jones gateway of his garden (Fig. 1).

Danby was prompted to set up his garden in Oxford by Thomas Clayton, the professor of medicine. But no doubt it was his own experiences which made him demand a wall to defend the garden against friends and foes as well as against frost. The wall took twelve years to build and proved strong enough to meet all these dangers. Civil war in the seventeenth century, a bridge and road scheme in the eighteenth century, and an expansion plan in the nineteenth century were all withstood by Danby's wall.

Jacob Bobart had been given a 99-year contract as keeper of the garden for himself and his heirs in 1637, a contract which allowed a far-sighted policy. By 1641 he had produced the necessary heir and by 1648 he had issued a catalogue of the 1,600 plants that he had collected. Many had been grown from seed sent by other gardens and, in about 1666, he or his son raised the hybrid plane and recognized it as a hybrid. It is now known as the London plane but its finest specimens are still to be seen in Oxford.

Evidently the garden flourished for the 82 years that it was managed by the Bobarts, in spite of financial difficulties. Loggan in 1675 shows their orangery and the four gated enclosures which they had made for their beds. Here Pepys and Evelyn came with other inquisitive visitors; here the physicians learnt their drug plants, among them Radcliffe who built the Camera with the profits of his profession. Here, too, Robert Hooke must have sought out the plants for his *Micrographia*. And here the younger Bobart began his collaboration with Robert Morison[2].

Morison came from Aberdeen, fought for Charles II and followed him into exile, and then studied several sciences in Paris. He was uncouth in appearance but the King liked him and, after his restoration, made him his own physician as well as his own gardener. Sponsored by Charles in 1669 he undertook the additional duties of professor.

Morison brought with him from France several "striped" herbs and trees including the mottled sycamore. They still survive in the garden, embodied in the great classified collection of variegated plants. Next, in collaboration with the younger Bobart, he began a detailed account of the flora of Oxfordshire; the joint experience of the two men of raising plants from seed gave them a new point of view. Their recognition of the pro-

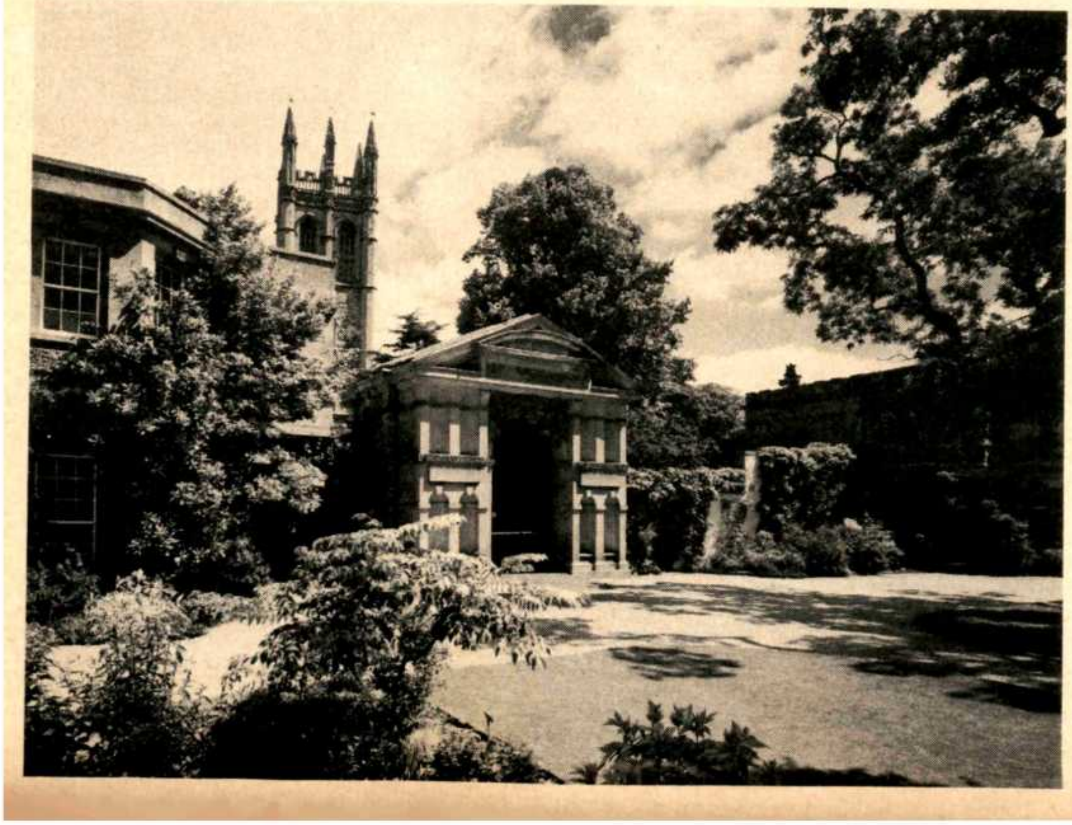

Fig. 1 The Inigo Jones gateway

cesses of sexual reproduction (which they shared with John Ray) led them to use the reproductive rather than the vegetative organs as the basis of classification and helped to make explicit the daring idea of genetic relationship, the slow advance of which was to cover the next three hundred years.

When Morison died prematurely in London in 1683, knocked down by a coach in the Strand, his salary, which was to have been paid by the King, had long been in arrears. The younger Bobart then became the unpaid professor and had to complete their joint work alone. It was this devoted work which must have attracted the attention of William Sherard, then an undergraduate in law at Oxford. Later Sherard in his capacity as British consul at Smyrna from 1703 to 1717 acquired a fortune and was able at last to indulge his botanical interest. He then began to make extensive journeys collecting plants, a library and, most important of all, a collaborator—Johann Dillen or Dillenius.

Dillenius was one of a succession of German botanists who excelled as draughtsmen and, by their comprehensive labours, made it possible to establish the systematic ideas of Ray, Morison and later Linnaeus. Sherard first installed Dillenius as Foreign Secretary of the Royal Society and then set to work to establish him as professor at Oxford, with an endowment both for the chair and for the garden. He was careful to exclude the danger, endemic in Oxford at that time, of any connexion with the Church.

The immediate fruit of Sherard's gift was the production of Dillenius's *Historia Muscorum*, the most thoroughly illustrated early account of the lower plants; in this way the practice of plant illustration took root in Oxford. The next professor, Humphry Sibthorp, did little himself. He may, have had Joseph Banks in the audience of his single lecture but we have to suppose that it was the garden and not the lecture that later inspired Banks to establish the Royal Gardens at Kew. Sibthorp's artistic interests are shown, however, by his acquisition not only of seed of the Chinese ginkgo but also of a Chinese painting of the tree, now on show at the Divinity School in Oxford. Accordingly it was a botanical artist, Georg Dionysius Ehret, that Sibthorp engaged as head gardener. Ehret stayed only a year for he would not take orders from Sibthorp. He made his way to London, but his descendants left their mark in Oxford. The fourth generation gave us Sir Arthur Evans, Keeper of the Ashmolean Museum, by whose enterprise the plant decorations at Knossos were to be discovered.

The urge to collaborate with artists and to seek them out abroad descended to Sibthorp's young son for whom he made way in 1784. For John Sibthorp arrived in Vienna to find that the fifth century illustrations of Dioscorides had recently been brought from Constantinople and, by order of Maria Theresa, had been engraved and some twenty-five copies printed. Equipped with one of these and with ample funds, he was accompanied by yet another German artist, Ferdinand Bauer, as he made his way to Greece with the object of having every plant in the classical catalogue drawn again from nature and printed and published in the modern style. He and Bauer later extended this original purpose, first to include the general flora of Greece and then the fauna as well.

Before this plan could be fulfilled Sibthorp died after only two journeys in Greece. But he had endowed the publication of his work. Bauer completed the illustrations, and after forty-four years all the 960 coloured plates had appeared in the ten volumes of his splendid *Flora Graeca*.

It was now 1840, however, and times had changed. The study of physic and practice of draughtsmanship had ceased to be the mainsprings of plant science. New possibilities had arisen and a new kind of teacher appeared in Oxford to seize the opportunity. This was Charles Daubeny, an amiable man who was willing to expound any science known at the time—except theology. He was elected in succession to the chairs of chemistry, botany and rural economy and he held them concurrently. Quick to learn, it was said he had picked up what botany he needed from the De Candolles during a few months in Geneva. He was neither profound nor original and he did not know enough to be pedantic. But he was willing to try other people's ideas and eager to teach them. The result was that he and his contemporary Acland proved to be the most effective of university innovators.

The young Daubeny realized the value of Liebig's experiments with mineral fertilizers as soon as he heard of them. He at once tried them out on plots in what he called the Botanic Garden. His pupil John Lawes took the idea home with him and founded Rothamsted. Later, an older Daubeny at once saw the merits of evolutionary theory and when the British Association came to Oxford in June 1860 it was Daubeny who opened the Darwinian debate. The title of his paper (*On sexuality in plants*) pointed back to Morison and forward to the present day[3]. And it was Daubeny who concluded the debate with a party that evening at his house in the Botanic Garden: in the heart, as we may say, of enemy country.

Daubeny and Acland saw the need for unifying the sciences and fitting them into a larger scheme of education. It was a development of this vision when, within a few years of his death in 1867, Lawson and Lankester were joining together to teach a course in biology in the Botanic Garden. But this development was not to prosper. The craving for specialization in teachers, the demand for independence of professors, but above all the great fear in the university of expanding science, turned the current of opinion in the opposite direction. In these circumstances the university appealed to Dr Hooker[2], the director of Kew, for guidance. It was relieved to learn from him that botany in Oxford could well stand by itself and could stand for ever on the four acres of the Botanic Garden.

With this guidance, teaching as well as research fell into decay. The attachment of botany to medicine, which could have carried both subjects into a creative experimental period (putting Mendel and Garrod together), remained static for a further eighty years in the forms of an ancient syllabus. In 1883 Lawson emigrated and the Sherardian Chair fell vacant; once again there was no paid teacher or manager in the garden. In 1901 Daubeny's now useless experimental field was sold. And appropriately, forty years later, the superintendent's seed list was still titled in Latin and his office was still lit by the light of a single candle.

Today these setbacks and holdbacks can be seen from a happier position. In 1944 the garden itself was doubled in size and on the new ground there has been arranged a collection of roses whose history of hybridization and selection is now defined by pedigree and also by chromosomes. In 1954 a Genetic Garden, now in the University Parks, was added to display, with materials both for teaching and research, not only the results but the processes of evolution. And in 1969 an anonymous benefactor put a third garden at the disposal of the university, the established and now rehabilitated arboretum of Nuneham Courtenay.

We can now look back at the contrasted succession of naturalists and experimenters who have worked and taught in the Botanic Garden. Through them runs the continuity of the garden itself with its collections of plants, its series of glass-houses (now rebuilt for the seventh time) and its long line of gardeners. Notable among these are the Bobarts and the Baxters—fathers and sons—whose skill has been passed on from generation to generation and who have maintained the garden, disseminating their knowledge and materials worldwide through catalogues, exchange lists and guides. In the future, even more than in the past, we may expect that the practical wisdom of the garden and of the gardeners will continue to hold together the branching strands not of one but of several sciences.

General Model for the Structure of all Myosin-containing Filaments

J. M. SQUIRE[*]

Biophysics Institute, Aarhus University, University Park, DK-8000 Aarhus

It is suggested that the way in which the molecules are packed is common to all types of myosin filament. This leads to quantitative predictions about the component molecules.

It has been known for some time that thin actin-containing filaments, all of basically the same structure, occur in all the types of muscle so far studied[1-6]. These muscle types include vertebrate striated muscle (VStM), vertebrate smooth muscle (VSmM), insect fibrillar flight muscle (IFM) and molluscan muscles (MM). On the other hand, it is generally accepted that the myosin-containing filaments in the muscles mentioned are structurally quite different[5-11] apart from the following points of similarity. (i) All the myosin filaments are known to have an axial repeat of about 144 Å. (ii) It is thought that the heavy meromyosin portions[12] of the myosin molecules which form the filaments project from the surfaces of the filaments to form cross-bridges which can interact with neighbouring actin filaments[8,13]. Evidence of such projections has been obtained directly by electron microscopy (refs. 10, 11 and 15–17 and J. V. Small, and J. M. Squire, in preparation) and has been deduced from X-ray diffraction studies of intact muscle[13,14,18,19].

The apparent differences between these myosin-containing filaments are considerable. (i) The filaments can either be cylindrical (VStM, IFM and MM) or ribbon-like in shape (VSmM)[9]. The cylindrical filaments vary greatly in diameter and length although they probably all taper at each end, there is probably end to end polarity of the cross-bridges and probably a bare zone half way along the filaments[20]. The VSmM myosin ribbons have opposite polarity on opposite faces (ref. 17 and J. V. Small, and J. M. Squire, in preparation). (ii) Those myosin-containing filaments which have been analysed structurally (VStM, IFM and VSmM) have projections arranged on nets which apparently have quite distinct symmetry and spacings (except for the common 144 Å axial period) in the different types of filaments. In VStM the myosin projections are thought to be arranged on a two-strand 6/1[†] helix of repeat 429 Å (ref. 8), in IFM[11] they are thought to be arranged on a two-strand 16/3 helix of true repeat about 1150 Å and in VSmM the projections are thought to be arranged on each face of the ribbon in a lattice of approximate dimensions $a=100$ Å (across the ribbon face), $b=150$ Å and $\gamma=74°$ which corresponds to an axial repeat of about 720 Å (ref. 17).

The relationship between projections in these models of the different filaments is shown in Fig. 1. In VSmM it is very probable (J. V. Small, and J. M. Squire, in preparation) that each lattice point in Fig. 1*a* is associated with the origin of the heavy meromyosin portion of one myosin molecule. In biochemical estimates of myosin content for VStM[20] it seems that there may be two myosin molecules associated with each lattice point (see ref. 8, page 418). In insect flight muscle the estimates of myosin content suggest that there are either two molecules per lattice point which seems to agree with Reedy's observations of transverse sections of insect muscle in the electron microscope[11] or there are three molecules per lattice point[21].

It is known that the myosin molecules extracted from different muscles, although different in some respects, have basically the same form[12] and approximately the same molecular weight[5,22]. They consist of a two-chain α-helical rope in the rod portion of the molecule which is linked at one end to a globular unit (the myosin head)[20,23,24] comprising two large globular subunits[12] which may be associated with several light chains[25,26]. One might ask why these similar molecules pack together in such different ways in different muscles. On the other hand, one might consider whether there are alternatives to the existing models[8,11,27,28,30] for the structures of these filaments which will satisfactorily account for the published experimental data and in which the packing of myosin molecules is basically the same in all types of myosin-containing filament. This communication represents the first step in the exploration of such an idea.

Clues to Basic Myosin Filament Structure

I have quoted results from the analysis of the structure of the myosin-containing ribbons in VSmM[9,17]. The ribbons and their cross-bridges have been visualized directly by electron microscopy. Optical diffraction analysis of micrographs of thin longitudinal sections in which the planes of the ribbon and the section were parallel has given direct information about the cross-bridge lattice on the faces of the ribbons (ref. 17 and J. V. Small, and J. M. Squire, in preparation). Fig. 1*a* shows the form of this lattice. We can therefore start with this evidence and use it to help to deduce alternative structures for the other myosin-containing filaments.

---

[*] Present address: Biophysics Department, King's College, 26–29 Drury Lane, London WC2.

[†] The notation m/n helix has been used throughout to denote a helix which repeats after n turns in which there are m residues.

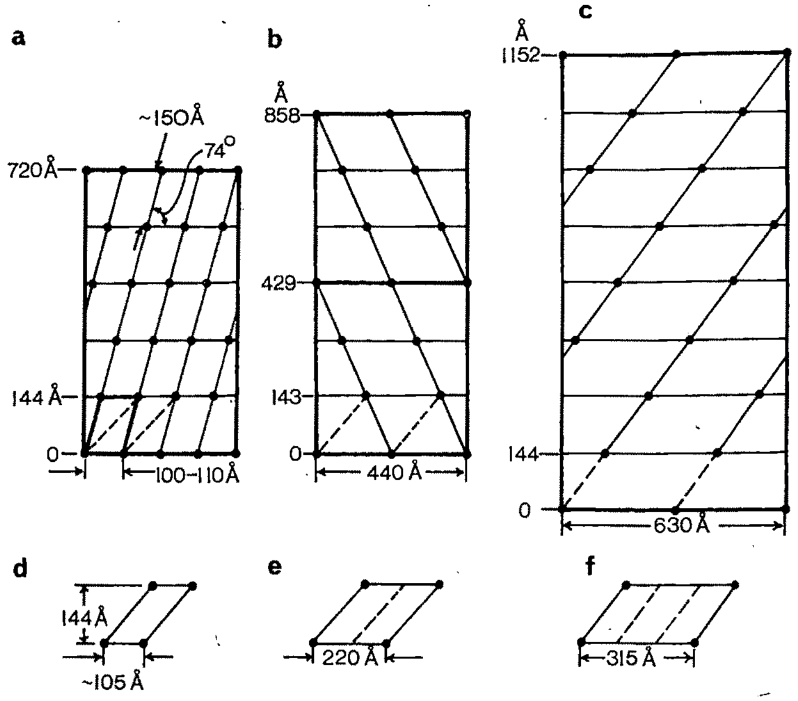

Fig. 1 *a*, The probable lattice of cross-bridges on each face of the myosin ribbons of vertebrate smooth muscle (ref. 17 and J. V. Small, and J. M. Squire, in preparation). *b*, Radial projection of the cross-bridge lattice in the model of the myosin filaments in vertebrate striated muscle proposed by Huxley and Brown[8]. *c*, Radial projection of the model for the cross-bridge lattice on the thick filaments of insect flight muscle proposed by Reedy[10]. *d*, *e* and *f* show repeating units in *a*, *b* and *c* respectively and demonstrate how these units are related.

First of all, if we take two of the repeating units (Fig. 1*d*) on the ribbon lattice shown as a dashed line in Fig. 1*a* we generate a repeating unit similar to that in the two-strand 6/1 helix of VStM (Fig. 1*b* and *e*). It is thought that there are probably two molecules per lattice point in the VStM filaments on the basis of two-strand 6/1 helical symmetry[8]. This suggests that a four-strand 6/1 helical structure (Fig. 2) with one molecule per lattice point (as for the ribbons) might be a possible alternative arrangement to the two-strand 6/1 helix. Such a four-strand 6/1 helix would generate the observed repeat of 429 Å, it would have a residue repeat of 143 Å giving the observed meridional X-ray reflexion and in projection at right angles to the filament axis (that is, the view obtained in longitudinal section of muscle[29]) it would appear almost identical to the same projection of a two-strand 6/1 helix. The only difference in the X-ray diffraction pattern would be that the intensity distribution on layer lines other than the third, sixth, and so on would relate to J_4 and higher order Bessel functions but not to J_2 Bessel functions as for the two-strand 6/1 helix. Using the intensity profile on the first layer line given by Huxley and Brown[8] it is possible to estimate (without attempting to fit this curve exactly) that a J_4 Bessel function in this region would relate to a helix of radius about 160–170 Å. These layer lines arise solely from the arrangement of cross-bridges on the myosin filament[8] and most of the mass of the cross-bridges is located in the heavy meromyosin regions which form the bridges. It is therefore not unreasonable that most of the diffracted intensity on first and second layer lines should relate to a radius of 160–170 Å which lies between the surface of the filament backbone (radius about 70 Å) and the surface of the actin filaments (approximate radius 200 Å)[8]. In this case it would seem that the myosin heads are quite close to the neighbouring actin filaments. It will be shown elsewhere that the proposed model can account for the observed exchange of mass from myosin to actin when a relaxed muscle goes into rigor[13]. It is therefore possible that the four-strand 6/1 helix is a satisfactory alternative model for the myosin filament in VStM.

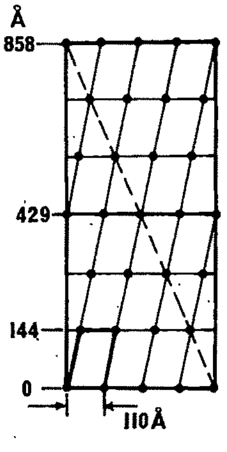

Fig. 2 Possible alternative model for the cross-bridge lattice on the thick filaments of vertebrate striated muscle in radial projection. The bold line outlines a repeating unit similar to that of the lattice in Fig. 1*a*. The dashed line represents one of the four 6/1 helical strands.

Next we can consider the structure of the myosin-containing filaments in insect flight muscle. This time Fig. 1 shows that three repeating units of the ribbon lattice (*d*) would give a repeating unit rather like that on the proposed two-strand 16/3 helical model for these filaments (*f*). If we take the estimate of myosin content[21] which gives three molecules per lattice point on this model (and not two), then an alternative model with the same helical symmetry but with six molecules equally spaced around the myosin filament on one level seems possible. This would generate a six-strand 16/3 helix (Fig. 3) with a long repeat of about 1150 Å. The experimental evidence from which the original model was deduced was from X-ray diffraction work[16] and electron microscopy[10,11,16]. The electron micrographs of longitudinal sections of insect flight muscle were analysed by optical diffraction and reflexions which were orders of a repeat of 1150 Å were observed. From the X-ray diffraction results it was deduced that the residue repeat of the cross-bridge lattice on the myosin filaments is about 144 Å. These results taken together led Reedy to propose the two-strand 16/3 helical model for the myosin filaments. The alternative six-strand 16/3 helix also has a repeat of 1150 Å and a residue of 144 Å and would equally well account for these results.

The other experimental evidence which needs to be explained is the appearance of "flared-X" configurations of the projections in Reedy's very elegant electron microscope work on serial

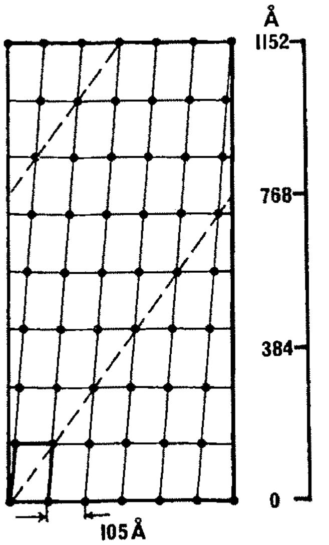

Fig. 3 A possible model for the thick filaments in insect flight muscle; radial projection of units arranged on a six-strand 16/3 helix of repeat 1152 Å. The dashed lines follow one and a half turns of the 16/3 helix.

thin transverse sections of glycerinated insect flight muscle[11]. These seem to show that there are at most only four cross-bridges with origins within one repeat of 146 Å along the myosin filaments. But Reedy states[10] that the "flared-X" configurations cannot be convincingly demonstrated in sections of relaxed insect flight muscle where presumably the myosin heads are not necessarily cross-linked to actin filaments. It is therefore possible that cross-bridges are only visible in Reedy's micrographs if they were cross-linked to actin before fixation. In this case the proposed six-stranded model would require that even in a rigor muscle (in which it is commonly assumed that all the cross-bridges are attached to actin) only four out of six of the cross-bridges on one level are cross-linked. These would then form the flared-X configurations seen in Reedy's micrograph and the remaining cross-bridges would not be preserved and visualized. Evidence for this will be given elsewhere (J. M. Squire, in preparation). It is therefore possible that a model for the myosin filaments in insect muscle in which there are six cross-bridge origins on one level may adequately account for the existing experimental data on the structure of these filaments.

Implications of Alternative Models

I have now arrived at the situation where the structure of the myosin-containing filaments in VSmM, VStM and IFM might be explained in terms of models with basically the same distribution of myosin heads on the surfaces of the filaments. If it is assumed that the myosin molecules pack together with about 1000 Å of the rod portion of the molecules associated with the backbone of the filaments (the remainder forming the cross-bridges) and also that the myosin rods are close packed in the backbone with a separation of about 20 Å, then the suggested arrangements of projections would require the rod portions to pack into a surface layer of myosin molecules of thickness about 30–40 Å. This may of course vary for cylindrical filaments of different total diameter and will be slightly larger for the smallest filaments. Taking reasonable values (which can only be approximate) for the dimensions of the backbones of the filaments being considered (about 140 Å diameter in VStM[8,30], about 200 Å diameter in IFM[10,11] and the thickness of myosin ribbons in VSmM about 145 Å (ref. 17 and J. V. Small, and J. M. Squire, in preparation)) then the filament profiles drawn in Fig. 4 are obtained. An approximation has been made here in that differences in filament structure in the bare zones and tapered ends of the cylindrical filaments have been neglected. The diameters given do not relate to the bare zone but to the regions on the filaments from which most of the cross-bridges originate. In these regions the filaments would all consist of a core of protein other than myosin surrounded by a layer of myosin of thickness 30–40 Å. The observations of "hollow" filaments (or at least filaments which have a central core with different staining properties from the periphery) in muscle cross-sections are quite numerous[16,31] and favour this sort of model. Szent-Györgyi *et al.*[32] have also suggested that there may be a constant surface area per cross-bridge (and therefore a constant thickness of myosin) on the surfaces of the paramyosin filaments of different molluscan muscles. This is discussed in the next section.

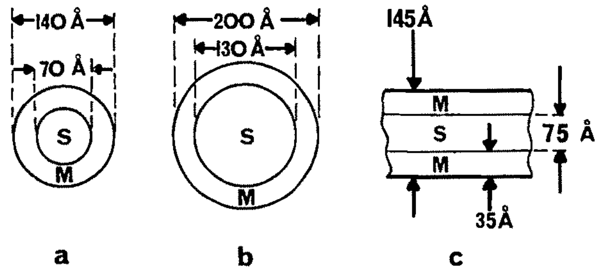

Fig. 4 Profiles of different myosin-containing filaments assuming the myosin rods are confined to a layer of thickness 35 Å on the surface of the filaments. *a*, Vertebrate striated muscle filaments; *b*, insect flight muscle filaments; *c*, ribbons in vertebrate smooth muscle. The myosin projections do not form part of this layer.

If we now consider just those filaments which are cylindrical in shape we can calculate approximately the percentage volume of the filament backbone which will be taken up by the core in filaments of different diameter if the myosin is all in a surface layer of thickness, say, 35 Å, and it is assumed that 60% of the mass of myosin molecules is in the projections and does not form part of the filament backbone. Fig. 5 shows this percentage volume (V_c) plotted as a function of the diameter of the backbones of the filaments. The two points which would correspond to the models illustrated in Fig. 4 for VStM and IFM are shown on this graph together with points related to other models for these filaments.

Paramyosin-containing Filaments

If the ideas mentioned above have any basis in reality, then the paramyosin-containing filaments in molluscan muscles should have the same sort of structure with a 35 Å layer of myosin muscles surrounding an inner core of paramyosin. In this case we are in the fortunate position of having experimentally determined values for the proportions of paramyosin (P) and myosin (M) in particular muscles. We can therefore plot several points on Fig. 5 which correspond to experimental results for filaments of widely varying diameter. Recent estimates of the ratio P : M by weight in different muscles are 25% : 75% in *Pecten* striated adductor muscle (private communication of preliminary results by P. M. D. Hardwicke, and J. Hanson); 50% : 50% in *Venus mercenaria* white adductor muscle[32], 33% : 67% in the translucent adductor muscle of *Crassostrea virginica*[32] and finally in *Crassostrea* opaque adductor muscles 57% : 43%[32] or 75% : 25% (private com-

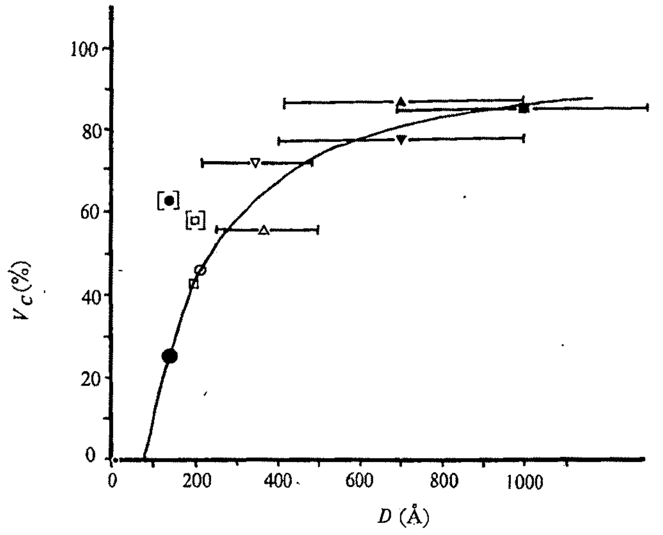

Fig. 5 The bold line represents a plot of the volume of the core (V_c) expressed as a percentage of the total volume of cylindrical myosin-containing filaments of different diameter (D), assuming that there is a layer of myosin of thickness 35 Å on the surfaces of these filaments, and that 60% of the mass of the myosin molecules is in the cross-bridges and does not form part of the backbone. ● and □ represent the appropriate points for filaments in VStM and IFM on the basis of the models shown in Figs. 2 and 3 respectively. The same symbols in brackets refer to existing models[8,10] for the myosin filaments in the muscles. The remaining points represent experimental results obtained from the relative amounts of paramyosin and myosin in different molluscan muscles. Error bars on these points represent the standard deviation of the filament diameters about the mean assuming the sort of distribution of filament diameters observed in *Crassostrea* opaque adductor muscle[34]. ○, *Pecten* striated (P. M. D. Hardwicke, and J. Hanson, personal communication); ▽, *Venus* red[32]; ■, *Venus* white[32]; △ *Crassostrea* translucent[32]; ▼, *Crassostrea* opaque[32]; ▲, *Crassostrea* opaque adductor muscles (P. M. D. Hardwicke, and J. Hanson, personal communication).

munication from P. M. D. Hardwicke, and J. Hanson). In *Pecten* the paramyosin filaments have a diameter of about 200 Å to 250 Å (except in the bare zone). In the other muscles the paramyosin filaments can have a variety of diameters. Published estimates of the range of diameters (which also include the effects of the tapering of the filaments) are as follows: 200 Å to 500 Å in *Venus* red muscle[33], 500 Å to 1500 Å in *Venus* white muscle[15], 150 Å to 600 Å in *Crassostrea* translucent muscle[15] and 200 Å to 1500 Å with a peak of the distribution at about 700 Å (standard deviation 300 Å) in *Crassostrea* opaque adductor muscles[34]. Although these sizes cannot be taken too literally it is probable that "average" values of the diameter will reflect the relative filament sizes in the different muscles. Fig. 5 shows how the experimental figures relate to the model and demonstrates that in each case there is sufficient paramyosin to fill the core of the different filaments.

Although there is obviously considerable uncertainty in the results, we can conclude from the general agreement between the theoretical curve and the plotted points that, at least, the model is consistent with the available data. This serves to emphasize one point made in Szent-Györgyi *et al.*[32] that the surface area per myosin head is probably a constant feature of all paramyosin-containing filaments. As in the other filaments this area would be about 144 Å × 100–110 Å = 15,000 Å^2.

On this basis one can suggest possible packing arrangements for the myosin heads on the surfaces of different paramyosin-containing filaments. The paramyosin in these filaments is known to pack to give a surface appearance[35] well known as the Bear–Selby net (Fig. 6*a*). The axial repeat of the net is always about 720 Å but the "a" spacing varies greatly in filaments from different muscle types and also with the diameter of the filaments within one muscle type[7]. Fig. 6 shows the Bear–Selby nets of filaments in four different molluscan muscles (for details see caption) and illustrates how these nets can be subdivided very simply (assuming all the lattice points in the Bear–Selby net are equivalent) to give repeating units of area about 15,000 Å^2. The mean "a" spacings are obtained mostly from X-ray diffraction results[36] and are assumed to be similar to the "a" spacings on the surface of the paramyosin core of the filaments[7]. It is therefore quite possible that the lattices drawn in Fig. 6 represent the packing distribution of myosin on these filaments. It should be noted, however, that in VSmM evidence has been obtained that the filament backbone and the cross-bridge lattice on the myosin ribbons do not have the same axial repeat (J. V. Small, and J. M. Squire, in preparation). In spite of this the present model would require that the myosin molecules pack with a side-spacing of about 100 Å. Evidence in support of this is shown in Fig. 7 where a micrograph of a paramyosin filament ("a" spacing, 630 Å) from the anterior-byssus retractor muscle (ABRM) of *Mytilus* is shown by self-convolution[37] to exhibit a lateral repeat of about one fifth of the "a" spacing (that is, 120–130 Å) which is generated by a rectangular net of the sort drawn in Fig. 6*e*.

Discussion and Predictions

So far I have tried to show that it may be possible to interpret the existing experimental data on the form of the myosin-containing filaments in different muscles in terms of one basic structure. The details of this interpretation will be given later

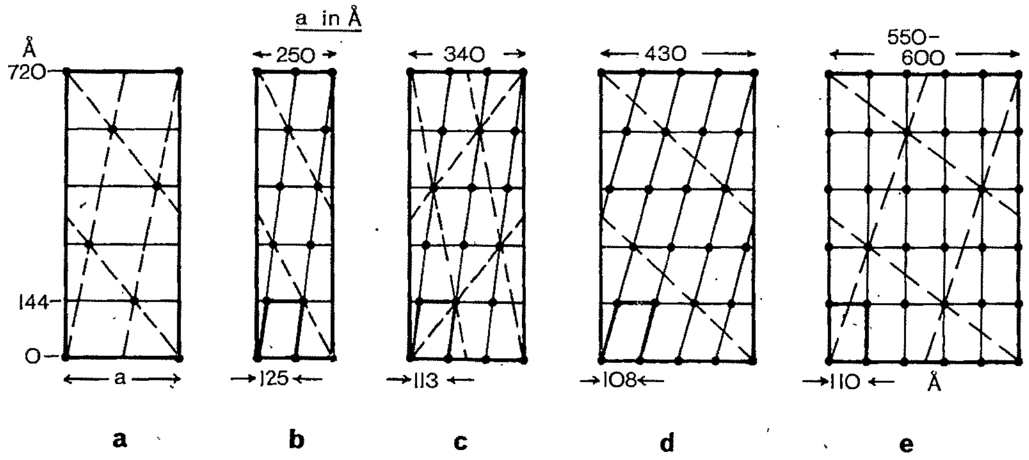

Fig. 6 *a*, The lattice (Bear–Selby net) on the surface of paramyosin filaments from which the myosin has been removed; *b–e* represent subdivisions of the Bear–Selby nets on the surfaces of paramyosin filaments in different molluscan muscles to give repeating units of area 15,000 Å^2. It has been assumed that lattice points in the Bear–Selby nets are all equivalent. *b*, *Venus* adductor muscle; *c*, *Crassostrea* adductor muscle; *d*, *Mytilus* adductor muscle; *e*, *Mytilus* ABRM.

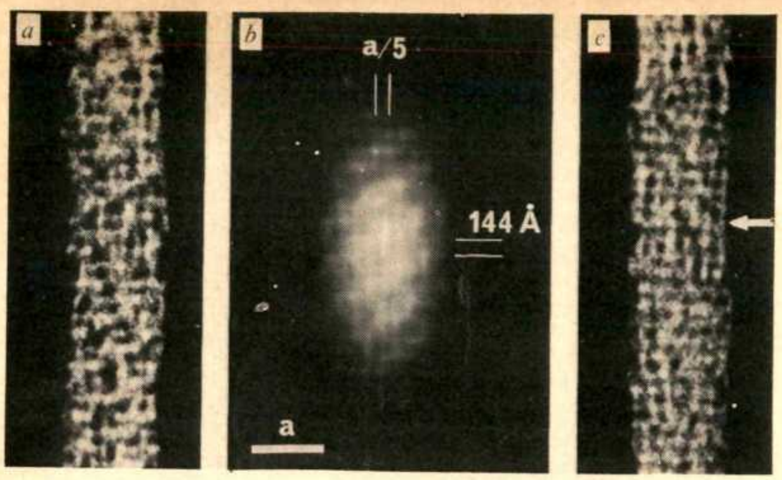

Fig. 7 *a*, Electron micrograph of part of a negatively stained paramyosin filament (courtesy of Professor J. Lowy) from *Mytilus* ABRM; *b*, self-convolution function of part of the filament in *a* which shows that "a" spacing of the Bear–Selby net on this filament is clearly divided into five sub-periods; *c*, another region of the same filament as *a* showing a regular near-rectangular arrangement of subunits (compare Fig. 6*e*).

(manuscript in preparation) but I would like to list some of the predictions from this idea which can be tested experimentally. The following predictions assume that all the myosin filaments contain a core protein and are not hollow. The numerical values given obviously depend critically on the exact values taken for the filament diameters (which are only known approximately) and may need to be modified when even more accurate values are available. (i) All myosin-containing filaments of the same backbone diameter will have approximately the same proportion of myosin to core protein by volume and also by weight if the core proteins have the same density. (ii) In general the cores of myosin-containing filaments will have a diameter (or thickness) equal to the total diameter (or thickness) of the filaments less about 70 Å. (iii) In particular the core of the myosin-containing filaments in VStM would have a diameter of about 70 Å and would contain about 10–15% by weight of the total mass of the filaments. This assumes that the density of the core protein is the same as that of the myosin rods and that the projections contain 60% of the mass of the myosin molecules. A model with two molecules per 144 Å repeat would have about 40% of the filament mass in proteins other than myosin. (iv) In insect flight muscle approximately 20–25% of the mass of the myosin filament would be in the core (using the same assumptions) and the diameter of the core would be about 130 Å. Reedy's model with four myosin heads per 146 Å repeat would have about 40–45% of the filament mass in the form of proteins other than myosin. (v) In VSmM the ribbons which have a core of thickness about 75 Å (J. V. Small, and J. M. Squire, in preparation) would have a total ribbon thickness of about 145 Å and the core would account for approximately 25–30% of the total mass of the ribbons. (vi) The structure of the myosin layer will be different in the regions of cylindrical filaments corresponding to the bare zone. On the basis of the type of molecular packing scheme proposed by Huxley[20] in which myosin molecules pack antiparallel in the bare zone, the type of packing scheme proposed recently[38] from studies of myosin assembly may well occur if modified to fit the filament lattice described here. The thickness (35 Å) of the layer of myosin rods in regions other than the bare zone is that required to close pack the rod portions of about two or three molecules, and it is possible to generate very simple packing arrangements for the myosin rods in these layers which will produce the required surface lattices. Details of these will be given elsewhere. The lattices which have been drawn in Figs. 1*a*, 2, 3 and 6 are not all identical, but the very small differences in packing which would change one lattice to another are attributable to the small differences in chemical composition of the rod portions of the different myosin molecules involved. It is also possible that the packing of the core protein(s) affects the precise ordering of the myosin molecules on the surfaces of the filaments. (vii) One further implication of the model is that the core protein(s) and not the myosin in a filament will determine the precise shape and size of that filament. On this basis the vernier length-determining mechanism proposed by Huxley and Brown[8] would require the presence of at least two core proteins in the thick filaments of VStM and IFM.

Many experiments come to mind which would test the ideas presented here. The extraction and identification of core proteins, together with an estimation of their quantity, is one obvious type of experiment. Electron microscopy could be used to analyse further the cross-bridge arrangements on the myosin-containing filaments of different striated muscles. If it turns out that there is a structure common to all myosin-containing filaments it will be an open question whether or not there is any relationship between that structure and the function of the different muscles in which the filaments occur. One might suggest that the overall shape and size of the filament affect the speed and function of the different muscles but that the precise cross-bridge lattice does not. It would still remain to be answered whether this form of lattice would be critical for an efficient acto-myosin interaction during contraction of a muscle and therefore for an efficient sliding filament mechanism.

I thank Professor J. Lowy for permission to use the micrograph shown in Fig. 7 and him, Professor J. Hanson, Dr J. Haselgrove, Dr J. V. Small and Dr P. J. Vibert for comments on the text.

Cordilleran Tectonic Transitions and Motion of the North American Plate

PETER J. CONEY

Department of Geology, Middlebury College, Middlebury, Vermont

This article examines the relationship between tectonic events in western North America and in the North Atlantic Ocean.

I WISH to propose that there is a correlation between the timing of principal tectonic events in western North America since late Jurassic time and submarine data from the North Atlantic Ocean. The correlation is particularly striking if inferences about relative plate motions from Atlantic magnetics[1] are combined with inferences about absolute plate motions[2-4].

An analysis of the timing of tectonic events in western North America since late Jurassic suggests that important periods of tectonic reorganization (tectonic transitions) took place at about 80 m.y. BP and at about 40 m.y. BP. The data strongly indicate that the tectonic transitions were felt from Alaska to northwestern South America and that they represent fundamental turning points in the tectonic evolution of the Cordillera. The tectonic transitions are best described as boundaries of duration about 5 to 10 m.y. which separate longer periods of up to 60 m.y. The transition periods mark reorganizations of tectonic behaviour, whereas the longer periods separated by transitions are more internally consistent.

The 80 m.y. Transition

The principal significance of the 80 m.y. transition is that it marks the boundary in time and space between classic Laramide orogeny[5] and Nevadian–Sevier orogeny[6]. The transition extends, however, from Alaska to northern South America, far from type areas in the western United States.

Features associated with the transition include the end of major plutonism in the Sierra Nevada of California[7] and the termination of Franciscan deposition[8,9]. In southern California an important unconformity at the base of the Asuncion Formation at about 80 m.y. places a roof on major metamorphism and plutonism[10,11]. In southern Alaska, plutonism was initiated near 80 m.y. after a pause of more than 50 m.y. (ref. 12), and deformation of the slate–greywacke belt in the Kodiak–Kenai–Chugach mountains around the Gulf of Alaska began[13-15]. There is some evidence from northwestern Canada that right strike-slip on the Tintina fault diminished after 80 m.y. (ref. 16), but through going right strike-slip on the Chatham fault in southeastern Alaska may have started about this time[17]. In the Canadian Cordillera the transition marks the boundary in space and time between late Jurassic to early upper Cretaceous Columbian orogeny[18] and Laramide orogeny[18]. There is a low in the frequency of radiometric age determinations from western Canada at about 80 m.y. just before a compound peak extending to 40 m.y. (ref. 19), and there is a marked increase in amount of detritus shed from the Cordillera eastward over the plains from about 80 m.y. to late Palaeocene[20]. Most deformation to the west of the Sevier orogenic belt of eastern Nevada and western Utah, and within this belt, ceased at about this time[6] whereas Laramide orogeny[21,22], accompanied by a distinct increase in plutonism, broke across the Cordilleran foreland soon afterwards. From the southwestern United States to southern Mexico, widespread carbonate shelf conditions in the Mexican geosyncline terminated near 80 m.y. and were followed by detrital wedges, plutonism, and major compressive deformation[23,24]. In the Greater Antilles, arc volcanism, plutonism, emplacement of ultramafics and compressive deformation seem to be bracketed by Turonian (about 85 m.y.) and upper Eocene (about 40 m.y.)[25-28]. Deformation and metamorphism in the Venezuelan Coast Ranges ceased in late Cretaceous time and were replaced by a distinctly different tectonic behaviour involving considerable oblique right strike-slip and related thrusting[29].

Widespread deformation and plutonism initiated or intensified near 80 m.y. in the northwestern Andes of South America[30,31].

Transition at 40 m.y.

The principal significance of the 40 m.y. transition is that it marks the end of Laramide compressive deformation in the western United States[32]; the transition can, however, be tracked from northwestern Canada south to the Isthmus of Tehuantepec in southern Mexico, and in the Greater Antilles. In Western Canada, with the exception of the Cascade–southeastern British Columbia region, plutonism and volcanism also almost cease at 40 m.y. (ref. 19), and in the western United States there is a pause in igneous activity[33]. After this pause there was a widespread increase of ignimbrite eruption in the Rocky Mountains and Great Basin[33,34]. In the Greater Antilles, plutonism, volcanism, emplacement of ultramafics, and compressive deformation apparently finished near 40 m.y., but the Lesser Antilles appear to have initiated activity at about this time[25]. Even in California, compressive deformation involving thrusting of Great Valley rocks over Franciscan rocks appears to have ceased near late Eocene time[35].

Several regions are not noticeably affected by the 40 m.y. transition. Southern Alaska, west of the Fairweather fault system, seems to have experienced plutonism from about 80 m.y. to 15 m.y., and compressive deformation from about 80 m.y. to 35 m.y., then again from about 20 m.y. to the present[15]. The northwestern Andes are not strongly effected by the 40 m.y. transition, and tectonism and plutonism, which accelerated after 80 m.y., have continued intermittently to the present[30,31]. Tectonics from Alaska to South America after 40 m.y. has been very variable from region to region, but the timing of volcanism, plutonism, compressive deformation, rifting, and strike-slip faulting fits well with predictions from submarine magnetics in the northeastern Pacific Ocean[36]. A mid-Tertiary tectonic transition, reported to have taken place between about 30 and 9 m.y. from region to region around the Pacific margin[37], is characterized by renewal of strike-slip and related compressive deformation on the San Andreas fault of California, block faulting in the Great Basin, volcanism and plutonism in the Aleutians, southern Alaska, the Cascades, and in Mexico and Central America[36,38–41].

Transitions and Plate Motion

The fact that both the 80 and 40 m.y. tectonic transitions cut through the whole array of data for western North America strongly suggests that these important turning points in Cordilleran tectonic evolution are the result of fundamental reorganizations in plate motions.

Changes in relative plate motions in the northeastern Pacific are indicated at about 55 m.y. and 7 m.y. by departures from parallelism of adjacent magnetic anomalies at these times[42]. Atwater[36,43] has also suggested that changes in plate motions took place at about 80 m.y. and about 15 m.y. as well. There is apparently nothing in the geometry of magnetic stripes in the northeastern Pacific Ocean which would suggest that anything unusual, such as the end of the Laramide orogeny and related deformation, occurred between, say, 50 and 40 m.y. on the adjacent North American continent. This suggests that we are looking in the wrong ocean.

Turning to the North Atlantic for relative motions of the North America plate, Pitman and Talwani[1] suggest that changes in relative plate motion occurred at about 80, 63, 53, 38, and 9 m.y. (their work was based on the analysis of magnetic anomalies). Although spreading between North America and Africa may have started after 180 m.y. and continued to the present, it is important to realize that spreading between North America and Eurasia apparently commenced at about 80 m.y. This is suggested by the fact that north of the Azores, the oldest anomalies and extrapolated time lines adjacent to present continental shelves are 80 m.y. old or less. This would suggest that spreading broke into the North Atlantic north of the Azores at about 80 m.y. and that spreading subsequently moved into the Arctic, thus separating the two continents. A major reorganization of plates at about 80 m.y. is indicated. Also, Pitman and Talwani[1] suggest that spreading between North America and Europe almost ceased between 38 and 9 m.y. The evidence for this is the close proximity of anomalies 15 (38 m.y.) and 5 (9 m.y.). From the analysis of sea-floor spreading in the North Atlantic, the 80 and 40 m.y. time lines seem important because the start of spreading between North America and Europe at 80 m.y. and its almost complete termination near 40 m.y. bracket the Laramide orogeny and related deformation in western North America. This suggests that both the 80 m.y. and 40 m.y. tectonic transitions, and the tectonic responses in the western Cordillera before, between, and after these transitions, were strongly influenced by motions of the North America plate; these were reflected in the relative spreading history recorded on the floor of the North Atlantic.

Absolute Plate Motion

If the proposal mentioned previously is valid, there is a strong incentive to determine absolute motions of the North America plate during the past 180 m.y. The only hypothesis which would permit analysis of absolute motion is that of Morgan[2–4] who has resurrected a long dormant notion of Wilson[44] that aseismic ridges and seamount chains on the ocean floors are generated by plate motion over mantle "hot spots" and mark dead reckoning tracks of absolute plate motion. A similar idea has been used by Dietz and Holden[45]. Seamount chains in the North Atlantic are of particular concern because they might provide a fix on the trajectory of the North America plate. The principal seamount chain west of the Mid-Atlantic ridge is the New England (or Kelvin) chain which extends from off Cape Cod in a southeasterly direction towards the Corner Rise near 34° N, 51° W. The only "hot spot", or convection plume[2–4], apparently capable of generating the New England–Corner Rise chain is the Azores[3]. Dating of the time of formation of the New England–Corner Rise chain would perhaps give the direction of absolute motion of North America during that time.

The White Mountain magma series of New England is a complex of granitic intrusions, rink dikes, calderas and volcanics which apparently initiated activity about 180 m.y. ago[46]. The complex cannot be related to subduction at a continental margin and seems to have more to do with the opening of the Atlantic Ocean[47]. Morgan[3] has suggested that the New England seamount chain might anchor on the White Mountain magma series and that both may have been produced by the Azores "hot spot". This suggests that the seamount chain was generated by a northwesterly motion of the North America plate over the Azores "hot spot" as the plate moved away from a proto-Atlantic ridge after 180 m.y. BP. The age of the southeast end of the chain near the Corner Rise is apparently 80 m.y. old or less, because anomaly 32 is close by[1] and drilling at Joides Site 10 (ref. 48) was into Campanian sediments just south of the southeast end of the chain. Because the Azores lie northeast of the Corner Rise, motion of the North America plate must have abruptly changed from northwesterly to southwesterly after the "hot spot" constructed the Corner Rise at or after 80 m.y. The change in plate motions suggested by initiation of spreading between North America and Europe at about 80 m.y. may correspond to the "elbow" at the Corner Rise. No clear seamount chain extends from the Corner Rise to the Azores, but the Corner Rise heads in that direction. Continuity may have been broken by proximity of the "hot spot" to the spreading ridge axis and associated transform faults[44]. Relative motion data[1] suggest that North America presumably drove southwesterly to south-southwesterly after 80 m.y., then slowed down between 40 m.y. and 9 m.y. Thus the northwesterly rotation between 180 and 80 m.y. brackets Nevadian–Sevier–Columbian orogeny, and the southwesterly rotation between 80 and 400 m.y. brackets the Laramide orogeny.

Conclusions

I propose that after the North America plate broke away from the Africa plate between 180 and 150 m.y. it migrated northwesterly over the Azores "hot spot" until about 80 m.y. (Fig. 1*a*). During this time the leading edge of North America failed over an overridden and entrained Benioff zone producing the Nevadian–Sevier–Columbian orogeny. A mid to late Jurassic age for initiation of actual separation[49] would fit well with the initiation of detrital wedges shed eastward from the Cordillera starting in upper Jurassic time[6,20]. It seems likely that this northwesterly rotation drove the Alaska–Kolyma[50] arm of the North America plate into the trailing edge of Eurasia in upper Jurassic to lower Cretaceous time[51] to produce the Verhoyansk Mountains and several intraplate adjustments in Alaska. Some transform rifting between North America and Eurasia in the Arctic is indicated. Once North America and Eurasia had locked and the Alaska–Kolyma peninsula between them had consolidated, North America began separating from Eurasia north of the Azores at about 80 m.y. and rotated southwesterly about a pole near northeastern Alaska. As spreading later broke into the Arctic, the rotation became more complex and eventually reached its present position at the head of rifting in Siberia. The change

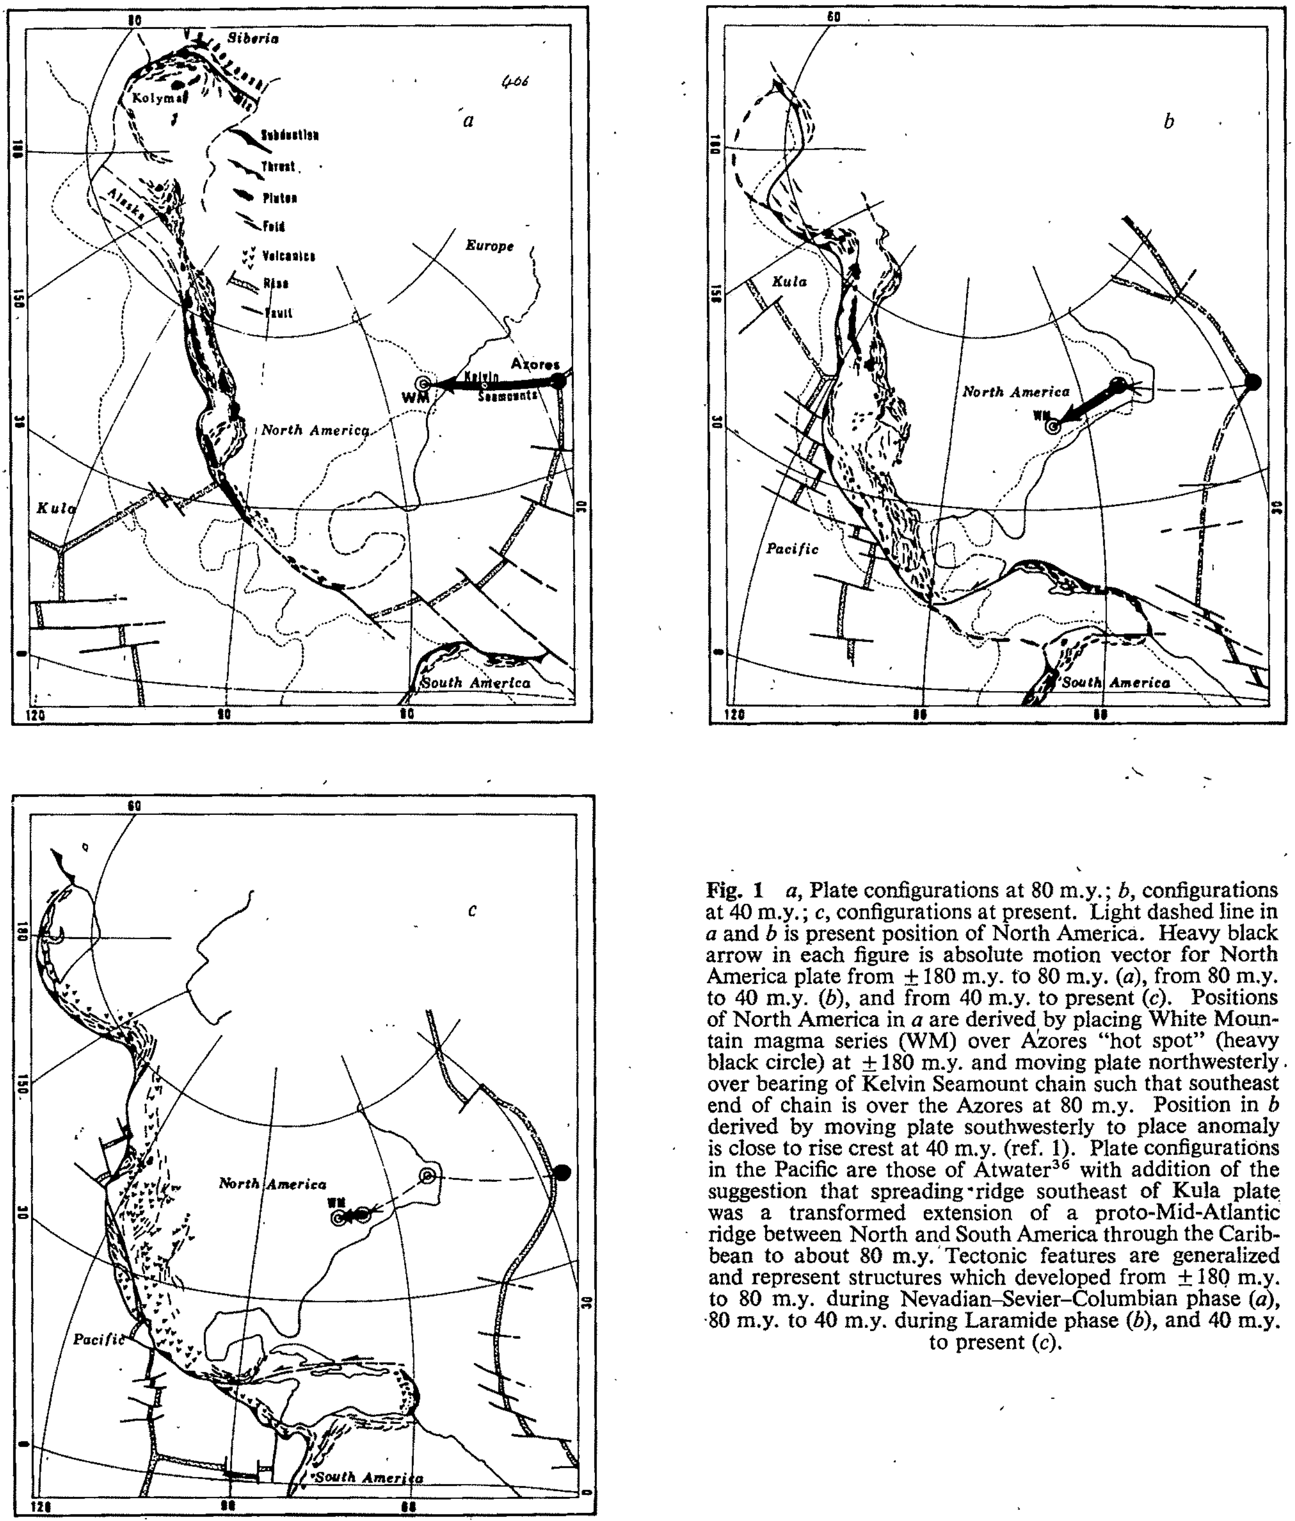

Fig. 1 *a*, Plate configurations at 80 m.y.; *b*, configurations at 40 m.y.; *c*, configurations at present. Light dashed line in *a* and *b* is present position of North America. Heavy black arrow in each figure is absolute motion vector for North America plate from ±180 m.y. to 80 m.y. (*a*), from 80 m.y. to 40 m.y. (*b*), and from 40 m.y. to present (*c*). Positions of North America in *a* are derived by placing White Mountain magma series (WM) over Azores "hot spot" (heavy black circle) at ±180 m.y. and moving plate northwesterly over bearing of Kelvin Seamount chain such that southeast end of chain is over the Azores at 80 m.y. Position in *b* derived by moving plate southwesterly to place anomaly is close to rise crest at 40 m.y. (ref. 1). Plate configurations in the Pacific are those of Atwater[36] with addition of the suggestion that spreading ridge southeast of Kula plate was a transformed extension of a proto-Mid-Atlantic ridge between North and South America through the Caribbean to about 80 m.y. Tectonic features are generalized and represent structures which developed from ±180 m.y. to 80 m.y. during Nevadian–Sevier–Columbian phase (*a*), 80 m.y. to 40 m.y. during Laramide phase (*b*), and 40 m.y. to present (*c*).

in motion at about 80 m.y. apparently caused the 80 m.y. transition, and the new southwesterly motion from 80 to 40 m.y. initiated widespread failure of the Cordilleran foreland to produce the Laramide orogeny (Fig. 1*b*). A slowing of that motion after 40 m.y. ended that orogeny. I suggest that the 30° bend in the strike-slip faults of Alaska[52] can almost be eliminated by a rotation of the Corner Rise to the Azores about a pole in northeastern Alaska, thus explaining the Alaska orocline[15,52–54]. Other features, such as subduction of Atlantic lithosphere by the Greater Antilles between 80 and 40 m.y., are perhaps also explained by North America plate motion.

Since 40 m.y. (Fig. 1*c*) North America has moved in more of a southwest by west direction towards the East Pacific Rise; eventual contact with the rise off southern California in mid-Tertiary time[36] and possible changes in Pacific plate motions near 25 m.y. (ref. 41) explain much of the tectonic history after 40 m.y. Motion of North America and South America past an almost stationary Caribbean plate was probably slightly convergent and explains many features on the margins of the Caribbean such as oblique right strike-slip in northern Venezuela[29], compressive and left strike-slip deformation in Chiapas, Mexico and Guatemala[55,56], disruption of the Greater Antilles and Central America along the Bartlet–Motagua fault zones[57], volcanism in the Lesser Antilles and present seismicity[58].

The close correspondence of phases of major compressive deformation during Nevadian–Sevier–Columbian andLaramide Cordilleran tectogenesis with timing of North America plate motions suggests to me that compressive tectonics in western North America are the result of abortive west-directed efforts at subduction of continental lithosphere on the leading edge of an actively driving continental plate. This deformation was perhaps facilitated by softening of the plate margin (up to 1,000 km wide) by complex plutonic patterns associated with overridden, entrained and sometimes double[59] subduction zones. This suggests that active plate motion somehow transmits compressive stress through the plate and that Cordilleran tectonic styles such as those in the Rocky Mountain fold and thrust belt are due to massive westward cratonic underthrusting as visualized by Misch[60,61]. By contrast, it would appear that active driving and underthrusting of oceanic lithosphere are easily accomplished and little stress is transmitted across subduction zones from the subducting oceanic lithosphere to the upper plate much beyond the arc. If North America had remained fixed during Mesozoic and early Tertiary time the Cordilleran orogen would more likely have resembled present day western Pacific arcs and margins where active subduction-related tectonics occurs in relatively narrow belts compared with Cordilleran styles. Thus if an Andean–Cordilleran type orogen exists[62] it is confined to leading edges of actively driving continental plates, and one can conclude that several other combinations of absolute motions are capable of producing as many other orogenic types.

I am grateful to William R. Dickinson and Tanya Atwater for discussions. Norman Silberling, Ben Page, David Jones, George Plafker, Eli Silver, Warren Hamilton, Peter Lipman, Greg Davis, Trobe Grose, Peter Misch, and J. O. Wheller were also most helpful. Manik Talwani kindly provided a preprint of work in the North Atlantic, and Eli Silver a preprint of work on the Hawaii–Emperor seamount chain. I would finally thank Jason Morgan for a lecture and discussion at Stanford University and a preprint which provided the framework for consideration of possible absolute motions.

New Point γ-ray Source Lib γ-1: Evidence for Time Variation and Possible Identification with PKS 1514-24

DURING the past 2 yr evidence has been presented for the existence of four point sources of high energy γ-radiation ($E_\gamma > 50$ MeV). Three were found by the Case-Melbourne (C-M) collaboration using high altitude balloon flights from Australia (Fig. 1) and two of these sources, Gγ 2+3 and Gγ 341+1, coincided closely with known high energy X-ray sources[1,2]. A group from the Moscow Physical Engineering Institute detected a source with a counter telescope on Cosmos 251[3]. Three aspects of the Russian source are particularly noteworthy: (1) the source position, $54° < \alpha < 75°$, $+4° < \delta < +9°$, contains the unusual Seyfert galaxy 3C 120[4] which varies at both radio[5,6] and optical[7] frequencies; (2) the γ-ray flux is $F_\gamma = 5 \times 10^{-4}$ γs cm^{-2} s^{-1} ($E_\gamma > 100$ MeV), a factor of 30 greater than any of the C-M sources; and (3) most of the detected γ-ray flux must have been due to photons above 500 MeV, because inserted between the counters of the Cosmos counter telescope were 3.7 radiation lengths of lead in which multiple scattering and energy loss greatly reduce the efficiency between 100 and 500 MeV. The Russian group's claim for time variability of 3C 120 as a γ-ray source, because it was not observed on earlier surveys, is not valid. The surveys in this energy range which were cited (refs. 8 and 9) did not cover this region of the sky. The OSO-3 detector (ref. 10), which did cover this area, has a sensitivity to point sources which is about the same as the reported flux from 3C 120.

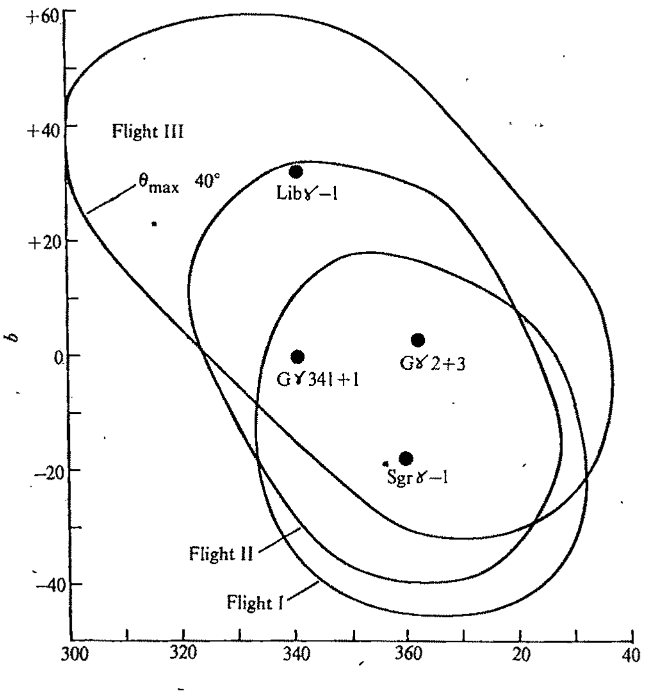

Fig. 1 Sky regions covered by the three flights. Boundaries are shown where the exposure is 50% and events are restricted to zenith angles $0 < 40°$. The black dots represent the positions of the four sources so far observed including the new source Lib γ-1 at $l = 340°$; $b = 30°$.

In this article we report a further point γ-ray source Libra γ-1 detected on the balloon flight of November 26, 1969, which was described earlier (flight III of ref. 2). The signal-to-noise ratio is 6σ for $E_\gamma > 100$ MeV, better than for any of the previous sources and furnishing further confirmation for the existence of this type of object. No excess was seen from this direction on an earlier flight, so for the first time we have direct experimental evidence for the time variation of a γ-ray source. The angular resolution circle in the direction of Lib γ-1 includes PKS 1514-24[11] which is also an optical variable[12,13].

The method of analysis is similar to that used previously[1,2] except that, after the approximate source position was ascertained from the search programme which had rectangular bins of $\Delta\alpha = 4°$, $\Delta \sin\delta = 0.08$, a series of concentric annular rings of equal area was drawn about the preliminary location of the source: $\alpha = 227°$, $\delta = -22°$. The radius of the first circle was 2.12° with an outer radius of 6° for the eighth annulus. The higher flux from Lib γ-1, combined with the reduced atmospheric background found at the 8.8 GeV geomagnetic cutoff for flight III, made this more detailed analysis possible. In Fig. 2 is shown the number of events for succeeding rings proceeding out from the source position. After the fourth ring, which has a radius of 4.2°, the intensity has decreased to the background level. The number of events for the energy groups—*a*, all energies (the effective threshold is 50 MeV); *b*, $E_\gamma > 100$ MeV; *c*, $E_\gamma > 500$ MeV—are listed in Table 1. For $E_\gamma > 100$ MeV there is an excess of 40 events above the 45 predicted from the background level, a 6.0σ result. The flux for $E_\gamma > 100$ MeV is $F_\gamma = (2.4 \pm 0.6) \times 10^{-5}$ γs cm^{-2} s^{-1}, greater than for Sgr γ-1, Gγ 2+3, or Gγ 341+1, but still a factor 20 less than for the Cosmos 251 source.

Our flight II (ref. 2) also had a good exposure to this region but, as can be seen in Fig. 2*d*, no evidence for Lib γ-1 was found on this flight, which was made on February 26, 1969. Thus only an upper limit can be set. With 95% confidence the flux is $F_{95} < 1.4 \times 10^{-5}$ γs cm^{-2} s^{-1}. The γ-ray flux increased by at least a factor of two over this nine month interval.

It is not surprising to find a time variation in the γ-ray flux from a localized object since a great variety of time variations is seen at lower frequencies. In particular high energy X-ray sources have appeared and disappeared between exposures and have also exhibited flare type of emission with a time scale of a few minutes[14]. We have examined our data to see if any variation occurred during the flight itself, but as is shown in Fig. 3, the number of events per half hour interval follows the expected response within the statistical accuracy.

Table 1 Number of Events detected in Different Energy Groups

Flight date and geomagnetic cutoff	Source	Energy groups	No. x in central area*	Background in equal area N*	D_x	P_x	Flux γs cm^{-2} s^{-1}
III Nov. 26–27, 1969 2224–0636 UT 8.8 GeV	Lib γ-1	All energy $E>$ 100 MeV $E>$ 500 MeV	121 85 25	75 45 14	6.4×10^{-7} 4×10^{-8} 5×10^{-3}	6.4×10^{-5} 4×10^{-6} 0.39	$2.8\pm0.8\times10^{-5}$ $2.4\pm0.6\times10^{-5}$ $0.7\pm0.4\times10^{-5}$
II Feb. 26–27, 1969 1815–0205 UT 4.5 GeV	Lib γ-1	$E>$ 100 MeV	60	66	0.82	1.0	95% upper limit 1.5×10^{-5}

D_x is probability of one distribution having number x or greater with mean N.

P_x is probability of one "central" area with number x occurring in an area 100 times the central area—that is, the area observed (assuming Poisson distribution).

* To nearest whole number.

Recently Bond[15] and Biraud[13] have pointed out that the radio source PKS 1514-24, identified as an E or N galaxy[11,16], coincides with the remarkable optically varying object AP Lib, which has been observed since 1935 to vary in magnitude between 14.5 and 16.4. A variation of 0.7 magnitude was observed in this source over one 5 h interval. In a systematic search for coincidences between irregular variable stars and radio sources Biraud added AP Lib and W Com to BL Lac and BW Tau which were already known. Our preliminary position for Lib γ-1 is $\alpha=227°\pm2°$, $\delta=-22°\pm2°$; 2.7° of arc from the optical and radio position of PKS 1514-24, $\alpha=228.7°$, $\delta=-24.2°$ and within our angular resolution circle.

It is remarkable that two of the three γ-ray sources which are not correlated with X-ray sources should coincide with two of the four objects listed by Biraud. An earlier γ-ray survey[9] covered BL Lac and W Com but they should be observed again for as long an exposure as possible in view of the time varying nature of Lib γ-1.

Shklovsky[17] has proposed a theory which explains the radio variations of 3C 120 and predicts surges of γ-rays from it and similar objects such as QSOs and Seyfert galaxies which show time variations at lower frequencies. The γ-rays are generated by bremsstrahlung from the fast electrons which produce the varying radiation at lower frequencies by synchrotron radiation. Shklovsky predicts the surges of γ-rays should last the order of several days or weeks and be separated by intervals the order of a year. Our observation is consistent with this time scale since we could detect no large variation over 6 h for Lib γ-1 but a definite variation over 9 months. If Shklovsky's theory is correct, γ-rays should be observed

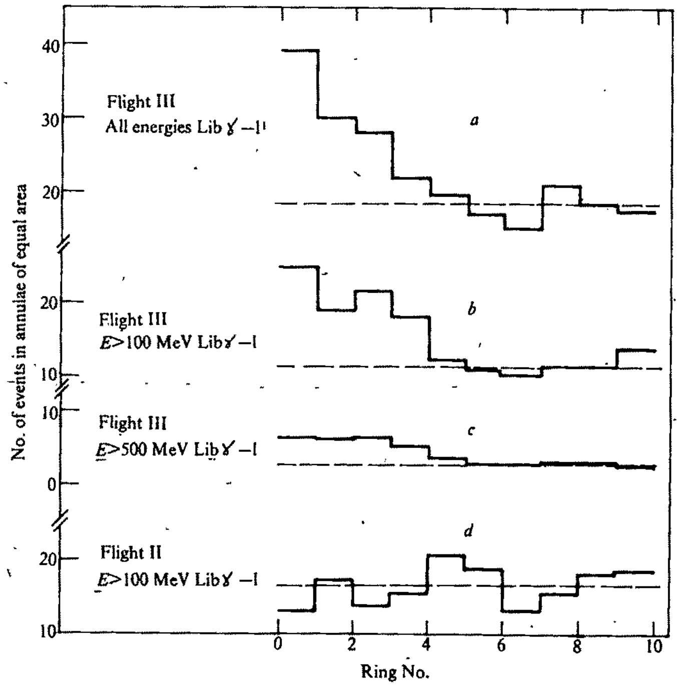

Fig. 2 Number of events plotted for circular annulae about the central position of source Lib γ-1 for flight III and flight II. The radius of ring number 1 is 2.1° and of ring number 8 is 6.0°. The dashed lines correspond to the means for the rings from number 4 to number 8.

Table 2 Comparison of γ-source Positions with Objects listed by Biraud[13]

Possible γ-source	RA	Dec.	Radio and/or optical source	Radio and optical position RA	Radio and optical position Dec.	Type
Lib γ-1 (ref. 1)	$227°\pm2°$	$-22°\pm2°$	AP Lib PKS 1514–24	228.7°	−24°	E or N, variable
(ref. 3)	$54°<\alpha<75°$ $+4<\delta<+9$		BW Tau 3C 120 PKS 0430+5	67.5°	+5°	Seyfert, strongly variable
			W Com ON 231	184.5°	+28°	Variable
			BL Lac VRO 42 22 01	330.0°	+42.0°	Similar to AP Lib

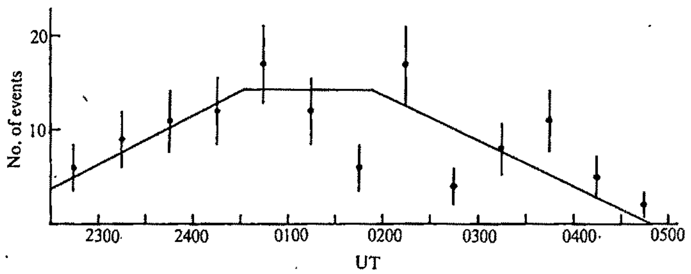

Fig. 3 Number of events per half hour interval received from the source direction during flight III. The full line shows the expected response curve for a constant source.

from a given object only 1–10% of the time and thus supposedly our second period of observation coincided with an outburst. An extended period of observation would then be required to delineate the time history of Lib γ-1. The γ-ray energy spectrum will furnish an additional test of the theory. If the spectrum follows a power law in the 10–100 MeV region, the corresponding electron energy spectrum can be deduced. If, however, it is a pion spectrum with the characteristic peak at 70 MeV (which may be red-shifted if PKS 1514–24 is far away), nucleon–nucleon collisions or nucleon–antinucleon annihilation will be responsible for the γ-radiation and Shklovsky's mechanism will be ruled out.

Short Term Variability of Pulsations in the X-ray Flux from Cygnus X1

IN a recent sounding rocket flight in the southern hemisphere (launched from Woomera, South Australia, on November 11, 1970) the X-ray source Cygnus X1 was observed by a 1,000 cm^2 collimated proportional counter sensitive to X-rays in the range 2–14 keV. Each X-ray event was indicated through the telemetry link by a 300 μs analogue pulse whose height was proportional to the incoming photon energy. This method of data transmission allows good timing accuracy together with a reasonable spectral resolution.

The data were folded using a technique similar to that used by Boldt *et al.*[1] at a number of trial periods in the range 50 ms to 1.2 s, and a chi-squared statistical test carried out on the resulting light curve to search for the presence of significant periodic variations in the X-ray flux.

The detector observed the source twice during the flight, the two scans being separated by 55 s. During the first scan significant fluctuations were observed at periods of 57.50, 115.24 and 229.74 ms. Table 1 shows the significance of the departure from the expected count rate. *P* is the probability that such a value of chi-squared would arise from random data with no pulsation present. The smaller the value of *P* the more significant the fluctuation. Analysis of the second scan revealed no significant pulsation at the $P=0.01$ level at any period in the range tested. The maximum values of chi-squared

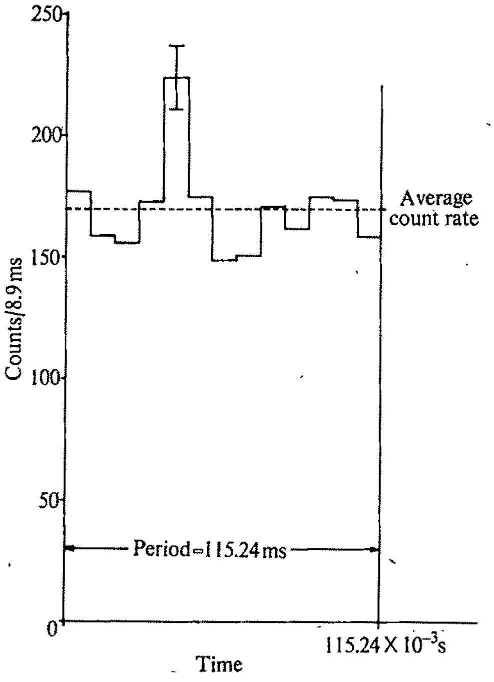

Fig. 1 "Light curve" at 115.24 ms period.

and the periods at which they were observed are also shown in Table 1. We interpret these results as indication of a drop in the fluctuating fraction of the X-ray output of the source in the 55 s separating the two scans. If similar behaviour is present at higher energies it may explain the negative result of Manchada *et al.*[2].

Table 1 Significance of Departure from Expected Count Rate

Period		Chi-squared (for $\nu = 10$)	P
Scan 1	57.50 ms	29.4	0.001
	115.24 ms	24.0	0.01
	229.74 ms	23.3	0.01
Scan 2	55.66 ms	19.5	0.04
	113.55 ms	15.5	0.10
	231.93 ms	14.4	0.11

The steady flux from Cygnus X1 was the same as measured by previous observers and showed no change between the two scans to within the experimental accuracy of 3%.

Fig. 1 shows the light curve at 115.24 ms, the only light curve in these data that is easily interpreted at the present time. By altering the number of phase bins within the light curve we have estimated the width of the pulse and also the maximum count rate during the pulse. These parameters and estimates of the pulsed energy output of the source are listed in Table 2. As the light curves at the other periods reported here are more complex we defer discussion of their interrelationship to a later communication.

Table 2 Measured Parameters of the 115.24 ms Light Curve

Period	115.24 ms
Pulse width	9.2 ± 0.4 ms
Count rate during pulse	0.64 ± 0.18 photons cm^{-2} s^{-1} in range 2–14 keV
Average flux	1.31 ± 0.05 photons cm^{-2} s^{-1} in range 2–14 keV
Energy in pulse as a fraction of total energy	0.04 ± 0.01
Pulsed energy (with period 115.24 ms) radiated by source, in energy range 2–14 keV (assuming a distance of 1.0 kpc (ref. 5)	1.5×10^{34} erg s^{-1}

The only period detected in this flight that has been previously reported is that of 230 ms. Other observers have detected periods of 290 ms and 1.1 s (ref. 3) and 73 ms (ref. 4), although these were not significant in our data. We note, however, that there are certain harmonic relationships between some of these periodicities.

We thank the staff at MSSL, BAC, BAC(A) and SRC (SRMU) for their assistance in this project. A. M. C. acknowledges an SRC studentship.

Soft X-ray Emission from Galactic Radio Spurs

Shklovsky and Sheffer[1] have recently raised the interesting possibility that the galactic radio spurs could be soft X-ray sources. As radio spurs have often been considered to be very old supernova remnants[2,3], and since three old remnants have been found to be soft X-ray sources[4,5], this idea has particular merit. Shklovsky and Sheffer point out that the soft X-ray (0.21 to 0.28 keV) map of Bowyer *et al.*[6] shows enhanced emission in the northern galactic hemisphere in a region coincident with secondary radio ridges of the North Polar Spur[7] and that this correlation may provide experimental verification of the hypothesis concerning the possible supernova remnant origin of the spurs.

The purpose of this letter is to question the proposed association between radio spurs and soft X-ray emission in general and to take issue with the particular identification of soft X-ray emission observed by Bowyer *et al.* with the North Polar Spur. The main points of our argument are that an independent interpretation of the radio spurs exists[8] which shows most of these features are not related to SNR. A possible exception is the Cetus Arc[9], a configuration in the southern galactic hemisphere, which we discuss in depth. We conclude on theoretical grounds that this object is not likely to be an X-ray source. From the observational viewpoint the soft X-ray enhancement observed by Bowyer *et al.* can be interpreted in terms of solar X-rays resonantly scattered in the Earth's atmosphere. Other investigators who have scanned the North Polar Spur and portions of other galactic spurs (in particular the Cetus Arc) at large solar zenith angles have not observed any enhancement at soft X-ray energies.

With regard to possible interpretations of the galactic radio spurs, we call attention to the fact that Mathewson[8] has been able to explain most of the observed radio features in terms of synchrotron radiation from electrons spiralling along a helical component of the local magnetic field. With this interpretation, he also accounts for the polarization orientation of the nonthermal galactic radio background and the large-scale orientation of the optical polarization vectors of nearby stars.

One feature Mathewson's model is not able to explain is the Cetus Arc. The spectral index of the polarized radiation between 408 and 620 MHz is steeper in this region than in others in the Galaxy[10], and H_α filaments[11,12], H_β radiation[13], and neutral hydrogen (M. P. Hughes, A. R. Thompson and R. S. Colvin, unpublished results) have been detected in the region. It seems reasonable to interpret that this feature is an old and unusually large supernova remnant. If the Cetus Arc is indeed such a remnant, it is useful to estimate whether it is likely to be a soft X-ray emitter. The X-ray emission spectrum of a supernova remnant varies with time as it is strongly influenced by the dynamics of the expansion. Three phases can be distinguished in the expansion of a typical shell[14,15].

(1) The free expansion phase, which proceeds up to a time when deceleration effects become important. The diameter at such a time is $D = 4.2\ (M/M_\odot)^{1/3}\ n_H^{-1/3}$ pc, where M is the ejected mass and n_H the unperturbed interstellar number density.

(2) A deceleration phase which is energy-conserving (or adiabatic). During this phase the shell diameter varies as

$$D \approx 25.8 \left(\frac{E_0}{n_H}\right)^{1/5} \left(\frac{t}{10^4 \text{ yr}}\right)^{2/5} \text{pc} \qquad (1)$$

where E_0 is the energy released in the explosion in units of 7.5×10^{50} erg and t is the age in years. In this case the shock velocity is given by

$$v_s \approx 505 \left(\frac{E_0}{n_H}\right)^{1/5} \left(\frac{t}{10^4 \text{ yr}}\right)^{-3/5} \text{km s}^{-1} \qquad (2)$$

Heiles[16] demonstrated that this phase continues only up to a time when radiation losses become important and thereafter the assumption of energy conservation is no longer valid. Cox[15] has shown that when line emission by heavy elements is included in the radiative losses, the thermal energy content of the whole remanant varies with time as

$$\frac{E}{E_0} = 1 - \left(\frac{t}{t_c}\right)^{17/5} \qquad (3)$$

where $t_c = 5.6 \times 10^4 \ E_0{}^{4/17} \ n_H{}^{-9/17}$ yr. The shell diameter at this time is

$$D_c = 50.8 \ E_0{}^{5/17} \ n_H{}^{-7/17} \text{ pc} \qquad (4)$$

Shortly after the remnant has cooled to a dense shell, it enters the next and final phase.

(3) The momentum-conserving phase in which the radius varies as

$$D \sim \left(M_0 v_0\right)^{1/4} \ n_H{}^{-1/4} \ t^{1/4} \qquad (5)$$

where $M_0 v_0$ is the shell momentum at the time equation (5) becomes first applicable. Assuming the final shell momentum is 75% of the momentum at the time the temperature of a mass element drops faster from radiation than from expansion, the shock velocity in this phase is

$$v_s \approx 165 \ E_0{}^{16/17} \ n_H{}^{-1} \left(\frac{D\text{pc}}{40}\right)^{-3} \text{ km s}^{-1} \qquad (6)$$

During phase 1 and early in phase 2 the X-ray emission is most likely nonthermal in nature and due to the high-energy tail of the same electron distribution responsible for the nonthermal radio emission[17]. This is probably the case for Cas A, Tycho's supernova and the Crab Nebula. The spectra have already steepened in the X-ray range due to radiation and expansion losses. Continuous injection of high-energy particles seems indicated over a time scale of hundreds of years. For remnants late in phase 2, the X-ray emission is probably thermal radiation from the shock-heated plasma present in the shell. The temperature behind the shock is, for a monoatomic gas,

$$T = \frac{3\mu}{16k} v_s^2 \qquad (7)$$

where μ is the mean mass per particle, k is Boltzmann's constant, and v_s is the shock velocity. Using $\mu = 0.61 \ m_H$, corresponding to a 10% helium abundance by number, for $E_0 = n_H = 1$ and $t = 10^4$ yr, we see from equations (2) and (7) that $T \sim 3 \times 10^6$ K.

As a tentative test of these ideas, we list in Table 1 the diameters, ages and shock speeds for two well studied remnants, Vela X and the Cygnus Loop, with a comparison between the values obtained from equations (1), (2) and (7) and the observations[4,5]. For Vela X, it is assumed the age of the pulsar PSR 0833–45[18] to be that of the remnant. For the Cygnus Loop, the expansion velocity of the filamentary system may not be representative of the shock velocity[22] and a new estimate for the parameters has been obtained by scaling the Vela X values to the diameter of the Loop using equation (2).

Although our understanding of supernova remnants is far from complete, the reasonable agreement between theory and experiment for these two remnants lends confidence to attempts to use these models to predict the emission spectrum of the Cetus Arc. To do this, we need an estimate of the linear diameter and expansion velocity of this feature.

Hughes *et al.* (unpublished work) have compared the neutral hydrogen absorption velocities observed in the spectra of extragalactic radio sources in the direction of the Cetus Arc with velocities obtained from optical absorption lines in the spectra of nearby stars with known distances in this region. From this they obtain a distance to the centre of the Arc, assuming spherical symmetry, of $d \leq 170$ pc. The linear diameter, as implied from the radio angular diameter, is then $D \leq 240$ pc. The upper limit for the proper motion of the H_α filaments is 0.5 arc s yr^{-1} (ref. 11) and this provides an upper limit for the expansion velocity of $v_s < 90 \text{ km s}^{-1}$.

From a comparison of these values with equations (4) and (6), we see that the Cetus Arc ought to be well into the momentum-conserving phase. Cox has computed a number of detailed models for supernova remnants in this phase[15]. The model which is most appropriate for comparison with the Cetus Arc is characterized by $v_s = 70 \text{ km s}^{-1}$. For this model, Cox derives a shock temperature of $T \sim 6 \times 10^4$ K. Alternately, using equation (7), we find that for $v_s < 90 \text{ km s}^{-1}$, the corresponding temperature is $T < 9.5 \times 10^4$ K. In either case, the upper limit for the temperature of the Cetus Arc is at least a factor of 40 below that needed in order for this object to be a source of soft X-rays, and almost all the energy is radiated in the form of ultraviolet, visible, and infrared lines.

Direct estimates of conditions in the Cetus Arc can be made by scaling values relevant for Vela X to the 240 pc diameter of the Arc using either equations (1) and (2), relevant for a remnant in phase 2, or equations (5) and (6), relevant for a remnant in phase 3. This approach assumes that the parameters E_0 and n_H are the same in the two objects. In equations (1) and (2), the ratio E_0/n_H enters as the one-fifth power; hence, the effects of any possible differences in these parameters tend to be minimized while the remnant is in phase 2. In equation (6), however, this ratio enters directly, so estimates for v_s while the remnant is in phase 3 are less reliable. In Table 1 we list the values for the age, shock velocity, and shock temperature for the Cetus Arc derived in this manner. With both models, the predicted shock speeds are consistent with the observational upper limit; and in both cases, the temperature is far below that necessary for the object to be a source of soft X-rays.

Considerable soft X-ray data that relate directly to this subject are available. The soft X-ray enhancement detected by Bowyer *et al.*[6] near the North Polar Spur is best interpreted

Table 1 Observed and Computed Parameters for Old Supernova Remnants

Source	Diameter (pc)	Age (yr)	v_s (km s^{-1})	kT (keV) Observed	kT (keV) Predicted	References
Vela X	35	1.13×10^4	600	0.23	0.4	5, 18, 19
Cygnus Loop	41	6.7×10^4	*110*	0.37	0.014	4, 20, 21
		1.8×10^4 *	440		0.23	
Cetus Arc	240	1.4×10^5 *	30	—	1.3×10^{-3}	11, and Hughes *et al.* unpublished
		2.7×10^7 †	2		5×10^{-6}	

Note: Velocity in italics is an observational value. For the Cetus Arc the observational upper limit to the velocity is $v_s < 90 \text{ km s}^{-1}$. The corresponding temperature is $kT < 8.0 \times 10^{-3}$ keV.

* Computed using energy-conserving theory, scaled from Vela X.

† Computed using momentum-conserving theory, scaled from Vela X.

as the result of atmospheric scattering of solar X-rays, because the Sun was close to the horizon at this position in the sky at the time of their flight[23]. This effect has been examined in some detail by Tomblin[24] and appears to be well understood. Other investigators have scanned portions of galactic radio spurs at soft X-ray energies with more favourable solar zenith angles: Henry *et al.*[25] and Palmieri *et al.* (unpublished work) have scanned the North Polar Spur; Bunner *et al.*[26], Hayakawa *et al.* (unpublished work) and Baxter *et al.*[27] have scanned Loop III[28]; and Bunner *et al.*[26,29], Hayakawa *et al.* (unpublished work) and Baxter *et al.*[27] have scanned the Cetus Arc. No soft X-ray enhancements are present in the published data of these investigators near the positions of these features.

We conclude both on theoretical and observational grounds that galactic spurs are not, in general, sources of soft X-ray emission. The Cetus Arc may well be a supernova remnant; if it is, however, it has long ago ceased to be a source of X-ray emission.

Is Mercury from Hawaiian Volcanoes a Natural Source of Pollution?

THE development of more sensitive techniques[1] for the analysis of mercury has resulted in reports of previously unsuspected amounts of mercury in the environment. There are now several well documented cases of mercury pollution deriving from industrial sources, but sources of other forms of mercury pollution, as in ocean-going fish[2], for example, are not so well defined[3]. The widespread distribution of mercury in the environment may, however, be in part a consequence of the physical properties of the element, the manufacture of the element by the smelting of cinnabar, and the fact that certain microorganisms can convert mercury to the gas dimethyl mercury.

Another possible source of atmospheric mercury is vulcanism. A recent review[5] states that "data on mercury contents of fumaroles are lacking because of the rarity of volcanic eruptions and high-temperature fumaroles and, until recently, the lack of adequate methods of analysis. Hawaiian and Alaskan fumaroles should be studied". We now report that the active vulcanism on the island of Hawaii is producing significant amounts of mercury.

Atmospheric mercury was obtained by drawing 0.2–0.4 m^3 of air through 15×150 mm U-tubes containing traps of 10 ml. of concentrated H_2SO_4, 1 ml. of concentrated nitric acid and about 500 mg of powdered copper (reagent grade). Variations on this procedure included the use of different glassware and the replacement of copper by silver, gold and other heavy metals.

Field air samples were collected using a portable battery-powered pump (Mine Safety Appliances No. 92–814, Bureau of Mines Approval No. 2F-2004). After sample runs of 30 to 90 min duration, trapping vessels were sealed for analysis at the laboratory in Honolulu. Further samples were collected using Mine Safety Appliances No. 93-494 cellulose filters, which retain particles down to 0.3 μm diameter.

Table 1 Atmospheric Mercury Levels in Selected Hawaiian Sites

Sample site and time	Trap	Volume of air sample (m^3)	Hg μg/m^3
A, Manoa Campus, University of Hawaii, Honolulu (Oahu)			
1700–1900 h, April 18, 1971, temp. 25° C, clear, no wind	(1) Cu/acid	0.50	0.034
	(2) Ag/acid	0.47	0.019
	(3) Cu/acid	0.40	0.065
		Average	0.04
B, Ala Moana Beach, Mamala Bay, Honolulu (Oahu)			
1200–1400 h, May 13, 1971, temp. 30° C, clear, mild breeze from north	(1) Cu/acid	0.36	0.60
	(2) Cu/acid	0.36	0.71
	(3) Cu/acid	0.36	1.41
		Average	0.91
C, Sulfur Banks, Hawaii Volcanoes, National Park (Hawaii)			
1000–1200 h, April 10, 1971, temp. 20°–22° C, intermittent light rain	(1) Cu/acid	0.36	26.6
	(2) Charcoal	0.34	26.3
	(3) Cu/acid	0.36	17.1
		Average	23.3
1100–1300 h, May 8, 1971, temp. 22° C, clear to light rain	(1) Cu/acid	0.15	15.4
	(2) Cu/acid	0.34	27.4
		Average	21.4
	(3) Cellulose filter	0.34	0.38
	(4) Cellulose filter	0.24	0.50
		Average	0.44

Trap contents were transferred quantitatively to acid-washed flasks containing 100 ml. of concentrated nitric acid and diluted to 200 ml. with distilled water. Portions of 20 ml. were analysed for mercury content by flameless atomic absorption at the 253.65 nm resonance line. We used a Utopia Instruments flameless mercury analysis kit[6] and a 10 cm absorption cell mounted on the burner of a Beckman 1301 atomic absorption spectrophotometer. Samples were compared with appropriate blanks and standards. The results are summarized in Table 1. The Sulfur Banks within Hawaii Volcanoes National Park is a site where steam and gas are emitted more or less continuously through crevices and cracks which vent into the open air. Control samples were taken in the Manoa Valley which has light traffic and no industry. Tradewinds usually carry clean air masses over the head wall of the valley. A second control site was urban, non-residential, and in proximity to heavy traffic, but also was without industrial development.

Table 2 Boiling Points of Selected Mercury Compounds

Compound	Boiling, sublimation (S) or decomposition (D) point (°C)
Hg	356.58
Hg_2Br_2	S 345
$HgBr_2$	322
Hg_2Cl_2	S 400
$HgCl_2$	302
Hg_2I_2	S 140, D 290
HgI_2 (β-form)	354
Hg_2O	D 100
HgO	D 500
HgS	S 583.5

The results show that 98% of the mercury issuing from the Hawaian fumaroles is either in the form of a gas or of particles less than 0.3 µm in diameter. Several mercury compounds as well as the pure metal may become gaseous under the conditions of temperature and pressure found in volcanic fumaroles (Table 2)[7]. The magnitudes of mercury content in these fumaroles' discharges agree quite well with reports from thermal areas in Kamchatka and the Kuriles[5]. The background figures for Honolulu seem high when compared with other reports, but this may simply be because this site is close to a volcano.

The Hawaiian Islands possess industries using mercury. The sugar industry (the state's third largest behind the military and tourism), for example, has used mercury-containing fungicides. Mercury batteries, lamps and switches are used by many individuals and businesses. Military consumption of mercury is not known. In spite of the industrial consumption of mercury in Hawaii, however, it is still reasonable to suspect that the volcanoes supply large quantities of mercury to the environment. During a period of heavy volcanic activity it is not uncommon to have a high atmospheric turbidity extending along the island chain. This haze may be very noticeable in downtown Honolulu on the island of Oahu, more than 200 miles NNW of the source. Since our laboratory has turned its attentions toward mercury studies this phenomenon has not recurred so that we have been unable to verify the efficacy of atmospheric dispersal of mercury from volcanic activity. We are now planning a programme of continued air monitoring for mercury.

In conclusion, we do not wish to discount the mercury contribution of industrial pollution, but only to suggest that in Hawaii, at least, natural as well as human factors may be at work.

We thank Park Superintendent Balaz and Chief Ranger Hewitt of Hawaii Volcanoes National Park for their cooperation and advice in the course of this study; Adele Shimabuku and James Barres for field collection and sampling; and also Dr Irving Breger, United States Geological Survey, for reviewing this manuscript. This work was supported in part by a grant from the National Aeronautics and Space Administration.
